"A" Connections: in telephony, the completion of a current between two subscribers on the same exchange. See "Telephony," § (5).

"A"–"B" Connections: in telephony, the completion of a circuit between two subscribers on different exchanges. See "Telephony," § (6).

Abraham, H., work of, on the measurement of "v." See "'v,' Measurement of," § (5).

Absolute Measurements of Electrical Units: the measurement of electrical units in terms of the fundamental units of mass, length, and time. See "Electrical Measurements," § (8) *et seq.*

Summary of results. See "Electrical Measurements," §§ (20), (35), and (37); "Units of Electrical Measurement," § (1).

Absolute Systems of Measurement: systems in which the units of length, mass, and time are taken as fundamental units. See "Electrical Measurements," § (1); "Units of Electrical Measurement," § (1).

Absorption (Dielectric): the absorption of energy by the dielectric when a condenser is first charged and then discharged. See "Capacity and its Measurement," § (8); "Dielectrics," § (4).

Accumulators: cells employed for storing electrical power. See "Switchgear," § (14); "Batteries, Secondary," § (1).

Accuracy Characteristics of Ammeters and Voltmeters. See "Direct Current Indicating Instruments," § (15).

Admittance: the reciprocal of the reactance of an alternating current circuit. It is measured by

$$\left(L\omega - \frac{1}{K\omega}\right)^{-1},$$

L and K being the inductance and capacity of the circuit, ω the pulsatance. See "Inductance, The Measurement of," § (3).

Aerial Cables, Use of, in Telephony. See "Telephony," § (2).

Agnew Dynamometer: a form of heavy current dynamometer, employed for the measurement of current or power. See "Alternating Current Instruments," § (11).

Agnew Galvanometer. See "Vibration Galvanometers," § (17).

Air Condensers (Electric). See "Capacity and its Measurement," § (32).

For radio-telegraphic work and measurement of capacity at low frequencies. See "Radio-frequency Measurements," § (28).

Of variable capacity. See "Capacity and its Measurement," § (32) (ii.).

Alexandersen Alternator, The: a machine for the generation of current of radio frequency. See "Wireless Telegraphy Transmitting and Receiving Apparatus," § (5).

Alkali-chlorine Cells. See "Electrolysis, Technical Applications of," § (28).

Alternating Current, measurement of, with vibration galvanometers. See "Vibration Galvanometers," § (42).

Alternating Current Bridges, use of, for capacity measurements. See "Capacity and its Measurement," § (48).

Alternating Current Electrolysis, as shown by the corrosion of underground structures by stray alternating currents. See "Stray Current Electrolysis," § (19).

ALTERNATING CURRENT INSTRUMENTS AND MEASUREMENTS FOR COMMERCIAL FREQUENCIES [1]

(Instruments for acoustic and radio frequencies are not included)

I. Physical Properties made use of

§ (1).—Three properties of the electrified condition of matter are commonly made use of in electrical measuring instruments.

[1] Further details of many of the instruments mentioned in this section, together with references to literature, are given in "Electrical Measurements," *F.A. Laws* (McGraw Hill), 1917.

They are: (1) The electromagnetic forces resulting when currents flow in neighbouring conductors, or when one current is replaced by a constant magnetic field. (2) The electric forces resulting when neighbouring conductors are at different electrical potentials. (3) The heat which is generated in a portion of a circuit carrying a current causing a rise of temperature. Electrical methods, such as change of resistance or thermovoltages, are commonly used as the change-of-temperature detectors.

Voltmeters, ammeters, and wattmeters of the moving-coil or dynamometer type and oscillographs are examples of the first kind. Induction instruments also fall in this class. Electrostatic instruments are examples of the second class. The chief types are voltmeters and wattmeters.

In the third class are various types of thermo-ammeter depending on temperature changes, either of the main conductor carrying the current to be measured, or of a secondary circuit close to it, which is heated by radiation or convection. They are especially valuable for very high frequencies, 10^3 to 10^7 per second.

II. Electromagnetic Instruments

These comprise voltmeters, ammeters, wattmeters, and subsidiary apparatus of special types, such as phase indicators, synchroscopes.

The voltmeters, ammeters, and wattmeters are made either without iron or with iron. In the case of instruments containing iron more than one method of using it is employed.

§ (2) Instruments without Iron. — The common principle employed in electromagnetic instruments without iron is illustrated in *Fig.* 1,

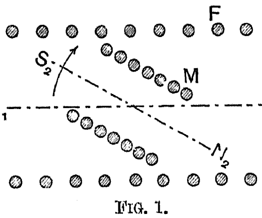

Fig. 1.

in which the interaction of magnetic fields produced by a fixed coil or coils F and by a second movable coil M, often of smaller dimensions, results in a tendency for the movable coil to turn in the direction indicated by the arrow, if the direction of the magnetic fields is as shown.

When the coils have their axis parallel the torque is zero; the system being stable if the fields are in the same direction. If the fields are in opposite directions the system is unstable.

Instruments operated by the interaction of currents in a movable and a fixed coil or coils are conventionally termed dynamometer instruments. They are of two types. Imagine the fixed coil to be divided into two halves. In the one type the current flows in the same direction in the two halves, producing an *axial* field; in the other the current in the two halves of the fixed coil flows in opposite directions, producing a *radial* field. Most makes of commercial instruments are of the axial type. The Kelvin balance is an example of the radial type.

§ (3) Method of Reading. (*a*) *Null Instruments*; (*b*) *Indicating or Pointer Instruments*.—The indications of an instrument may be read by measuring the force required to keep the moving part in equilibrium, which is generally a position of symmetry. Such instruments may be described as null instruments. In many types the moving part is allowed to deflect to a considerable extent against some opposing force, and the deflection is a measure of the quantity required. Such are termed indicating or pointer instruments.

§ (4) Null Instruments.—In the case of an instrument of the axial type the torque is a maximum when the coils are at right angles, assuming that the field produced by the fixed coil is approximately uniform. In such a position the torque is but slightly affected by small displacements. If an opposing torque is applied to the moving part, equal to the magnetic torque, the moving coil may be kept perpendicular to the fixed one. If the opposing torque is measured, as, for example, by the measured deflection of a spring, such deflection becomes a measure of the magnetic torque. The torque, for constant relative position of the coils, is proportional to the product of the intensities of the two fields and therefore to the product of the currents in the coils. If the same current passes through the two coils in series the torque is proportional to the square of the current, so that the current is proportional to the square root of the torque, *i.e.* to the square root of the deflection of the instrument spring.

§ (5) The Siemens Dynamometer.[1]—This instrument (*Fig.* 2), once much used as a secondary standard, especially for alternating currents, works on this principle, the current in the moving part being led into and out of it through mercury cups placed in the axis of rotation. The pointer attached to the spiral spring usually makes one turn for the full reading of the instrument. The formula for calculating the current is $C = K\sqrt{D}$, where D is the rotation of the top end of the spiral spring which is necessary to restore the quadrature position of the two circuits. The displacement of the moving coil is limited to a few degrees each side of the position of balance. The value of K must be determined

[1] *Laws*, p. 77.

by calibration with continuous or alternating currents of known value.

The Kelvin balance and more convenient portable instruments have largely superseded the Siemens instrument; but some of the

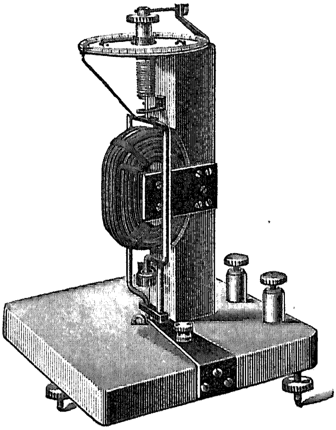

FIG. 2.

most accurate wattmeters have been designed on this principle (Duddell-Mather, Drysdale).[1]

§ (6) KELVIN BALANCE.—This is an electro-magnetic instrument for measuring the current or power in a circuit by the force required to restore equilibrium in a manner similar to the operation of a balance. The currents in the two halves of the fixed coils run in opposite directions. The magnetic field is thus radial. In this instrument a restoring force is applied to the moving part to bring it back to the equilibrium position which it assumes when there is no current passing. The axis of rotation is horizontal, as in the ordinary balance, instead of being vertical, as in most other instruments. The restoring force is the effect of gravity on a moving mass, which may be several grams, and which can be moved along the balance arm till the equilibrium position is attained.

The instrument and a diagram of the circuits are shown in *Figs.* 3, 4.

The larger, upper and lower turns represent the four fixed coils which are commonly wound on slate. The moving coils work between them with sufficient clearance to allow of a few degrees of tilt. The current in the upper and lower coils at one end of the balance are in opposite directions to one another. They therefore produce a "consequent" field between them which is radial, and the current in the moving coil placed in the field causes a vertical force to act on it. The direction of the currents at the other end of the beam is such that not only do the forces add, but also the current in the moving coil is in the opposite direction to what it is in the end first considered. The result is that the instrument is unaffected by a constant external field. Such a field produces equal and opposite forces on the two moving coils. The instrument is therefore astatic.

The current is led into and out of the moving part by a number of fine bronze strips in parallel. These also take the weight, and act as the fulcrum of the balance. Owing to the relatively large surface a very large current can be carried by a very small total cross-section of copper by this method. A similar scheme for leading in the current has been adopted in the standard ampere balance used for realising the value of the ampere, but in this instrument the balance beam is supported on a knife-edge of agate of the usual form.

When used in the manner shown, in which the current goes through all the coils in series, the forces are proportional to the square of

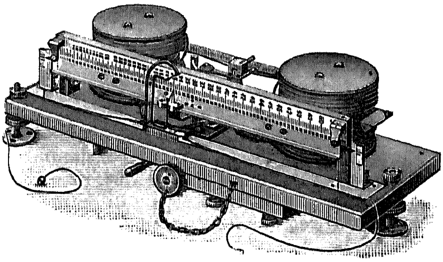

FIG. 3.

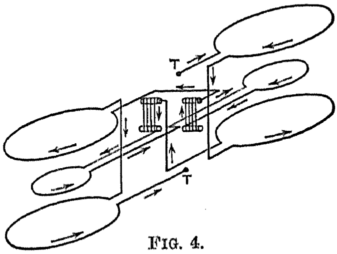

FIG. 4.

the current, so that the current is proportional to the square root of the reading of the position of the sliding weights. To cover the range of which the instrument is capable four different weights are generally provided. By this means in the 100-ampere instrument, for instance, full-scale reading is obtainable at 100, 50, 25, and 12·5 amperes. The instrument is not so sensitive at the lower ranges. The weight for 100 amperes is about 60 grams and the couple about 2000 gram-centimetres.

Like all instruments having conductors of comparatively large cross-section, there is an error due to frequency in the larger sizes;

[1] See § (10).

but up to the 600-ampere size this is negligible for commercial current measurements at ordinary frequencies. The balance can be relied on to about 0·2 per cent at full load and can be calibrated by continuous currents.

This type of instrument may also be used as a wattmeter by sending the main current through one set of coils and a current proportional to the voltage in the circuit through the other. In practice the moving coils are the voltage coils, and are wound of many turns of fine wire with an added resistance in series, the amount of which depends upon the voltage to be dealt with. On account of the large magnetic field that is required the inductance of the moving-coil circuit is very considerable and the current in it lags behind the voltage. The phase displacement may produce serious errors unless allowed for, as will also eddy-current effects, if the fixed-coil circuit is insufficiently stranded. The scale is a "linear" one, not a "square law."

§ (7) Indicating or Pointer Instruments. —If the moving coil is allowed to deflect against a spring or the force of gravity instead of being completely restored by mechanical force, a pointer P, attached to the coil, can be made to indicate the product of the two currents. In this manner a practicable deflection of about 100° is obtainable. A very large number of modern instruments operate on this principle, the products of different manufacturers differing in detail, but all similar as regards fundamental theory.

From the general principles of the interaction of circuits, it will be seen that if the initial position of the moving coil is as shown at A (*Fig.* 5), and the full-scale deflection as

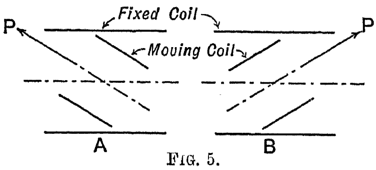

Fig. 5.

shown at B, the scale divisions representing the current in one coil (the current in the other coil remaining constant) will be nearly equal. Similarly if the current measured passes through both coils the scale division will approximately follow a "square law," as in the case of the Siemens dynamometer.

If the fixed coil is divided into two halves separated from each other, as in the Helmholtz galvanometer, an approximation to a uniform field may be obtained midway between them, in which the moving coil moves. This construction facilitates the insertion of the moving coil. Lord Rayleigh has pointed out that over a considerable angular deflection very close approximation to constancy of force can be obtained with circular coils whose radii have the ratio $\sqrt{0{\cdot}3}$ or 0·548.[1]

§ (8) Indicating Dynamometer Instruments. (i.) *Ammeters.*—The general outline of electromagnetic instruments given above shows that a current may be measured by passing it through a fixed and a moving coil in series, and that if the resulting force is opposed by a spring the deflection of the pointer is an approximate measure of the square of the current.

The moving coil is supported either by a metallic strip or by hard pivots working in jewelled cups. Two bronze helical springs usually supply the controlling torque, and are so arranged that any tendency and change of zero which might occur, due to change of temperature, etc., if one spring alone were used, is counteracted by the direction in which the other tends to move.

For small currents, up to about 0·5 ampere, the springs are used also for leading the whole current into and out of the moving coil.

This type of instrument is suitable for currents of all ordinary commercial frequencies and often considerably higher, and in the case of small currents, in which the cross-section of the winding is small, the type is suitable for frequencies of several hundreds or even thousands a second. Above 0·5 ampere the current becomes too large to be carried by the springs, which, if made of sufficient section to carry it without undue heating, would be too stiff for the forces involved.

A fraction of the current, $\frac{1}{2}$ ampere or less, is therefore passed through the moving coil, which is connected to the ends of a resistance, placed in series with the fixed coils; this carries the remainder of the current, following the principle used to a very large extent in continuous current measurements.[2] In addition to correct resistance ratios between the two circuits in parallel, the proper division of current must be also obtained with alternating currents of the frequencies for which the instrument is designed. The relatively fine-wire circuit of the moving coil has a measurable inductance which may be appreciable in instruments designed for high precision. The effect of this inductance in reducing the current through the moving coil, and, in the case of wattmeters, the phase angle introduced, may be compensated by a condenser placed in parallel with the series resistance which is commonly added to such a moving coil, partly to diminish the effect of temperature on the resistance of the circuit, and partly for adjustment purposes.

The compensation is practically perfect for commercial frequencies when $L=Cr^2$, the

[1] Lord Rayleigh, *Phil. Mag.*, Dec. 1886, xxii. 470.
[2] See "Direct Current Indicating Instruments," §§ (1) and (20).

symbols representing the inductance capacity and resistance of the parts of the circuit shown in the diagram (*Fig.* 6).[1]

The moving coil carries the condenser current as well as the current through the resistance r. The current through L and r would naturally diminish with increase of frequency due to the inductance of L. The

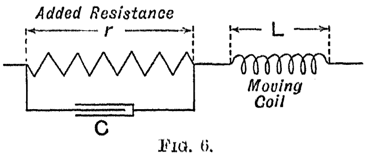

FIG. 6.

current through C and L will increase with frequency. If the values are chosen in accordance with the above equation the compensation is practically perfect both as regards magnitude and phase.

Many of the difficulties of the measurement of large currents are avoided by the use of current transformers. The main current to be measured traverses the primary of a transformer the secondary of which is connected to a low-resistance ammeter. The ratio of the turns is such that the nominal secondary full-load current is 5 amperes, and for industrial ammeters about 400 ampere-turns are used for commercial frequencies. Where accuracy is of importance 1200 ampere-turns are desirable.

(ii.) *Voltmeters.* — The indicating dynamometer voltmeter is practically an ammeter with the circuits arranged to carry about 0·05 ampere or more. For the finest instruments small currents are used, while for large instruments more power and larger currents are required.

In series with the circuit through the moving and fixed coils a sufficient quantity of resistance alloy wire, practically inductionless, is added, depending upon the voltage which it is desired to measure. In the case of the finest apparatus this added resistance is sufficient to render negligible the effects of inductance and temperature for voltages of 100 or more. In the case of voltages of the order of 10 or less the temperature correction may be appreciable, and an adjustable resistance is sometimes added which is set to correspond to the reading of a thermometer which is permanently fixed with its bulb inside the instrument. Compensation for inductance can be carried out as in the case of the ammeter.

For voltages above 500 or 1000 a potential transformer[2] is used to step down the voltage to a safe and easily measured value. Just as 5 amperes has been adopted for current transformers, so 110 volts has been adopted as the standard low-pressure voltage of potential transformers. The primary side is wound to suit the supply voltage, which may be anything from 200 volts to 66,000 or more. Sometimes transformers of a ratio of unity, such as 110 : 110, are used for isolation purposes.

(iii.) *Wattmeters.* — A wattmeter measures the mean value of the instantaneous product of the current and voltage of a circuit.

In the type of instrument under consideration the fixed coil may be similar to that of an ammeter of the same current capacity, while the moving coil with a high resistance in circuit is supplied by the voltage in question.

The instrument may be looked upon constructionally as half-ammeter and half-voltmeter. It has a nearly linear scale and for most technical purposes it is used at approximately constant voltage.

As in the case of ammeters for large currents a 5-ampere instrument is used with current transformers; and for large voltages a potential transformer is used with a secondary voltage of 110. For an account of the forces acting in a wattmeter, see § (20).

§ (9) GENERAL METHOD OF COMMERCIAL MEASUREMENT, USING AMMETERS, VOLTMETERS, AND WATTMETERS.—A complete set of instruments for ordinary commercial measurements consists of a voltmeter reading up to about 120 volts, with perhaps a second range obtained by the addition of an extra resistance to read up to double this value, an ammeter to read 5 amperes, and a wattmeter for 110 volts 5 amperes. All other higher voltages and currents are catered for by the use of potential and current transformers, the voltmeter and pressure circuit of the wattmeter being in parallel, and the ammeter and current circuit of the wattmeter being connected in series to the secondary circuit of the transformer.

Ammeters, voltmeters, and wattmeters of this class are very similar instruments. In the ammeter and wattmeter practically identical fixed coils are used for the main current. The moving-coil circuits in the voltmeter and wattmeter are also very similar, both having high resistances.

In the ammeter the moving coil with little or no added resistance is connected either across the fixed coils or across added resistance in the main circuit.

§ (10) WATTMETERS (DRYSDALE AND DUDDELL-MATHER).—These wattmeters are examples of the type analogous to the Siemens dynamometer ammeter, in which the reading is obtained in terms of the amount of rotation which has to be applied to a helical spring in order to bring the moving coil to its initial position at right angles to the fixed coil.

(i.) *Drysdale Wattmeter.* — The fixed coils carry the main current and are arranged in

[1] E. B. Rosa, *Bull. Bur. Standards*, 1907, iii. 43; *Laws*, p. 313. See "Inductance, Measurement of," § (3).

[2] See "Transformers, Instrument," § (8).

ten sections which can be put in series or parallel or intermediately by a cylindrical commutator, so that the same ampere-turns are obtainable with currents in the ratio of 1, 2, 5, 10. The moving coil is attached to a mica support, and being divided into two parts in which the currents flow in opposite directions, it is astatic to stray fields. The whole wattmeter movement is duplicated, so as to make the instrument available for use on two- or three-phase circuits. The two elements of the meter are placed vertically one above the other, with the moving coils fixed to the same mica support, so that the torques of the two meters are added together. The two elements are placed with their axes of symmetry at right angles to one another,

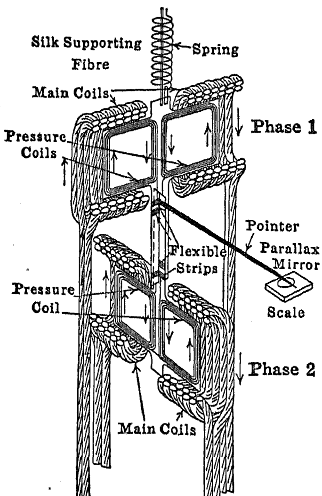

FIG. 7.

so as to ensure the least possible interference of one on the other. No metal other than the windings is used in the construction of the important parts of the instrument in order to avoid the possibility of error due to eddy currents which might be set up in such metal parts (*Figs.* 7, 8).

This wattmeter and the Duddell-Mather instrument are similar in design and operation. The main difference is that, in the latter, astaticism is achieved by having two moving coils in the same plane, one above the other. These are connected in series, and the current flows through them in opposite directions. The fixed coils are duplicated in a similar manner. The Duddell-Mather instrument is only made in the single wattmeter form.

(ii.) *Duddell-Mather Wattmeter.*—The fixed coils are divided into ten sections, which can be connected in series or in parallel or intermediately, so that full-scale deflection can be obtained with currents of the ratio of 1, 2, 5, 10. The instrument is made in seven

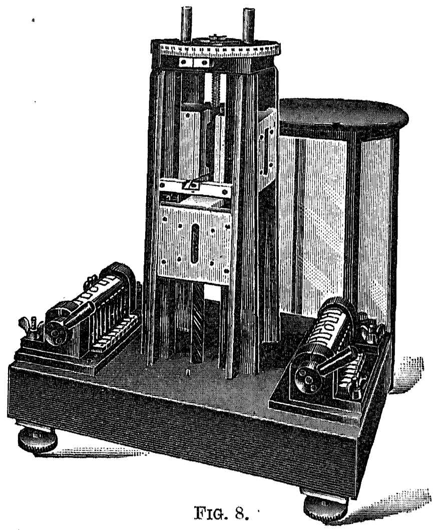

FIG. 8.

sizes, covering altogether a wide range of currents, from 0·1 to 1000 amperes (*Figs.* 9, 10).

Astaticism is obtained by duplicating the various coils and arranging that the currents go in opposite directions in each set.

The current coils are shown at C and the moving coils at *c*. They are fixed to a sheet of mica which is extended below at P, where it acts both as an air damper inside a glass

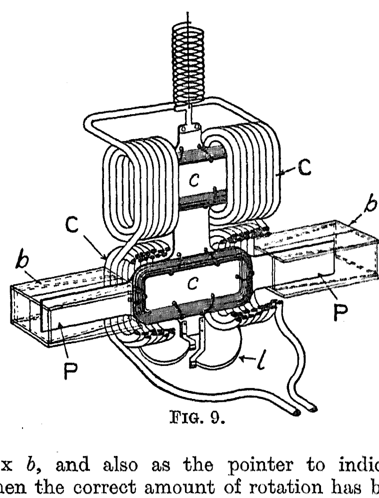

FIG. 9.

box *b*, and also as the pointer to indicate when the correct amount of rotation has been applied to the control spring. This is ensured by making it appear coincident with the fine line marked along the centre of the box when viewed from above. The current is led into the moving coils by fine ligaments *l*.

The voltage used on the pressure circuit is quite low, about 1 volt, and external resistances are added to suit the voltage of the

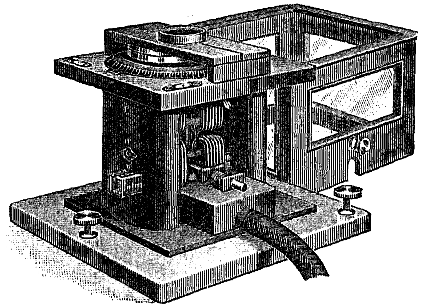

FIG. 10.

circuit. These resistances are made on a loom. The warp, about 8 inches wide, is made of silk threads, and a fine silk-covered resistance wire is used as a weft. In this way a resistance very free from inductance is constructed, which, when mounted zigzag fashion round porcelain rods, enables excellent cooling to be obtained.

For voltages above 5000 it may be desirable to immerse the resistance in oil. They may be made in sections in this manner for circuits up to 100,000 volts.

A valuable feature of this wattmeter is that the pressure coil and resistances are wound with much thicker wire than is sufficient to give full deflection when the current and voltage are in phase, so that if the current and voltage are small, nearly in quadrature, giving only a small deflection, the current in the pressure circuit may be increased up to ten times, if desired, by reducing the added resistance. In this way full deflection may be obtained with a power factor of 0·1. When used on the 100-volt range the resistance of the moving coil is $\frac{1}{10}$ of the whole, and being of copper its change of resistance with temperature may become important.

To determine the effect, if any, of the inductance of the pressure coil, which may be appreciable at low power factors, a special coil and switch is arranged so that an additional inductance equal to that of the coil may be switched into the circuit without altering the resistance. This gives a very valuable method of giving a direct indication of the magnitude of the inductance error when using the instrument at power factors of the order of 0·01 on circuits of 100 to 200 volts. On circuits of several thousand volts the effect would be very small; but in such cases the currents due to distributed capacity, between the various parts of the high added resistances and their surroundings, might cause errors which are difficult to determine. They can be reduced by a somewhat elaborate system of electrostatic shields fed from subsidiary resistance used as a potential divider.[1]

§ (11) AGNEW DYNAMOMETER.[2]—A dynamometer instrument in which the magnetic field, surrounding a cylindrical linear conductor carrying a comparatively large current, acts on a small coil close to it, tending to turn the coil so that its plane becomes perpendicular to the field cutting it.

This type of instrument was specially designed for the measurement of large currents, up to 5000 amperes (*Figs.* 11, 12).

A circular horizontal conductor, which may be tubular for the sake of water cooling, carries the main current. Close to it is suspended a small coil carrying a current which may be derived from the potential points of a

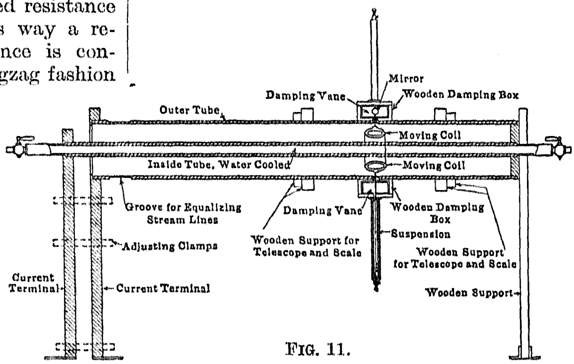

FIG. 11.

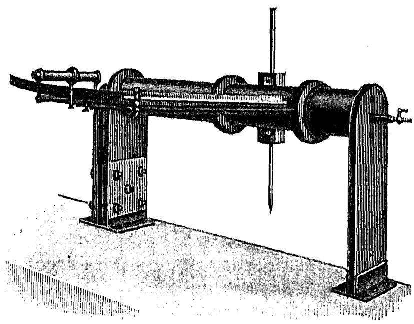

FIG. 12.

resistance through which the main current passes, in which case the instrument operates as a "square law" ammeter; or the moving coil may be fed from a separate circuit, in which case it may be used as a wattmeter.

[1] Orlich and Schultze, *Archiv der Elekt.*, 1912, i. 1.

[2] "A Tubular Electrodynamometer for Heavy Currents," P. G. Agnew, *Bull. Bureau Standards*, 1912, viii. 651; *Laws*, p. 87.

In practice two similar coils are used, one above and one below the tube. They are rigidly connected together without touching the tube, and are wound of insulated silver wire. In the illustration they are shown for clearness nearly at right angles to their working position. A torsion suspension is used. The main return conductor takes the form of a concentric tube enclosing the central conductor, and the moving coils.

It is important that the distance of the small coils from the central axis should remain constant. Provided symmetry is observed in the current distribution the indications of the instrument are independent of the diameter of either of the tubes. The instrument's indications are therefore independent of any symmetrical redistribution of currents in the conductors due to skin effects when alternating currents are used. This is a particularly valuable property of this type of instrument.

§ (12) Irwin Dynamometer Instruments.—These are electrodynamometers of the moving-coil type. The moving coil is placed between two fixed coils in which the currents circulate in opposite directions. They are made as ammeters, voltmeters, and wattmeters. The instrument is similar to the Kelvin balance as regards the magnetic field produced by the fixed coils. The currents circulate in opposite directions, giving rise to a radial field between them. In the Kelvin balance the moving coil tends to move axially in this field, either towards one of the fixed coils or the other according to the direction of the current passing through it.

In the Irwin instrument the moving coil is of the form ᗡD, there being two D-shaped coils so mounted that the force acting on the system is one of rotation and not one of translation.

The force acting on the coil is opposed by a spring in the usual way. As the currents in the effective parts of the coil flow in opposite directions, the instrument is unaffected by stray fields, assuming the intensity of such fields in the neighbourhood of the moving coil is constant.

§ (13) Instruments depending on the Use of Iron.—The force acting on soft iron in a magnetic field is used for operating alternating current instruments, such as voltmeters and ammeters, particularly those for use on switchboards.

They have a considerable advantage over instruments of the same type when used for direct currents in that the hysteresis error is negligible. When used for direct currents there is liable to be a serious difference between the indications when the current is rising and when it is falling. This can be made inappreciable in the case of instruments designed for alternating currents. They can also be made practically free from friction errors, since the rapid pulsation of the torque, combined with the slight vibration commonly present, assists in overcoming friction, the effect of which would otherwise be considerably more appreciable.

(i.) *Attracting Solenoid Type.*—A principle commonly used is that of the "sucking solenoid." The current to be measured is sent through a solenoid into which soft iron, usually in the form of a thin rod, is drawn against the force of a spring or of gravity. The relative size of the scale divisions can be adjusted to a considerable extent by the shape of the parts, by the value of the magnetic flux, and by variation of the effective pull through some device whereby there is an alteration of leverage as the deflection changes.

There are many modifications of this type. One of these is a simple arrangement by Elihu Thomson, in which the spindle of the pointer has an iron disc attached to it centrally, but on the skew. The disc is surrounded by a coil carrying the current and having its axis also inclined to the spindle. On the passage of the current the disc tends to set itself with its plane parallel to the magnetic field of the coil, thus producing a torque on the spindle to which the pointer is attached. The torque is commonly opposed by a spring.

(ii.) *Repulsion Type.*—A second principle made use of is the repulsion of two pieces of soft iron when placed close together in a magnetic field. A bar of iron in a magnetic field collects the flux in space near each end, the total energy being reduced by the concentration of flux in the length of the bar. If two soft-iron bars are placed parallel alongside one another in a magnetic field, they are magnetised and repel one another, since by separation the total energy is diminished. This motion is utilised to measure the strength of the current.

In another pattern of instrument each piece of soft iron is a thin sheet bent so as to form a segment of a circular cylinder; the two segments are concentric, and one can rotate about their common axis, carrying with it the indicating pointer of the instrument. The edges of the sheets are so shaped that when they become magnetised under the action of a current circulating in the coil of the instrument a torque is produced, which turns the movable segment about its axis. This motion is opposed, in some cases by a spring, in others by gravity, and the strength of the current is indicated by the motion of the pointer; the iron is so shaped as to produce as even a scale as possible. Excellent instruments of this type are made.

An example of the use of a moving iron instrument for measuring voltages up to 100,000

is shown in *Fig.* 13, which represents the arrangement of the apparatus at the National Physical Laboratory for generating, regulating, and measuring voltages up to 100,000. The voltmeter, of the iron repulsion type, is designed to have a very even scale for an A.C. instrument, and full deflection is produced by 500 volts. By the addition of resistances of integral multiples of that of the voltmeter, full-scale deflection can be obtained for 1, 2, 5, 10, 20, 40, and 100 kilovolts. The resistance boxes shown in the diagram are each insulated so that either end or the centre of the high voltage winding can be put at earth potential. The total resistance for 100,000 volts is 5 megohms.[1]

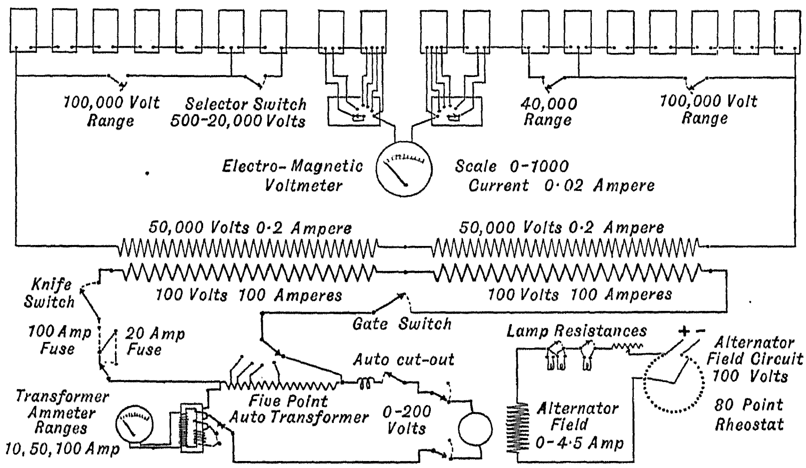

FIG. 13.

III. ELECTROSTATIC INSTRUMENTS[2]

§ (14) FORCES AVAILABLE. — Electrostatic instruments depend for their indications on the mechanical forces which arise when two materials are at a difference of electrical potential.

When two plane surfaces are at unit distance apart they attract or repel each other with a force F equal to $V^2A/8\pi d^2$, where V is the difference of potential in electrostatic units, A the area, and d the distance apart, the effect of the edges being neglected.

The order of magnitude of the forces available in instruments of this type may be illustrated by the following example (*Laws*, p. 245):

Let A be 100 sq. cm.,
V be 100 volts,
d be 1 cm.,

$$V=100 \text{ volts}=100\times10^8 \text{ electromagnetic units}$$
$$=\frac{100\times10^8}{3\times10^{10}} \text{ electrostatic units}$$
$$=\frac{1}{3} \text{ electrostatic unit;}$$
$$F=\frac{V^2A}{8\pi d^2}=\left(\frac{1}{3}\right)^2\frac{100}{8\pi}=\frac{100}{72\pi}=\frac{100}{226}=0{\cdot}442 \text{ dyne,}$$

which is about equal to the weight of 0·45 milligramme.

The forces available for instruments of this nature are therefore very small when ordinary commercial voltages of the order of 100 volts have to be dealt with. For higher voltages considerably more power is available as the forces go up as the square of the voltage. Above a few thousand volts the dimensions of the apparatus have to be increased on account of the electric breakdown of air at high stresses. This breakdown has been detected at the surface of a fine wire surrounded by a concentric metal cylinder, 10 cm. in diameter at 3000 volts difference of potential.

In spite of the rapid diminution of the force available at low voltages, instruments have been developed to read as low as 2 volts for full-scale deflection, using a fine-strip suspension.[3] Portable pivoted instruments giving full-scale deflection with 60 volts are also made.

§ (15) VOLTMETERS.—Practically all instruments of this type are founded on the types of instrument developed by Lord Kelvin.

They are of two general types:

(1) Those in which the movement of the attracted conductor is perpendicular to its surface (attracted disc electrometer).

(2) Those in which the movement is in the

[1] *I.E.E.* xlix. 6.
[2] Kelvin, reprint of *Papers on Electrostatics and Magnetism* (2nd ed.), 1884, p. 283 (Macmillan), a fundamental paper. See Bibliographies, *I.E.E.*, 1912, xlix. 53, and 1913, li. 327.
[3] Addenbrooke, *Electrician*, 1900, xlv. 901.

plane of the moving part (multicellular voltmeter).

The most important instrument depending on the attraction and normal displacement of

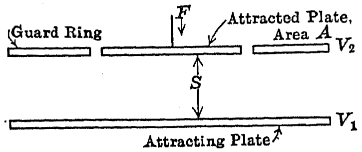

FIG. 14A.

parallel conductors is the Kelvin absolute electrometer. In this instrument the "edge" effect is avoided by a guard plate. The attraction of one plate is measured by the deflection of a spring which has to be calibrated by known weights (*Figs.* 14A, 14B).

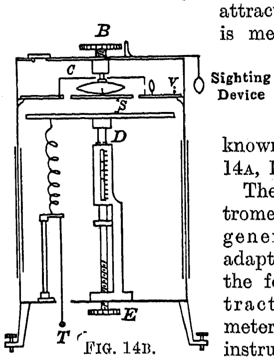

FIG. 14B.

The absolute electrometer is not in general use; but adaptations of it in the form of the attracted disc voltmeter are valuable instruments for the measurement of high voltages. The Kelvin pattern is made in two sizes—one up to 30,000 volts, and a larger one up to 100,000 volts. The latter is about 6 feet high and 3 feet in diameter. The sensitivity may be altered by changing the weight which the disc has to raise when it is attracted.

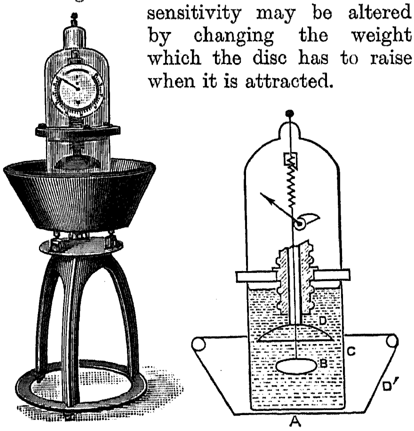

FIG. 15.

Other forms of attracted disc voltmeter for high voltages have been developed by Jona,[1] Siemens and Halske [2] (*Fig.* 15), Abraham.[3]

[1] *Science Abstracts*, 1905, 8B, No. 1390.
[2] *Laws*, p. 258. [3] *C.R.*, 1895, cxx. 726.

§ (16) ELECTROMETER TYPE OF VOLTMETER.—A more convenient form of electrostatic instrument for general purposes is obtained by allowing the attraction of the conductors to cause a rotation of one of them about an axis.

If the axis is vertical the suspension of the moving part may be by a fine strip of bronze, which acts as the conductor to the moving part. The restoring couple is supplied by the twist of the suspending strip. If the torque is sufficient a bifilar suspension may be used. To increase the torque the cellular type was developed in which as many as 10 or more "needles" are used. The needles are of a special dumb-bell shape, and a deflection of about 60° is obtainable. A pointer moving over a scale indicates the voltage applied.

This type of instrument has been used at the National Physical Laboratory for alternating measurements work of the highest accuracy.[4] A mirror is attached to the moving part and the indications are read on a scale 10 feet away and about 15 feet long. The instruments read to about 130 volts; and over the usual working part of the scale, 50 to 120 volts, the scale is divided to hundredths of a volt.

The dividing of the scale is done empirically by applying different voltages in integral steps of half a volt to the instrument from a special potential divider. The potential divider is supplied by continuous current, and the voltmeter forms the link between continuous current and alternating current measurements.

A precision form of this instrument by E. H. Rayner [5] has a very light moving system enabling a bifilar suspension to be used, practically abolishing the elastic fatigue, which is a serious disadvantage, in the case of torsion strip instruments used with this degree of sensitivity.

The needle has been modified in form, enabling a more even scale law to be obtained.

§ (17) AYRTON-MATHER VOLTMETER.—The design of the moving part N is shown in *Fig.* 16. It consists of two portions of a very light cylinder, and is attracted into the space between cylindrical inductors. Special consideration has been given to obtaining a high ratio between torque and inertia. The most sensitive form has a fine metal strip suspension and will give full-scale deflection with about 10 volts. Variable air damping is used. Portable pivoted instruments are made to

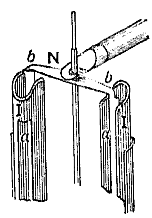

FIG. 16.

[4] Paterson, Rayner, and Kinnes (Bibliography), *Proc. I.E.E.*, 1913, li. 294.
[5] *Proc. I.E.E.*, 1921, lix. 138.

give full-scale deflection for 130 volts and upwards. At higher voltages sufficient power is available for use as a switchboard instrument. All such instruments will give little deflection till a third or a half full-scale voltage is applied. By suitably designing them a relatively even scale can be obtained for the top third of the range.

§ (18) ELECTROMETER INSTRUMENTS. — In the general form of electrometer instrument the moving conductor, termed the needle, is enclosed in a box consisting of four hollow quadrants nearly touching each other; a small central hole is provided for the suspension to pass through.

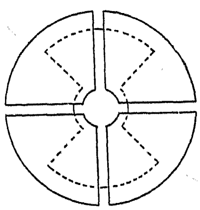

FIG. 17.

The moving conductor is, in plan, usually bounded by circular and radial lines as shown in *Fig.* 17.

The opposite pairs of quadrants are commonly connected together.

The needle is generally charged to a potential differing from that of the quadrants by from 40 to 200 volts. If the quadrants are connected together so as to be at the same potential, there will be no deflection of the needle provided there is complete symmetry. In practice a small deflection will result, which may be reduced to zero by slight adjustment of the instrument, such as by altering the level. If a small deflection remains it will not affect the accuracy of the readings, which must be taken from this "electrical zero" position.

When reading zero the needle should occupy an unsymmetrical position under one of the radial quadrant slits, and the adjustment should be such that its centre line will come opposite one of the slits at half-scale deflection. This will allow 10° to 15° deflection on either side, which, assuming a mirror is used, will give an apparent deflection of 40° to 60°.

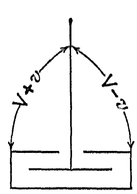

FIG. 18.

When the needle is charged to a potential V relative to the quadrants, they apply to it equal and opposite torques proportional to V^2.

Now suppose that instead of the quadrants both being at a potential V relative to the needle, one is charged to a potential $V+v$ and the other $V-v$, then the one set of quadrants will produce a torque proportional to $(V+v)^2$ and the other $(V-v)^2$ (*Fig.* 18). The resulting torque is $(V+v)^2-(V-v)^2=4Vv$. Assuming V is constant the torque is proportional to the difference of potential $2v$ between the quadrants.

If the instrument is allowed to deflect and the rate of change of capacity of needle and quadrants is linear over the working range, the resulting deflection is proportional to v.

In actual working it is often impracticable to divide up the voltage, $2v$, to be measured into two halves, since this would require a dividing resistance to keep the mean voltage of the needle equal to V (*Fig.* 19).

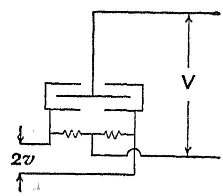

FIG. 19.

The common method of using the instrument is to keep one quadrant at potential V and to apply the potential, $2v$, to be measured, between it and the other quadrant whose potential will be $V \pm 2v$.

The torque in this case will be

$$(V \pm 2v)^2 - V^2 = \pm Vv + 4v^2.$$

The quadratic term is generally small, as v is commonly much less than V. In any case it is of little practical importance, as the instrument has to be calibrated empirically by applying known values of v from a standard cell, or, when the scale law is required to be known accurately at several points, by using a potential divider in the form of a suitable resistance carrying a known current.

As the instrument takes no current other than the very small capacity current which ceases, for continuous potentials, when full deflection is obtained, it has been largely used for physical research, especially in cases where an instrument requiring a continuous supply of power is inadmissible. The Dolezalek form has been much used in this manner.

In some early forms of Kelvin electrometer a comparatively short bifilar suspension is used which requires large voltages to operate it. It was developed at the time that atmospheric electrification was engaging Sir William Thomson's attention, when an instrument for several hundred volts was required.

§ (19) DOLEZALEK ELECTROMETER. — The Dolezalek instrument (*Fig.* 20) is designed for high sensitivity. The needle is made of "silvered" paper or aluminium, and is partly cut away to reduce the inertia without serious reduction of torque. The suspension may be of fine bronze or, where the highest sensitivity is required, silvered quartz or glass can be used, which gives much less control. By this means a sensitivity of 150 mm. can be obtained at 1 metre with 100 volts on the needle and 0·1 volt on the quadrants, using a suspension 0·006 mm. diameter. Suspensions of half this diameter can be used.

§ (20) ELECTROMETER AS A WATTMETER.— It has been shown that the torque on the

electrometer needle is proportional to Vv, where $V+v$ and $V-v$ are the differences of potential between the needle and the two sets of quadrants. This holds of steady voltages.

If the voltage varies the mean torque is proportional to the mean value of the product Vv. If V is proportional to the voltage in the circuit and v to the current, the instrument will indicate the mean power and will act as a wattmeter.

If the voltage varies sufficiently rapidly compared with the time of swing of the instrument the needle will take up a steady

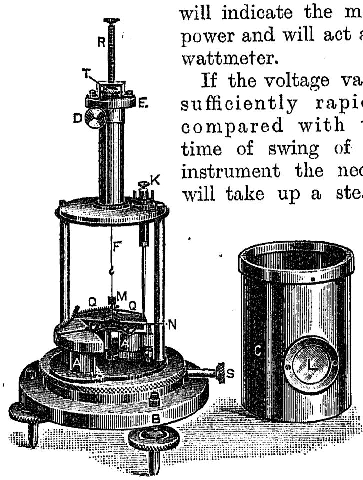

FIG. 20.

position, corresponding to the mean value of the product Vv. The product Vv has here a special significance, as in the general case the variations of V and v are not in phase.

Suppose the voltage between the needle and the mean of the two quadrants is represented by a harmonic function of the time, such as $V \sin \theta$ where $\theta = \omega t$, t being time and ω the pulsatance or radians per second—which is equal to $2\pi f$ where f is the frequency—and that the similar harmonic function $2v \sin (\theta - \alpha)$ represents the difference of potential between the quadrants, then the torque is proportional to the mean value of $2Vv \sin \theta \times \sin (\theta - \alpha)$ or

$$2Vv\,(\sin \theta^2 \cos \alpha - \sin \theta \cos \theta \sin \alpha).$$

The average value of ($\sin \theta \cos \theta$ or $\frac{1}{2} \sin 2\theta$) is zero throughout the range of θ from 0 to π, so the mean torque is proportional to $Vv \sin^2 \theta \cos \alpha$.

The average value of $\sin^2 \theta$ per cycle is $\frac{1}{2}$, thus the mean torque is proportional to $Vv \cos \alpha$. This is independent of frequency, assuming the needle potential has time to follow accurately the potential of supply. The value $v \cos \alpha$ may be looked upon as the component of the vector v in phase with V. The instrument gives no indication of the quadrature component $v \sin \alpha$.

It will be seen that superposed on the torque in a constant direction represented by $\sin^2 \theta \cos \alpha$ there is an alternating torque of double the frequency given by $\frac{1}{2} \sin 2\theta \cos \alpha$. The mean value of each component of the torque depends on α, and when α is 90° the term representing the unidirectional torque vanishes. The instrument reads zero, but the alternating torque to which it does not respond has then its maximum amplitude.

The unidirectional torque proportional to $\sin^2 \theta$ is not simple harmonic, while the oscillating torque of double the frequency is harmonic.

If α is 45° so that $\cos \alpha$ and $\sin \alpha$ are equal, we see that the relative amplitudes of the two torques are in the ratio of the average values of $\sin^2 \theta$ to $\frac{1}{2} \sin 2\theta$ taken between the values 0 and π for 2θ the harmonic component. This ratio is $\pi/2$, since the mean value of $\sin 2\theta$ during a cycle 0 to $\pi/2$ is $2/\pi$ and that of $\sin^2 \theta$ is $\frac{1}{2}$.

If V is proportional to the voltage of a circuit in which the pressure varies harmonically, simply, or complex, and v is proportional to the current in the same circuit, then the instrument indicates the mean value of the product of their in-phase vectors and therefore the power in the circuit.

The forces acting between the coils of the electromagnetic type of wattmeter, §§ (9), (10), (11), are quite similar.

§ (21) POWER MEASUREMENT BY THE ELECTROSTATIC WATTMETER.[1]—The use of the instrument as a wattmeter in this manner has been extensively developed at the National Physical Laboratory.

Among the advantages is the possibility of its very wide application, the same instrument being used for circuits varying from 100 volts to many thousands of volts, with currents from a fraction of a thousandth of an ampere up to several thousand amperes. It is also of the greatest value in the measurement of very small phase angles, fractions of a minute being easily measured in certain types of test.

Readings are made by reflected light on a scale 3 metres away. The scale, horseshoe-shaped, is about 5 metres long. The voltage used on the needle is generally 100, and up to 3 volts between the quadrants. The standard value is 2 volts, represented by 2000 divisions on the scale. To obtain the desired sensitivity the distance between the quadrants is made only 2 mm. Special attention has to be paid to the design and construction of the needle in these circumstances. The difference of potential, proportional to and in phase with the current, is obtained from the ends

[1] Orlich, *Science Abstracts*, 1904, vii. A, No. 159; 1909, xii. A, No. 694; 1909, xii. B, No. 632; Paterson, Rayner, and Kinnes, *I.E.E.*, 1913, li. 294.

of a resistance through which the current passes.

The resistances for the smaller currents, 0·1 ampere to 20 amperes, are made of constantan wire No. 24, double silk covered, twinned and silk covered again. A length corresponding to 2 ohms single, *i.e.* 4 ohms of twin wire, is cut off and forms a very non-inductive go-and-return resistance, capable of carrying half an ampere. The two wires at one end are soldered to the terminal blocks, and the other ends are soldered together, and are connected to another terminal block to form the "mid-point of the current resistance" which is required for making connection to the potential circuit.

For larger currents than 20 to 40 amperes the amount of heat to be dissipated becomes inconveniently great, and a tubular type of resistance is used for currents 50 to 2000 amperes.[1] These are made of manganin tube, the diameter and thickness being chosen so that about 50 cm. length is required to produce a two-volt difference of potential at the rated currents of 50, 100, 200, 500, 1000, and 2000 amperes. The tubes are enamelled inside to prevent corrosion, and are cooled by passing tap water through them; the conductivity of the water is negligibly small compared with that of the tube. A special contrivance is adopted to make the resistances as non-inductive as practicable. The potential leads from the ends of the tube are carried to the centre along a thin metal sheath wrapped on the tube and separated from it by a thin layer of insulation. By this means the effect of the current in the tube in producing an inductive E.M.F. in the potential circuit is reduced to a small fraction of what it would otherwise be, especially in the case of resistances for the larger currents. Except in special cases, where accurate quadrature measurements are involved, the induction error is negligible.

When voltages higher than 100 have to be dealt with, the needle of the wattmeter and of the electrostatic voltmeter, which is generally used in parallel with it, are connected to a potential dividing resistances. These are woven wire resistances as used in the Duddell-Mather wattmeter capable of carrying 0·05 ampere. The connections are arranged so that over one of the sections there is 100 volts drop when the circuit voltage is applied to a suitable part of the resistance.

Some of these resistances are in 5 sections of 20,000 ohms each; each section is capable of carrying 1000 volts. One of the end sections is subdivided into ten subsections, so that each will have 100 volts on it.[2] From the end one connections are made to the wattmeter and voltmeter. Such a method of division permits of a fraction equal to 100 volts being obtained when the supply voltage varies from 100 to 5000 volts in steps of 100 volts. Many other ratios can be obtained when required. For high voltages further similar resistances are put in series. The capacity current required by the instruments is negligible at ordinary frequencies (*Fig.* 21).

In all work of this nature it is essential that the instruments should be at earth potential. It is therefore arranged that the end of the potential dividing resistance and the middle point of the current resistance are connected to earth.

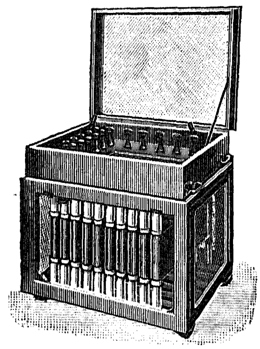

FIG. 21.

One of the main uses of the electrostatic wattmeter is for investigating the errors of other wattmeters and of watt hour meters. For this work an "artificial load" is used. The voltage required is generated by one alternator, a step-up transformer being used if required. The current is generated by a second alternator, generally through a step-down transformer if more than a few amperes are required. The connections are shown in the diagram (*Fig.* 22).

The electrostatic wattmeter is also very valuable for measuring small voltages if a voltage of the same frequency and phase can be applied to the needle, and also for measuring departures from the quadrature of two voltages by similar methods.

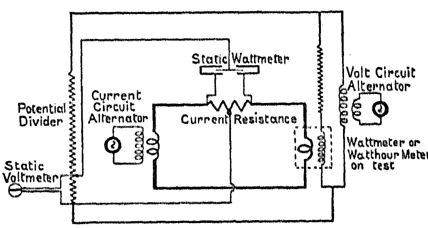

FIG. 22.

§ (22) ELECTROSTATIC WATTMETER ON A REAL LOAD OPERATING AT FULL-CIRCUIT VOLTAGE.—The consideration of the electrometer as a wattmeter has been confined to the case where the voltage between the needle and the average of the two quadrants has been kept constant, as can be done on an *artificial* load

[1] *J.I.E.E.*, 1908-9, xlii. 455. See also "Inductance, Measurement of," § (47).
[2] *J.I.E.E.*, 1913, li. 308.

in which the voltage and current are supplied from separate sources, either from separate machines or by the interposition of a transformer which provides the requisite insulation between the two circuits.

When used to measure the power on a real load the readings are modified by the effect of the power expended in the resistance R used for obtaining the necessary potential difference across the quadrants.[1] The power absorbed in the load is equal to the indication of the wattmeter less half the power ($\frac{1}{2}RI^2$) expended in the resistance R (*Fig.* 23).

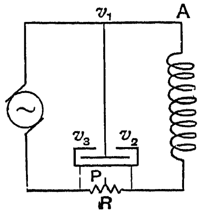

FIG. 23.

Let v_1 be the needle potential, v_2 and v_3 the quadrant potentials, then the force on the needle due to one set of quadrants is $(v_1-v_2)^2$, and to the other $(v_1-v_3)^2$. The resulting torque and deflection will be proportional to

$$(v_1-v_3)^2-(v_1-v_2)^2=2v_1v_2-2v_1v_3+v_3^2-v_2^2,$$

which may be written

$$2(v_2-v_3)\left(v_1-\frac{v_2+v_3}{2}\right).$$

If P is the middle point of the resistance R its potential is $(v_2+v_3)/2$, and $v_1-(v_2+v_3)/2$ is the difference of potential between A and P, v_2-v_3 is the voltage across R; and if R is noninductive $v_2-v_3=Ri$.

The instantaneous torque is proportional to

$$Ri\left(v_1-\frac{v_2+v_3}{2}\right),$$

i.e. to R × the watts expended in the circuit between A and P.

If I is the effective value of the current and W the watts in the circuit, then the deflection of the instrument is proportionate to $R(W+\frac{1}{2}RI^2)$, and $\frac{1}{2}RI^2$ must be subtracted from the apparent power measured by the instrument. When the power factor is low the correction may amount to a large fraction of the apparent power.

§ (23) ELECTROSTATIC WATTMETER ON A REAL LOAD OPERATING AT LESS THAN THE CIRCUIT VOLTAGE.[2]—When the voltage of the circuit is higher than that for which the instrument is designed a suitable fraction of the voltage may be used by exciting the needle from a potential divider, which often takes the form of an accurately divided high resistance capable of withstanding several hundred or thousand volts, the needle being operated at 100 or 200 volts. Let v_1' be the needle voltage, and N the multiplying power of the potential divider (*Fig.* 24).

$$N=\frac{R_1+R_2}{R_2}=\frac{v_1-v_3}{v_1'-v_3},$$

$$\therefore v_1'-v_3=\frac{1}{N}(v_1-v_3).$$

As in the case of a real load without a potential divider, the instantaneous torque is proportional to

$$=(v_2-v_3)\left(v_1'-\frac{v_2+v_3}{2}\right)$$

$$=Ri\left(v_1'-v_3-\frac{v_2-v_3}{2}\right)$$

$$=Ri\left(\frac{1}{N}(v_1-v_3)-\frac{v_2-v_3}{2}\right)$$

$$=\frac{R}{N}i(v_1-v_3)-\frac{R^2i^2}{2}.$$

If w is the value of the instantaneous power in the load

$$i(v_1-v_3)=w+Ri^2.$$

The instantaneous torque is proportional to

$$\frac{R}{N}(w+Ri^2)-\frac{R^2i^2}{2};$$

the mean torque

$$k\theta=\frac{R}{N}(W+RI^2)-\frac{R^2I^2}{2},$$

$$W+RI^2=\frac{N}{R}k\theta+\frac{NRI^2}{2},$$

$$W=\frac{N}{R}k\theta+\frac{N-2}{2}RI^2.$$

The value of $(N/R)k\theta$ is preferably obtained by calibrating the instrument on a real load with a suitable value of R, the needle being excited with the same voltage as that obtained from the potential divider when the instrument is in use.

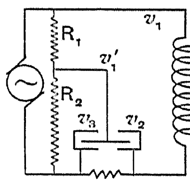

FIG 24.

If the power factor be low, the value of $RI^2(N-2)/2$ may be a large proportion of the total power indicated by the instrument, and to obtain the difference accurately very precise measurements of the current are necessary.

A special and very valuable case occurs when $R_1=R_2$, so that $N=2$ when the correction vanishes, and the necessity for the measurement of RI^2 disappears.

If R_1 is greater than R_2, so that $N>2$ and $(N-2)/2$ is positive, and if the power factor is low, the value of $[(N-2)/2]RI^2$ may exceed the power in the load. In such circumstances the wattmeter deflection will be negative, and

[1] Russell, *Alternating Currents*, 1904, i. 189.
[2] Russell, i. 195.

again an accurate measurement of I becomes necessary, especially for relatively large values of I, as the true power may be only a tenth of that indicated by the wattmeter deflection.

§ (24) ELECTROSTATIC WATTMETER USED FOR MEASUREMENTS OF POWER LOSS IN INSULATING MATERIAL.[1]—The power absorbed by insulating materials when subjected to alternating electric stress is generally greater than would be indicated by the measurement of the current passing under the influence of similar continuous potentials.

In the case of good insulators, such as mica and paraffined paper, the actual power lost under alternating stress may be less than one thousandth of the amount indicated by the product of the voltage and current, but the loss will be many times that calculated from measurements of resistances as measured by direct current.

In less perfect insulators the effect is often still greater and the power expended in the insulation may be sufficient to raise its temperature appreciably. In very many insulating materials used in electrical plant, such as varnished papers and cloths, the effect of increase of temperature is greatly to increase the loss. The heating may therefore become cumulative, in which case failure will occur, often indicated by a rapid rise of temperature, which may supervene after several minutes or hours of a much slower initial rise. A wattmeter will indicate the whole history of the process, and will, under suitable conditions, give a definite proof of inevitable failure, often a considerable time before such failure occurs and, in favourable circumstances, before permanent damage has been caused.[2]

Mr. G. L. Addenbrooke initiated the electrostatic wattmeter method for investigations of this nature, and other workers have developed it. For testing insulation in this manner the electromagnetic type of wattmeter is not often suitable, as the currents are very small. It can, however, be used in special cases, such as for testing long lengths of cable where a large amount of insulating material is tested at once.

By the electrostatic method even a few square inches of insulating material may be sufficient to give a satisfactory measurement. By varying the value of the resistance R, which can be done while the insulation is under test, a wide range of power and current can be dealt with. In this manner it is possible to measure a few hundredths of a watt at 10,000 volts.

The current is measured by an electrostatic voltmeter. If only a low voltage on R is admissible, this can be an instrument reading up to 2 volts. On circuits of several thousand volts a 10-, 60-, or 100-volt instrument may be suitable and is considerably quicker in action.

For work of this nature on insulating materials at low-power factors there is very great advantage in using the electrometer at half the circuit voltage in order to eliminate the correction $RI^2(N-2)/2$.

In the case of voltages of the order of 10,000, 5000 may be used on the instrument with great increase in torque above that possible with 100 volts. Clearances must, however, be considerably increased, and as a result accuracy of manufacture and adjustment becomes of much less importance. When the voltage is about 7000, using a clearance of 2 cm. between the quadrants and a needle with a well-rounded edge, the electric stress begins to ionise the air. The effect becomes appreciable in measurements on condensers at low-power factors.

Above such voltages the whole instrument can be put in mineral oil, which it is possible to refine so as to have a power factor of considerably less than 1 in 1000. By this means 60,000 volts has been used by C. E. Skinner of Pittsburg, between needle and quadrants, and instruments of this type promise to be of great value in the investigation of many technical problems.

§ (25) ERROR DUE TO CAPACITY CURRENTS.—It is of first importance when dealing with circuits of very low-power factor that the potential divider should be true not only in ratio but, what is more important, in phase when the needle is connected to it.

The needle, especially at high voltages, may take an appreciable capacity current, and it is difficult to prevent this upsetting of the phase of the point on the potential divider feeding it. By using a relatively large current in the potential divider the effect may be reduced; but this cannot be carried far without considerable cost and expenditure of a very considerable power.

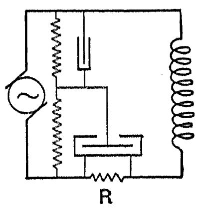

FIG. 25.

A better method would be to put a condenser across the upper part of the potential divider so adjusted as to provide a capacity current approximately equal to that of the wattmeter. This condenser would probably consist of plates in oil (*Fig* 25).

A more convenient way of avoiding such difficulties is to connect the needle to the middle point of the secondary winding of

[1] Miles Walker, *Am. I.E.E.*, 1902, xix. 1035; Rayner, *I.E.E.*, 1912, xlix. 3; Skinner, *J. Franklin Institute*, 1917, p. 667.

[2] Rayner, *I.E.E.*, 1912, xlix. 3.

transformer used to generate the high voltage (*Fig.* 26).

The resistance of the transformer winding, which will be probably of the order of 3000 ohms in the case of a transformer for 100,000 volts, is far less than any practicable external potential divider of the resistance type.

For instance, if a resistance as low as 1 megohm were used as a potential divider for 100,000 volts it would absorb 10 kilowatts.

The phase error produced would be about 300 times that when using the winding of the transformer itself as the potential divider.

At high voltages the capacity current taken by the quadrants which are connected to the

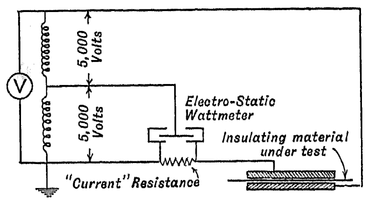

Fig. 26.

load side of the resistance R becomes comparable with the load current itself when testing small amounts of insulating materials. In such cases high values of R would be used and an appreciable deflection may be obtained, even when the high voltage connection to the load is interrupted. Such a deflection will vary as R. It may be allowed for by carrying out the test with different values of R and extrapolating[1] to the value indicated when R = zero.

IV. Power Measurements

§ (26) In Alternating Current Circuits.—Measurements of power in direct current systems are commonly made by ammeters and voltmeters, or, where higher accuracy is required, by a potentiometer.[2]

For alternating power measurements a wattmeter must be used, unless the phase relation between the voltage and current is known.

For commercial work indicating wattmeters are commonly used, with or without instrument transformers according to the voltage and current to be measured. For laboratory and research purposes other types are available.[3]

§ (27) Single-phase Measurements.—The voltage circuit of the wattmeter is supplied direct from the circuit to be measured, or from a step-down transformer in the case of high voltages. In the case of an electrostatic instrument a potential dividing resistance is commonly used. The current passes through the instrument direct, or for currents above 20 to 50 amperes, through a current transformer, which supplies a nominal full-load secondary current of 5 amperes, for which the indicating instrument is wound. In the case of electrostatic wattmeters a resistance is used in the current circuit of a value to give about 1 to 2 volts difference of potential on the quadrants.

Polyphase Power Measurements

§ (28) Two-phase Measurements.—A two-phase circuit is treated as two separate single-phase circuits. A wattmeter is placed in each circuit and the sum of the indications of the two gives the power. For commercial circuits instrument transformers are generally used.

Certain makes of both the portable type (such as some patterns by the Weston Co.) and of the laboratory type (such as the Drysdale instrument) are made with two wattmeter elements operating on the same axis, one above the other. One instrument only is then required, the total power being given by a single reading. Such instruments may be also used on three-phase circuits.

§ (29) Three-phase Measurements.—The measurement of three-phase power is commonly carried out by the two-wattmeter method.

The current circuits of two wattmeters form part of the circuits of two of the three con-

Fig. 27.

ductors while the potential coils are connected to the third conductor (*Fig.* 27).

The method is a special case of the following theorem enunciated by Blondel.[4]

If power be supplied to any system through n conductors in which are severally connected the current coils of n wattmeters, one terminal of the pressure circuit of each wattmeter being connected to its current circuit, and all the free terminals being connected together, then the total power supplied to the system is the algebraic sum of the n wattmeter readings.

If one of the conductors is chosen as the

[1] *Journal I.E.E.*, 1912, xlix. 45.
[2] See "Potentiometer, System of Measurement."
[3] See "Meters for Electrical Supply."

[4] "Measurements of the Energy of Polyphase Currents," A. Blondel, *Proc. International Elec. Congress* (Chicago), 1893, p. 112.

common point, so that the two ends of the potential circuit of this particular wattmeter are connected to the same point, and therefore no current passes through the coil, this wattmeter will read zero, and may therefore be removed. It follows that $(n-1)$ wattmeters will measure the power supplied through n conductors to any type of load, provided that the current in each $(n-1)$ of the conductors traverses the current coil of one of the $(n-1)$ wattmeters, while one end of the potential circuit of each wattmeter is connected to the nth conductor, and the other end to the conductor connected to the current circuit of that wattmeter.

§ (30).—The theory of the measurement by the two-wattmeter method of the power in a three-phase circuit may be deduced as follows.

The general case may be considered as corresponding to a combined star and mesh system, which reduces to either a simple star or mesh circuit by considering the appropriate currents equal to zero [1] (*Fig.* 28).

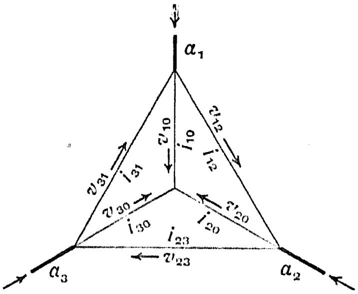

FIG. 28.

Taking instantaneous values for the voltages v and the currents i and a in the different conductors, and the positive directions those shown by the arrows,

$$a_1=i_{12}-i_{31}+i_{10},$$
$$a_2=i_{23}-i_{12}+i_{20},$$
$$a_3=i_{31}-i_{23}+i_{30},$$

so $\quad a_1+a_2+a_3=i_{10}+i_{20}+i_{30}=0.$

The power

$$p=v_{12}i_{12}+v_{23}i_{23}+v_{31}i_{31}+v_{10}i_{10}+v_{20}i_{20}+v_{30}i_{30}.$$

To prove the theorem it is necessary to eliminate one line current, say a_1, and the opposite voltage v_{23}.

$$v_{23}=-v_{31}-v_{12},$$

and $\quad i_{10}=-i_{20}-i_{30},$

so

$$p=v_{12}i_{12}+(-v_{31}-v_{12})i_{23}+v_{31}i_{31}+v_{10}(-i_{20}-i_{30})+v_{20}i_{20}+v_{30}i_{30},$$

$$p=v_{12}i_{12}+(-v_{31}-v_{12})i_{23}+v_{31}i_{31}+(v_{20}-v_{10})i_{20}+(v_{30}-v_{10})i_{30},$$

[1] Russell, *Alternating Currents*, i. 236.

and $\quad v_{10}-v_{20}=v_{12};$

or $\quad v_{20}-v_{10}=v_{21},$

and $\quad v_{30}-v_{10}=v_{31},$

so

$$p=v_{12}i_{12}+(-v_{31}-v_{12})i_{23}+v_{31}i_{31}+v_{21}i_{20}+v_{31}i_{30}.$$

and as $\quad v_{12}=-v_{21},$

$$p=v_{21}(i_{23}-i_{12}+i_{20})+v_{31}(i_{31}-i_{23}+i_{30})$$
$$=v_{21}\cdot a_2+v_{31}\cdot a_3.$$

That is, the instantaneous power is the sum of the products of the current a_2 and the voltage between a_2 and a_1, and of the current in a_3 and the voltage between a_3 and a_1. As a wattmeter measures the mean value of the instantaneous product of the current and voltage of the circuits connected to it, two instruments arranged as in *Fig.* 27 will measure the power whether the load be mesh or star or of any other configuration, and whether balanced or not.

A more general method of considering the theorem is as follows (*Laws*, p. 328).

Suppose a load system is fed by n wires carrying currents of instantaneous value i_1, i_2, i_3, i_n, and the potentials of these are v_1, v_2, v_3, . . . v_n; the instantaneous power is

$$p=i, v, +i_2v_2+i_3v_3+\ .\ .\ .\ +i_mv_n. \quad (1)$$

As a datum for reference of potential, take any point on the system. Let its potential be v_0; then the algebraic sum of the instantaneous currents being zero, we have

$$0=i_1+i_2+i_3+\ .\ .\ +i_n,$$

$$\therefore 0=i_1v_0+i_2v_0+i_3v_0+\ .\ .\ .\ +i_nv_0 \qquad (2)$$

Subtracting (2) from (1)

$$p=i_1(v_1-v_0)+i_2(v_2-v_0)+i_3(v_3-v_0)+\ .\ .\ .\ +i_n(v_n-v_0).$$

The mean value of $i_1(v-v_0)$ will be the indication of a wattmeter through whose current coil i_1 passes, and whose pressure coil is energised by the difference of potential (v_1-v_0). The total power is measured by n such wattmeters. If v_0 is made the same as one of the line potentials v_1, or v_2, or v_3, etc., that wattmeter will read zero and may be removed as mentioned previously. The potential v_0 may also be the common point of all the potential circuits of the n wattmeters, disconnected from any other part of the circuit. The sum of the readings is independent of the values of the resistances of the potential circuits, which may be all different provided each wattmeter is adjusted to read correctly when used alone on a simple single-phase circuit.

§ (31) Phase Relations in Three-phase Circuits.—The phase relation of current and voltage in the wattmeter circuits when measuring three-phase power by the two wattmeter method differ by thirty degrees, when the load is non-inductive.

In one instrument the voltage leads in

front of the current and in the other lags behind it.

A, B, and C (*Fig.* 29) represent the relative directions of the phase angles of the currents, and D, E, F of the voltages. Let the current coils of the wattmeters be placed in B and C. If the rotation of the vectors is counter clock-wise it will be seen that the current B leads on the voltage E and the current C lags behind the voltage in F. The angles are 30° in each case, the power is V.I. cos 30° and V.I. cos (−30°) where V and A are root mean square values. The total power is $W_B + W_C = 2$ V.I. $\sqrt{3}/2 =$ V.I. $\sqrt{3} =$ V.I. × 1·732.

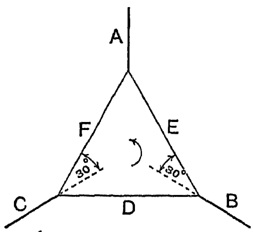

FIG. 29.

If the load be inductive the current vectors lag behind the voltage vectors.

If the lag be 30° the power on the B side wattmeter W_B becomes

$$W_B = \text{V.I.} \cos(30° - 30°) \quad = \text{V.I.}$$

$$W_C = \text{V.I.} \cos(-30° - 30°) = \text{V.I.} \times 0{\cdot}5.$$

$$\text{Total power} = W_B + W_C \quad = \text{V.I.} \times 1{\cdot}5.$$

The indication of wattmeter B has risen to a maximum; its current and voltage are in phase.

If the lag is increased to 60° we have

$$W_B = \text{V.I.} \cos(30° - 60°) \quad = \text{V.I.} \sqrt{3/2}.$$

$$W_C = \text{V.I.} \cos(-30° - 60°) = 0.$$

$$\text{Total power} = W_B + W_C \quad = \text{V.I.}\ {\cdot}866.$$

If the lag is increased to 90°, we have

$$W_B = \text{V.I.} \cos(30° - 90°) \quad = \text{V.I.} \times 0{\cdot}5.$$

$$W_C = \text{V.I.} \cos(-30° - 90°) = -\text{V.I.} \times 0{\cdot}5.$$

$$\text{Total power} = W_B + W_C \quad = 0.$$

The indications of wattmeter A have become negative, and in practice the current in it must be reversed and the reading subtracted. The numerical value of the indications of each wattmeter are the same as that of W_C at 30° lag.

§ (32).—The diagram (*Fig.* 30) shows the readings of the wattmeters on a balanced three-phase load, as the three-phase power factor varies, and can be used to determine the power factor from the measurement of the power by two wattmeters.

A. Power in the meter in which the current is in advance of the voltage.

B. Power in the meter in which the current lags behind the voltage.

The curves, which are sinusoidal, are continuous beyond the limits of the diagram, and are equally applicable to a "leading" load, being symmetrical about the vertical line representing zero angle of lag.

The power factor of a balanced three-phase circuit may be considered as the ratio of the actual power in the circuit to the value which would be obtained if the voltage and current vectors were rotated relatively till the power

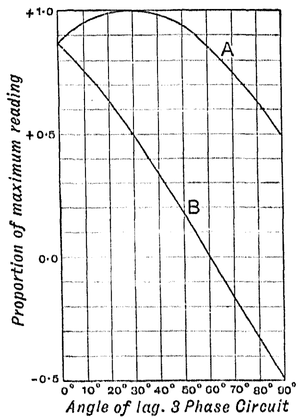

FIG. 30.

was a maximum, *i.e.* until the phase displacement was +30° in one circuit and −30° in the other, when measuring by the two wattmeter method.

§ (33).—The power factor may be determined from the ratio of the readings of the wattmeters.

It is represented by the ratio of

$$\frac{\cos(30° + \phi) + \cos(-30° + \phi)}{\cos 30° + \cos(-30°)}.$$

The relation over the useful range is shown in *Fig.* 31, where the abscissa is the ratio of the wattmeter readings.

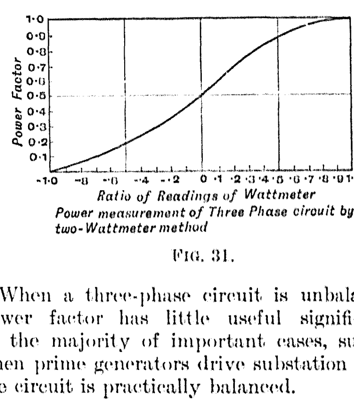

FIG. 31.

When a three-phase circuit is unbalanced, power factor has little useful significance. In the majority of important cases, such as when prime generators drive substation plant, the circuit is practically balanced.

V. Alternating Current Energy Meters

§ (34).—Alternating current integrating power meters of three types have been in general use.

(i.) Commutator meters.
(ii.) Clock meters.
(iii.) Induction meters.

(i.) *Commutator Meters.*—Commutator meters are now very little used, being largely displaced by induction meters. They are very similar to the direct current energy meters,[1] in which an armature with a commutator revolves in a field produced by fixed coils traversed by the current to be measured. The current in the armature is proportional to the voltage of the circuit. Little or no iron is used in the magnetic circuit, so that the fluxes are proportional to the currents in the two circuits and the torque on the armature is proportional to the product of the voltage and current. A retarding torque proportional to the speed is provided by a magnetic brake as in induction meters. Compensation for the phase displacement of the flux due to the inductance of the pressure winding is necessary for accuracy when the power factor is low.

§ (35) (ii.) *Clock Meters.*—The only type in common use is the Aron meter. It depends upon the change of rate of a pendulum which is acted upon by electromagnetic forces, either opposing or assisting the force of gravity. The pendulum has a horizontal coil of fine wire at its lower end, through which a current passes which is proportional to the voltage of the circuit. The current coil is fixed, also horizontally, just below the pendulum. In practice two pendulums are used, in one of which the electromagnetic force assists gravity and in the other it opposes. One pendulum therefore gains and the other loses when compared with the rate when no current is flowing. A mechanical differential gear integrates the difference in rate, which is proportional to the power; the energy is registered on dials in the usual manner. In order to allow for slight errors between the two pendulums, an automatic switch is provided which reverses the currents in the voltage coils periodically, and at the same time alters the train of mechanism so that the differential motion still causes the dials to move in the same direction as before.

The motive power is provided by a spring which is wound up electrically at short intervals. One advantage of this type of meter is that the smallest load will be integrated, whereas other types of meters are not expected to register if the load is appreciably under one per cent of its full value. A disadvantage of the meter is the time required to check its accuracy. There is no spindle rotating with a constant velocity, by the speed of which the accuracy of the meter can be quickly checked even at low loads. This is an essential part of other meters.

§ (36) (iii.) *Induction Watt-hour Meter.*—The induction alternating energy meter[2] is an integrating power meter which is operated by two or more alternating magnetic fields. These fields produce eddy currents in a disc or cylinder of aluminium or copper. The interaction of the currents and the fields produce a resultant tangential force on the disc, tending to rotate it. By suitable design and adjustment the torque may be made closely proportional to the mean value of the power to be measured. A retarding torque proportional to the velocity is provided by a permanent magnet or magnets which produce eddy currents in another part of the same disc. The result is that the speed of rotation is proportional to the power.

This type of meter is manufactured by many firms, the designs differing only in detail. It is used in very large numbers for the measurement of widely different amounts of power, such as several thousand kilowatts in many generating stations to a few watts in private houses.

Its general adoption is largely due to its mechanical simplicity. The operating part is a light disc, usually of aluminium, fixed on an axle, the whole weighing 10 to 30 grams. It is moved by the action of currents induced in it. There are no rubbing contacts to lead current into and out of the moving part. Its simplicity is ideal, and enables a robust meter to be made, which is not likely to be easily deranged. The actual paths of the currents produced in the disc and the interaction of these with the operating magnetic fluxes are among the most complicated matters in electrical engineering.

§ (37) Theory of Induction Meters.—An outline of the theory is as follows:

Let M (*Fig.* 32) be a C-shaped magnet with a small air gap in which a disc of aluminium can rotate without touching the magnet faces. Suppose the magnet is wound with a coil traversed by an alternating current I_1. There will be an alternating flux cutting the disc, in which eddy currents will be generated, represented by the dotted lines in diagram B, as shown by the arrows.

If S_1 and S_1' represent two other magnets similar to one another wound with another circuit carrying a current I_2 so that the flux at any moment is in the same direction in the parts vertically opposite to one another, the positions of which are shown by full circles in diagram B, it will be seen that, as the

[1] See "Meters for D.C. Electricity," Part III.

[2] H. G. Solomon, *Electricity Meters* (Griffin & Co.); *Laws*, p. 473.

circular eddy currents generated by the flux produced by M are in opposite directions where they cut these circles, and the fluxes due to S_1 and S_1' are also in opposite directions at right angles to the disc where they act on

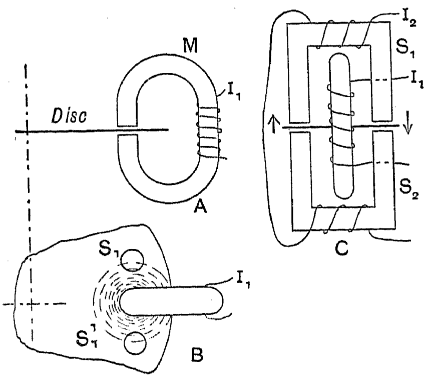

FIG. 32.

these currents, the two systems of fluxes produced by S_1 and S_1' will apply a tangential force to the disc in the same direction, and so tend to make it rotate.

Now the two fluxes due to the current I_2 in S_1 and S_1' also produce eddy currents which are acted on by the flux produced by M, resulting in a second system of forces acting on the disc.

These eddy currents are shown as dotted circles in *Fig.* 33.

The circular currents in the disc go in opposite directions at any instant, so that in the part of their path where they come within the sphere of action of M their radial direction is the same. The two fluxes therefore act in the same direction in producing torque on the disc.

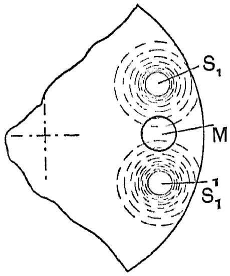

FIG. 33.

This torque, however, is in the *opposite* direction to that produced by the flux due to M just described, which generates the eddy currents in the disc acted on by the flux due to S_1, S_1'. The resultant is the difference of the two torques.

§ (38) PHASE RELATION OF FLUXES AND CURRENTS.—That this is so can be seen by a consideration of the phase relations of the quantities in wattmeters of this type (*Fig.* 34).

The magnet M is commonly wound with several thousand turns of fine copper wire and is connected across the pressure V_1 to be measured. The circuit being highly inductive, the current I_1 and the flux Φ_1 it produces will lag nearly 90°. Actually the angle of the useful flux is made exactly 90° by a special adjustment. The curves *a* and *b* show the relative relation of V_1 and Φ_1.

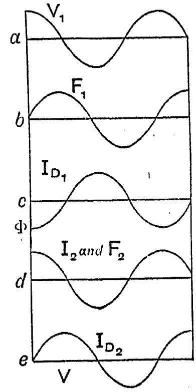

FIG. 34.

Φ_1 produces an E.M.F. E_1 in the disc, lagging 90° behind F_1. This produces a current in the disc I_{D_1} lagging somewhat behind E_1, on account of the self-inductance of the eddy currents.

Neglecting this lag, the phase of the eddy currents I_{D_1} is shown in *c*. The currents are acted on by the flux due to S_1, S_1'. In practice these are supplied with a current proportional and in phase with that in the circuit to be measured.

If the power factor is unity the current I_2 and the flux Φ_2 which it produces are in phase with V_1, as shown at *d*. The interaction of F_2 and I_{D_1} will therefore correspond to their being 180° out of phase, *i.e.* the disc will tend to rotate in the opposite direction to what it would if they were in phase. Now the current in the disc I_{D_2} produced by Φ_2 due to the current I_2 in S_1 and S_2 is in phase with the flux Φ_1. For the phase of I_{D_2} is shown at *e* neglecting the eddy current inductance error as before, 90° behind Φ_2. It is therefore in phase with the flux Φ_1.

The two torque systems are therefore in opposition, and the resulting torque is the difference.

The actual eddy currents in the disc are the vector resultant of the two systems of currents which are in quadrature.

§ (39) QUADRATURE ADJUSTMENT.—The important adjustment is that by which the useful fluxes produced by the two magnet systems are caused to have exact time quadrature when the power factor is unity.

The flux produced by the magnet M is a little short of 90° behind the voltage. An additional flux must therefore be produced in the air gap, the vector resultant of which with that produced by M must have the 90° lag. This additional flux is often produced by the addition of a coil of a few turns on the end of the magnet. The ends of the coil are connected to the end of a variable low resistance. The current and flux in this coil is not very different from 180° lag, so that the resultant with that of the useful portion of the primary

flux may be made to have the desired phase angle of 90°. This adjustment has to be made by trial and error, testing the meter at various power factors at approximately constant current and voltage.

Another method of obtaining quadrature between the two operating fluxes is to compensate the want of quadrature between flux and voltage in the pressure coil by splitting up the series (current) winding into two parallel circuits of different self-inductance. By adjusting the relative amounts of current in the two the phase in one of them can be given a value different from that of the total current which will compensate for the want of quadrature in the pressure windings.

§ (40) Light-load Adjustment.—To compensate for friction at light loads, so as to prevent the meter running unduly slow, the end of the shunt magnet is often surrounded by a closed circuit of aluminium or copper nearly touching the disc. By moving this at right angles to the line joining it to the centre of the disc and keeping it parallel to its surface, the currents in it will cause a time dissymmetry of the useful flux, and so produce a travelling field tending to rotate the disc.

To prevent a slow continuous creep of the disc, if the light-load adjustment is somewhat overdone, a few iron filings are sometimes attached to the disc at one spot, which cause it to stop when they come under the permanent brake magnet. Sometimes a short length of iron wire is fixed to the disc near the axle. This is bent so as to come sufficiently under the influence of the permanent magnet at the nearest point in its rotation to hold the disc still if there is no load on the meter.

§ (41) Full-load Adjustment of Induction Meters.—This is often done by varying the distance from the centre of rotation of the disc at which the permanent brake magnet is fixed, in the gap of which the disc rotates. The permanent magnet is generally fixed opposite the driving magnet so as not to be influenced by an accidental short-circuit current passing through the current coils.

Another method is to vary the effect of a magnetic shunt on the permanent magnet.

The alternating magnetic fluxes from the driving magnets also produce a material braking effect.

§ (42) Accuracy of Induction Meters.—Induction watt-hour meters have a calibration curve of the type shown in *Fig.* 35.

If the meter runs correctly at about 0·1 of full load and 0·5 per cent slow at full load, it is likely to run 0·5 per cent to 1·5 per cent fast at about half load.

The drop in speed at full load is largely due to the increase of series flux cutting the disc as the load increases. This increases the braking action and slows the meter. It may also be due to the falling off in permeability of the series magnets at the higher inductions and therefore of the flux they produce.

(i.) *Power Factor.*—The power-factor characteristic obtained by keeping the full-load

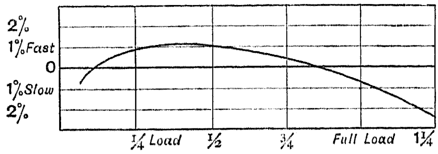

Fig. 35.

current constant and varying the real power, is practically a straight line, and may be given any desired inclination by varying the quadrature adjustment.

(ii.) *Starting Current.*—A meter may be considered satisfactory if it starts with less than 1 per cent of full load.

(iii.) *Speed.*—The full-load speed of meters of this type is commonly 40 to 50 revolutions a minute.

There is theoretically an error due to the speed of rotation of the disc. This enters as a ratio of the angular velocity of the disc to the electrical-phase velocity. The ratio is about 1 or 2 per cent. The effect is further reduced in that the alternating fluxes are kept small compared with that of the permanent magnet.

(iv.) *Counting Mechanism.*—The disc spindle is connected with the dial mechanism by spur or worm gearing. The dials are commonly geared to one another as simply as possible, so that one rotates in the opposite direction to the next, as is commonly done in gas-meters.

The more complicated mechanism required in a dial with cyclometer figures is sometimes found to result in sufficient friction to reduce the speed of the disc, especially at low loads, when a change over from one dial to another is being carried out. In the simplest forms of dial mechanism the friction ought to be negligible.

(v.) *Effect of Temperature on the Torque.*—The driving torque, being due to eddy currents which are dependent on the conductivity of the material of the disc, depends upon the temperature, since the disc is commonly made of aluminium, which varies in resistance about 0·4 per cent per degree. The torque diminishes with rising temperature. Since the braking is also due to similar eddy currents, the retarding torque varies in a manner to compensate for the alteration of driving torque.

This type of meter has a great advantage in this respect over practically all types of

continuous-current meters, with similar braking arrangements. In such continuous-current meters the braking torque depends on the temperature, while the driving torque is not easily given a compensating correction.

(vi.) *Frequency Error.*—The main error caused by change of frequency is due to departure from exact quadrature relation of the shunt and series fluxes. The change is not serious in practice as commercial alternating supply systems keep the frequency very constant.

(vii.) *Potential Error.*—There is a small error due to small changes of voltage. Such a change is due to the useful flux not being exactly proportional to the voltage, to possible slight departure of quadrature adjustment, and to alteration in braking force by change of the shunt flux.

(viii.) *Material of Disc.*—Aluminium is preferable to copper on the score of lightness. It has also been shown that the superior conductivity of copper enhances the effect of self-induction in the eddy currents, and that aluminium is preferable also in this respect. Discs are commonly pressed in order to make the metal "flow" slightly. Such treatment equalises any strains in the metal produced by rolling it into sheet form, and prevents warping. Some makers also corrugate them slightly to give them additional stiffness.

§ (43) Size of Meters.—Meters are commonly made for direct connection to circuits when the voltage is from 100 to 500 volts. The full-load current passing through the meter is generally between $2\frac{1}{2}$ and 50 amperes.

Use of Instrument Transformers.—Above these values the meters are usually supplied through special transformers, commonly known as instrument transformers. Potential transformers are universally made to give 100 to 110 volts on the secondary circuit to which the pressure coil of the meter is connected, whatever the primary voltage may be. Current transformers are likewise made with a 5-ampere circuit for the secondary, and meters are made for 5 amperes for full load to correspond.

In the case of high voltages there is the immense advantage that, by thorough insulation between primary and secondary of the transformers, the meter or other instruments in the secondary circuits are made safe to handle.

A watt-hour meter (or wattmeter) with a range of 100 to 110 volts and 5 amperes thus becomes a universal instrument. Used alone it will measure a load up to 0·5 kilowatt. Connected to a suitable potential transformer for 20,000 volts, and a current transformer for 1000 amperes, it will measure 20,000 kilowatts.

The instrument [1] transformers are therefore very important links in the measurement of power, and much attention has been given to their design and the measurement of their characteristics.

[1] See "Instrument Transformers."

§ (44) Two- and Three-phase Induction Watt-hour Meters.—The measurement of energy in a two-phase circuit or in a three-phase circuit by the two-wattmeter method requires two meters. This is commonly done by a double deck arrangement, driving a spindle and counting mechanism by means of two meter elements one above the other, the discs being fixed to the spindle a few inches apart. The same meter may be used either for two-phase or three-phase measurements, but unless it is accurately adjusted for power-factor error it will not register exactly the same for equal amounts of energy in the two cases on account of the phase relation of potential and current vectors being different in the two cases.

§ (45) Action of Braking Magnets.—In nearly all types of commercial integrating electricity meters for both alternating and continuous currents the main retarding force is produced by the action of a permanent magnet on a rotating disc or drum which moves in its air-gap. The disc or drum is commonly made of aluminium or copper.

This principle of applying a retarding force to a moving mass, by means of the interaction of a magnetic field and the current which it produces in a conductor cutting the field, is largely used for damping the oscillations of many types of electrical and other instruments.

If the dotted circle (*Fig.* 36) represents the section of the magnet at the air-gap, eddy currents will be produced in the part of the disc as it comes into the field of the magnet, as shown at A.

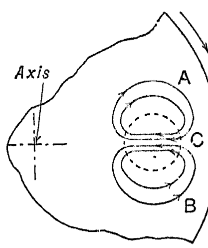

Fig. 36.

As the disc leaves the region of the magnet a similar system of eddy currents is generated at B. These will circulate in the opposite direction, so that the current C, produced by both systems in the part between the poles of the magnet, will be the sum of the two. The action of the field of the magnet on this current will be in the direction tending to oppose the rotation of the disc.

The braking force is proportional to the product of current and field, and, as the current is proportional to the velocity and the field is constant, the braking force is proportional to the velocity. When the conductivity and velocity are high the self-inductance of the currents in the disc may produce a slight distortion, and it has been

shown that aluminium may be preferable to copper in this respect as having a higher resistivity in addition to its lower density. Aluminium is practically always used in the case of induction meters.

Brake magnets are usually rectangular in cross-section, and for a given shape it is more advantageous to arrange the magnet as at E (*Fig.* 37) rather than F, as a greater torque for a given velocity is produced thereby.

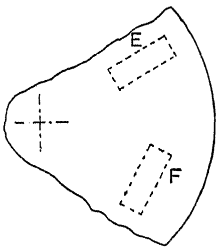

FIG. 37.

As the braking force varies with the linear velocity, the farther the magnet is placed from the centre of the disc the greater is its effect. Many meters have their rate adjusted by such alteration of position. This only holds up to a certain point, as the eddy currents are seriously interfered with when the magnet comes close to the edge of the disc.

VI. Phase Meters, Power-factor Meter, Synchroscopes

§ (46) Phase Meter or Power-factor Meter.—A phase meter is an instrument which indicates the phase angle between the potential and current in an alternating circuit.

As the cosine of the phase angle is equal to the power factor the instrument is commonly graduated in terms of power factor. They are generally termed power-factor meters.

(i.) *Power-factor Meters for Single-phase Circuits.*—The outline of the working of a phase meter is as follows. Two similar fine-wire coils A and B (*Fig.* 38) are fixed together

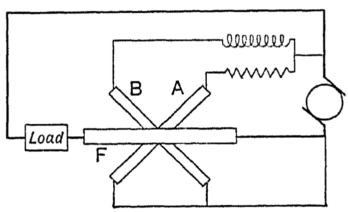

FIG. 38.

nearly at right angles, and are pivoted at their junction, and are placed within a fixed coil F which carries the load current, either directly or through a current transformer.

The coils A and B are fed from the source of supply with a large resistance in series with one (A), and a large inductance in series with the other (B). Suppose the ampere turns in each are the same. We have then two alternating fields, A and B, at right angles to one another, with nearly 90° phase displacement between them. These give rise to a rotating field which is perpendicular to the plane of A at the instant when the voltage of the circuit A is a maximum.

The forces between the fixed and moving coils may be deduced, as in *Fig.* 39, from the theorem of the equivalence of revolving and alternating magnetic fields.

An alternating magnetic field of maximum value 2H and period T may be regarded as equivalent to two equal fields, each of value H, revolving uniformly in opposite directions in the periodic time T. The angle which each revolving field makes with the direction of the alternating field is zero when the numerical value of their resultant is a maximum, *i.e.* 2H.

The rotating field due to the two moving coils may be considered as equivalent to a small magnet rotating in the periodic time T. Suppose this magnet has the direction MN at a given instant, and that at the same instant the field F_a due to the fixed coil is equivalent to the oppositely rotating fields F_1 and F_2, there will be mutual action between F_1 and

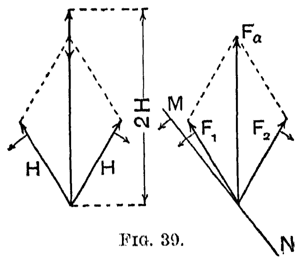

FIG. 39.

MN rotating in the same direction tending to pull them into coincidence.

There will be no resultant couple between MN and the oppositely rotating field F_2 when taken over a complete cycle. The moving coil therefore takes up a position such that the direction of F_1 becomes coincident with that of MN.

The planes of the coils A and F become coincident at unity power factor, and the angular departure from this position is a measure of the phase angle of the circuit.

The crossed coils must be free to turn through practically 360° to cover all possible power-factor conditions. They require the currents to be led into them by fine strips which have no appreciable mechanical control. To prevent them being damaged the motion of the pointer may be limited to one turn by a stop. In practice the power factor of a circuit generally keeps within a range of about 90°.

In the above it has been assumed that the currents in the moving coils are in quadrature. The lag in the inductive coil must necessarily, however, be less than 90°. If the coils are

at right angles an elliptical field will result; but if the coils are set at an angle equal to the phase difference between the currents in the coils a circular field of constant intensity is produced.

Such meters, depending on the inductance of a circuit to produce approximate quadrature, and requiring equality or constancy of ratio of ampere turns, can only be accurate at one frequency.

(ii.) *Power-factor Meter for Three-phase Currents.*—The power factor of a three-phase circuit has little practical meaning unless the circuit is balanced.

In this case use may be made of the current I_A in one line and the potential between this phase and each of the other two phases, v_1, v_2. The two potentials, v_1, v_2, have a time-phase difference of 60° (*Fig.* 40).

The moving coils are fixed at this angle and are fed from AB and AC with a high resistance in series.

We have therefore a rotating field produced by the two alternating fields which have a mechanical angular displacement equal to the time-phase displacement of the currents in the two circuits. The conditions are therefore the same as in the case of the single-phase meter.

The field produced by the fixed-current coil A may be regarded as equivalent to two fields

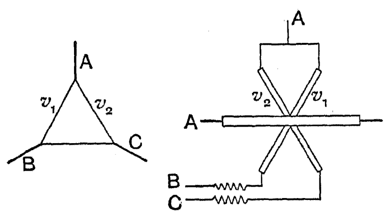

FIG. 40.

equal to $\frac{1}{2}I_A$, rotating in opposite directions; and the rotating field produced by the moving crossed coils "hangs on" to the one of two which rotates in the same direction. The equilibrium position of the coils is therefore a measure of the phase angle exactly as in the case of the meter for single-phase currents.

In the single-phase meter the rotating field has to be obtained by artificial phase displacement of the current in one of the moving coils. In the three-phase meter the phase displacement is ready to hand by using two of the line voltages. Such a three-phase instrument is therefore independent of frequency since no inductances are used. The rotating field may be produced by using three V-connected coils at 120° fed from each of the three phases of the system, instead of the two 60° coils mentioned above.

A balanced load has been assumed, and the phase measurement obtained by using the current in one line only. If the circuit is unbalanced, a sort of mean power factor can be obtained by taking the current in each of the other phases with suitably placed coils and obtaining an average effect. The result is hardly worth the complication in ordinary circumstances.

Power-factor meters and other similar apparatus are worked off instrument transformers as a general rule.

§ (47) GIFFORD POWER-FACTOR INDICATOR.—The Gifford indicator (*Fig.* 41) is not limited

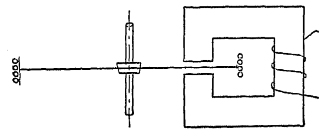

FIG. 41.

in its motion by the necessity of leading in the current to the moving part by metal strips.

The current is generated in the moving part by induction.

A C-shaped laminated electromagnet has a small air-gap in it in which a disc of mica fixed on the axle of the moving part revolves. Round the edge of the disc is wound a thin coil of wire which acts as the secondary circuit of a transformer, of which the winding on the magnet forms the primary. The operating forces are produced in a suitable winding connected in series with the secondary coil.

§ (48) SYNCHROSCOPES, SYNCHRONISERS.—These are apparatus for indicating when two alternating current machines are in phase, so that they can be connected in parallel without disturbance of the system.

The principles used are closely allied to those of the phase meter (*q.v.*). In the phase meter a definite direction in a system of movable crossed coils, rigidly connected together, takes up a position, as regards the current in a fixed third coil, which is equal to the phase angle of the circuit. Suppose the fixed third coil is supplied by a second alternator which is nearly in synchronism with the one supplying the moving coils. The current in the fixed coil will cause the moving coil system to rotate continuously at a speed corresponding to the difference in speed of the two machines, the phase difference passing through 360° in the time that one machine gains or loses one cycle on the other. The direction of rotation is a positive indication as to which is the faster machine. The moving coils of the synchroscope are fed through slip rings instead of fine metal strips as in the phase meter, so that it can rotate continuously. To increase the torque, an electromagnet may be used to supply the fixed field. The indicator is generally arranged so that the pointer points

vertically upwards when the machines are in phase and ready for paralleling.

§ (49) Synchronising Lamps.—Before synchroscopes were developed lamps fed by potential transformers from each machine were commonly used. Machines which require synchronising apparatus are practically always high voltage ones and require step-down transformers to supply measuring apparatus.

If the secondaries of the transformers are connected in series so as to add their voltages when the machines are in phase, the lamp fed by them glows brightly when the machines are in synchronism. If they are in opposition, the point of synchronism is indicated by darkness. Such a method gives no indication as to which machine is the faster.

A scheme of using three synchronising lamps on a three-phase circuit which indicates which machine is the faster is shown diagrammatically in *Fig.* 42.

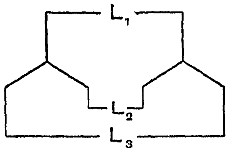

Fig. 42.

L_1, L_2, L_3 represent three lamps connected to the two machines.

At synchronism lamp L_1 is dark and lamps L_2, L_3 glow equally. As synchronism is departed from L_1 begins to glow; but a much more sensitive indicator is the difference in brightness between L_2 and L_3, since one increases and the other diminishes in brightness. The direction of the relative speed of the machines is indicated by whether L_2 or L_3 is growing in brightness as L_1 becomes dark.

§ (50) Weston Synchroscope.—The Weston synchroscope is a combination of a pointer instrument and a synchronising lamp.

The electrical circuit is of a dynamometer type controlled by a spring, which normally keeps the pointer vertical, pointing to synchronism. Suppose the fixed coil of the dynamometer is supplied by one machine through a condenser and the moving coil by another machine through a resistance. If the machines are in phase the two currents are in quadrature and there is no resultant torque on the moving coil. If the machines begin to go out of phase, the pointer will move in one direction or the other according to which machine goes the faster.

The instrument will also indicate synchronism when the machines are 180° out of phase.

To eliminate the ambiguity as regards true synchronism a synchronising lamp is added behind the pointer, which is itself behind a translucent screen and can only be seen when the lamp is glowing so as to throw a shadow of the pointer on the screen. The synchronising lamp only glows when the phase difference is within about 40° of zero. The pointer is out of sight at one end or other of its scale when the phase difference is considerable. The result is that the pointer is seen to move over the scale, which occupies some 90° in the region of synchronism, in such a direction as to indicate whether the incoming machine is fast or slow. The pointer goes backwards over the scale while the lamp is dark, so that the illusion of continuous rotation is produced as long as the machines run at different speeds. The pointer appears to rotate slower and slower as synchronism is approached, and finally stands vertical, fully illuminated, when synchronism is reached.

The instrument avoids the use of rubbing contacts, which have to be of very high quality to prevent appreciable friction and possible errors, which might be a very serious matter in paralleling modern high speed turbo-alternators.

VII. Frequency Meters

§ (51) Hartmann Kämpf Frequency Meter.—This is an instrument for indicating the number of oscillations per second of the current or voltage in an electric circuit. The word wavemeter is commonly used in the case of radio frequencies of a few thousand and upwards. A wavemeter is divided with an inverse time scale.

This (*Fig.* 43) is a quasi-mechanical meter of the vibrating reed type.

A thin strip of steel is supported by a solid block at one end and usually has the free end bent at right angles. Its length and thickness are adjusted till its free period is of the desired value.

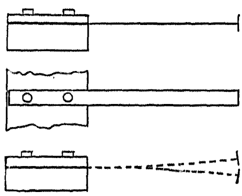

Fig. 43.

When placed on a part of a machine vibrating mechanically with this periodicity, such as a reciprocating engine, the reed will commence to vibrate. The vibration is detected by observing it endways at E.

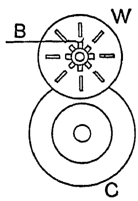
To cover the working range a number of reeds are arranged alongside one another, each adjusted to a definite frequency. The steps may be about 0·5 per cent or 1 per cent. The one closest to the period of the machine will vibrate with the largest amplitude. One or two reeds on each side may be "forced" to vibrate with lesser amplitudes.

As applied to an electrical frequency meter, the reeds are acted upon by an electromagnet through the windings of which a small current passes from the circuit to be measured, with a suitable resistance in series.

The reeds are attracted twice every complete period, so that a reed with a free period of 100 per second vibrates when acted upon by an alternation current of 50 ~ and it is marked 50. The steps are commonly quarter, half, or whole periods between one reed and the next. The final adjustment may be made by adding or scraping off paint or solder from the free end of the reed.

If the reeds are magnetised sufficiently strongly by a permanent magnet the effect of the alternating current magnet will be only to reduce and increase the force acting on the reed and not to completely reverse it. The reed will then only vibrate once instead of twice per period, and a reed with a free period of 100 will now respond to an alternating current of 100 instead of 50.

If such a permanent magnet is arranged to be put in or out of action as desired the range of the instrument is doubled.



§ (52) Weston Frequency Meter.—This meter makes use of the diminution of the current in an inductive circuit with increase of frequency in comparison with the constancy of a current in a simply resistant circuit.

Two crossed coils C_1, C_2 (*Fig.* 44) are connected to inductances L and resistances R as shown. Increase of frequency diminishes the current through C_2 owing to inductances L, and so increases the proportion of the current going through the coil C_1 and resistances R.

The coils C_1, C_2 being at an angle and carrying currents with phase difference give rise to an elliptical rotating field. A piece of soft iron P free to move inside the coils without control

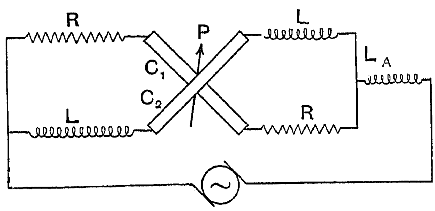


Fig. 44.

sets itself along the major axis of the ellipse. The direction of the axis in space varies with the frequency, so that a pointer attached to P may be made to indicate the frequency. L_A is an added inductance to limit the current taken when used on circuits of ordinary commercial voltages, and also to filter out to a considerable extent any harmonics which may be present.

Above a few hundred volts all such instruments would be operated by an instrument transformer with a secondary voltage of 100 to 110.

§ (53) A. Campbell Frequency Indicator.—A vibrating reed type of indicator in which the effective length of the reed is varied by a sliding clamp similar to the adjustment commonly provided for the regulation of pendulum clocks.

By this means one reed may be made to cover a considerable range of frequency. The motion of the clamp is effected by rack and pinion till the resonant amplitude is obtained; a pointer operated by the pinion mechanism indicates the frequency on a dial.

§ (54) Drysdale Frequency Indicator.—This (*Fig.* 45) is an instrument for determining the speed of shafts, etc.

A geometrical pattern on the end of the shaft whose speed is to be measured is illu-

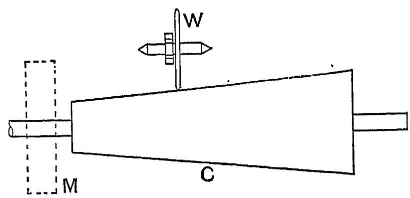

Fig. 45.

minated periodically by the light produced by an instantaneous electrical discharge through a neon tube. The frequency of the discharges is adjusted until the pattern appears stationary. The frequency is then read off from the setting of the mechanism required to produce the stationary effect. Neon is chosen on account of the visual brightness of the light emitted.

A conical brass cylinder C is rotated by a phonic wheel motor M, which is driven by a tuning-fork of known periodicity, say 50 ~.

On the cylinder rests a light brass wheel, which may be of a diameter about equal to the average diameter of the cylinder. This wheel is driven by the cylinder without any appreciable slip and has a small contact-breaker on it, B, which interrupts the primary current in an induction coil. The secondary circuit is connected to the neon tube, which illuminates the pattern on the shaft at every break of the contact-maker.

Suppose the frequency of the fork is 50 and the motor has 8 poles, the cylinder will rotate 50/8 times a second. If the contact-breaker has 8 parts and the jockey wheel is in contact with the cylinder where the diameters are the same, the neon tube will be illuminated $(50/8) \times 8 = 50$ times a second.

If the machine whose speed is being investigated is an 8 pole alternator giving a frequency of 25 ~, its speed will be 25/4 revolutions a second. A pattern on a disc at the end of the shaft repeated 8 times, *i.e.* every

45°, will pass an observer's eye $8 \times (25/4) = 50$ times a second. If the illumination is practically instantaneous, the pattern will appear at rest at the synchronous speed. If the speed of the machine differs slightly from the synchronous speed, the pattern will appear to revolve slowly. It is made to appear stationary by moving the jockey wheel parallel to the axis of the cylinder, increasing or diminishing its speed until the stationary effect is produced. This movement is read on a scale indicating the position of the wheel along the cone. To check the relative speed of the jockey wheel and cylinder, the wheel has radial slits in it, equal in number to the poles of the driving motor. The poles of the driving motor are observed through the slits, and they will appear to be at rest at certain definite relative speeds of wheel and cylinder, which enables the reading of the longitudinal scale to be calibrated at about 5 points.

By attaching a revolution counter to the spindle of the conical cylinder, the frequency of the fork can be obtained by observing the time taken for a few hundred or thousand revolutions.

If only certain definite speeds are required to be determined or kept constant which are not incommensurable with that of the fork, the apparatus is much simplified. The tuning-fork is made to interrupt the primary circuit of the induction coil, and a suitable pattern is drawn to suit the speed of the shaft. If a pattern, repeated n times in 360°, appears at rest, so will one of $2n$, $3n$, etc., but one of $n/2$ will not, if n corresponds to the "fundamental." By having various patterns with "over tones" and "submultiples" the real frequency of an unknown speed can be picked out when there might be some doubt as to whether the speed were a multiple or submultiple of that indicated.

VIII. Alternating Current Instruments. General Methods of Calibration

§ (55).—The indications of instruments for alternating currents are naturally based on the ohm, volt, and ampere. As these units relate primarily to continuous currents, there must be a link in the chain where the change-over from continuous to alternating quantities takes place. This change-over may be where it can be done most conveniently and accurately, which will depend largely on the equipment available.

Instruments used for alternating current measurements may be broadly classified as (1) those which must be calibrated by alternating currents and (2) those which may be calibrated by continuous currents.

Among the former are instruments which depend upon inductances, capacity, or phase displacement for their operation; such as induction ammeters, voltmeters, wattmeters, and watt hour meters, phase and power factor indicators, instrument transformers.

Among the instruments which may be calibrated by continuous currents, though errors frequently of considerable importance may result, are dynamometer type ammeters, voltmeters, wattmeters, electrostatic voltmeters and electrometers, oscillographs.

There are two technical limitations which govern the choice of methods, the one is that it is difficult to measure comparatively low alternating voltages and large alternating currents when high accuracy is required. Instruments for such purposes, which will operate by both alternating and continuous currents, will often have errors difficult to allow for if calibrated by continuous currents, without taking into account possible errors due to inductance, alteration of current distribution, etc., when used on alternating current circuits.

In the measurement of the quantities concerned in continuous current measurement, recourse is almost invariably made to the potentiometer for ascertaining the dimensions of the quantities concerned. The potentiometer avoids the necessity for measuring quantities by highly accurate deflecting instruments. It is equally accurate for measuring a few tenths of a volt as for a thousand volts and for a few millionths of an ampere up to several thousand amperes.

The use of the potentiometer for alternating currents is much more limited, and though it is of great value for special purposes, it cannot displace other apparatus where the highest accuracy is required. In such cases it is necessary to use a deflecting instrument.

The most convenient link, and for many purposes the most accurate, between alternating and continuous currents is the electrostatic voltmeter. Like many instruments for alternating currents the accuracy of reading falls off rapidly below about one-third of the full scale value; and to cover a considerable range two or more instruments may be desirable.

A convenient range for an instrument suitable for a large proportion of work of a technical nature is one which will read from about 20 to 130 volts. This type of instrument has been developed at the National Physical Laboratory as the primary link between continuous and alternating currents. Over the upper half of the range the scale is divided to 0·01 volt, so that at 100 volts readings to 1 in 10,000 can be made, the spacing per volt at 100 volts being about 90 mm. The readings are made by light reflected from a mirror on the instrument, on to the scale about 2½ metres away. A special potential divider enables the scale to be calibrated by continuous potentials at every half-volt. The potential divider consists of a number of

accurately adjusted resistances in series and carries exactly 0·02 ampere. The correctness of the value of this current is ensured by passing it through a resistance whose value in ohms is numerically equal to 50 times the voltage of a Weston cell. A Weston cell will be balanced when placed across this resistance; and a variable resistance in the main circuit is adjusted until this balance is obtained. The correct potential is then established on the potential divider shown in *Fig.* 46, in which A represents the 10 volt steps and B the 0·5 volt steps; C the resistance for balancing

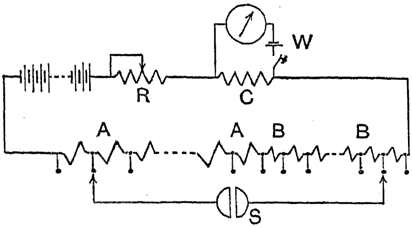

FIG. 46.

the voltage of the Weston cell, and R the adjusting resistance; S is the electrostatic voltmeter.

To eliminate the effect of contact difference of potential, which will generally have a value between a few hundredths and two- or three-tenths of a volt, the mean of the deflections obtained when reversing the polarity of the instrument is taken when using it on alternating circuits.

This type of potential divider was adopted as it avoids all slide wires which are commonly used when continuously variable quantities require to be measured. Slide wires of this nature often give trouble by wear and dirty contacts, and since calibrations half a volt apart suffice, there is considerable advantage in having all resistances in the form of coils, when consistent high accuracy is necessary.

The accuracy of such a potential divider depends upon the correctness and constancy of the ratio of the "cell" resistance to that of the rest of the resistances, especially such as are in common use.

Although the resistance of the part used to balance the Weston cell is practically incommensurable, approximately $50 \times 1{\cdot}0183$ ohms at 20° C., an arrangement of interconnections of the main coils of the potential divider, which are of 500 ohms each and are permanently connected in series, can be made which will give an equivalent resistance so close to such a value that the error may be neglected. The connections shown in *Fig.* 47 represent an equivalent resistance of $50 \times 1{\cdot}018518$, which corresponds to the E.M.F. of the cell at about 15° C. By slight variations of this scheme equivalent resistances corresponding to the E.M.F. of the Weston cell at several other temperatures can be obtained.

For the calibration of voltmeters above 120 or 200 volts other potential dividing resistances are used, a known fraction of the high voltage being applied to the voltmeter. For a large amount of work this fraction is so chosen that the electrostatic instrument indicates 100 volts.

The calibration of low-reading electrostatic voltmeters for use on alternating currents may be carried out in a similar manner by means of known continuous potentials. In instruments for 2 to 10 volts the contact effect is occasionally relatively important, and the difference on reversing may be so large as to make it doubtful whether it is correct to take the mean of the deflections as being the deflection for the same effective alternating potential. In such cases the best way is to calibrate by alternating current, using a resistance with 100 volts on it as a potential divider, and with an accurately calibrated 100-volt electrostatic voltmeter, across the

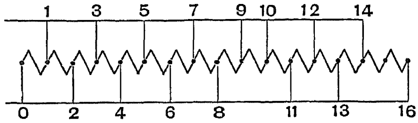

FIG. 47.

whole. The voltmeter to be calibrated is placed across a suitable fraction of the potential divider.

§ (56) DYNAMOMETER VOLTMETERS.—Most of the instruments in common use are intended for circuits of 50 to 100 volts or more. They can be calibrated by comparison with an electrostatic voltmeter, using a potential divider for the latter when necessary.

In the case of low-reading instruments, 20 volts or less, recourse may be had to a step-up transformer. Such a transformer may have its primary and secondary subdivided so that different ratios of the secondary to primary voltage may be obtained. In this way the voltage applied to the voltmeter under test may be transformed up to a voltage suitable for accurate reading on the electrostatic voltmeter.

The transformer, working practically on open circuit, takes a very small current—less than 0·001 ampere is practicable—so that when placed across a standard resistance R_1 carrying a few amperes the shunting effect is quite negligible. If the current in this resistance is accurately measured, the voltage on the resistance is known and so the transformer ratio determined.

The simplest way to determine accurately the value of such a current of a few amperes is to put it through a resistance R_2 capable of

carrying 100 volts or through a combination of such resistances in series or in parallel.

The voltage across the resistance is measured directly on the electrostatic voltmeter, which, as shown in *Fig.* 48, may be arranged so that it can be quickly switched over on to the secondary of the step-up transformer.

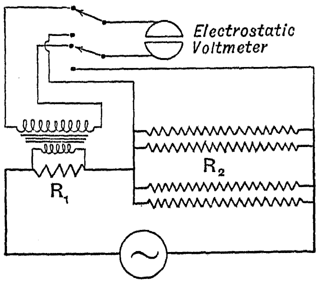

FIG. 48.

§ (57) CALIBRATION OF AMMETERS.—The method just described of using resistances, R_2, capable of carrying 100 volts each, forms a very simple and also the most accurate method of calibrating ammeters up to about 20 amperes.

Such resistances may be composed of two circuits wound on a wooden frame about 70×50 cm. Each circuit is 100 ohms and will carry one ampere without appreciable heating. Looked at endways, if one circuit be wound left-handedly the other circuit is wound right-handedly. The wires are tied closely together in the vertical parts and have therefore very small inductance. The two circuits are intended to be used in parallel, so that the difference of potential of adjacent wires is kept quite small, not more than about four volts; they are double insulated and varnished.

Each frame when supplied with 100 volts has exactly two amperes flowing through it, which may therefore be read to the same accuracy as the electrostatic voltmeter, about 1 part in 10,000.

For other currents such frames may be put in series or in parallel to suit the instrument to be tested. For still smaller currents finer wire and higher resistances, such as those of the Duddell-Mather woven-wire type, can be used.

For calibrating ammeters for larger currents the high-ratio transformer can be used.

For this purpose the current is passed through a resistance designed to give a convenient voltage (2 volts). The high-ratio transformer, calibrated in the manner described above, is placed across this, and the value of the current is indicated by the electrostatic voltmeter connected to the secondary, the transformer ratio being conveniently 1 : 50, giving 100 volts for 2 volts on the primary. The resistances should be without appreciable inductance. Currents up to 2000 amperes can be satisfactorily dealt with by this method.

In the case of currents larger than 2000 amperes instrument transformers are generally used. These can often be calibrated by using a current of say $\frac{1}{2}$ to $\frac{1}{10}$ of the rated current, passing it 2 to 10 times through the transformer so as to give the number of ampere-turns corresponding to full load.

Certain types of ammeters such as current balances and dynamometer type instruments can be calibrated by continuous currents, which are measured by a potentiometer. Precautions against errors due to the earth's and to stray fields must be taken, such as by reversing the current. In the case of instruments for large currents important errors may not be detectable by continuous currents, as the eddy current effect resulting in a different current distribution over the cross-section of the conductor when alternating currents are used may become appreciable.

The error in the Kelvin balance, for instance, at commercial frequencies is inappreciable in the 600 ampere and smaller sizes. They may therefore be calibrated by continuous currents.

In commercial measurements many difficulties are avoided by using special current transformers, the ratio of the turns being such that 5 amperes circulates in the secondary for full-rated current in the primary. Such instruments are made for primary currents of 5 amperes up to 30,000 amperes.

The accurate measurement of alternating *current* is, from a commercial point of view, not nearly so important as the measurement of *power*. Knowledge of the value of current alone does not give a measure of the power in a circuit, unless the phase relations between the current and voltage in the circuit are known.

The alternating current wattmeter is therefore a more important instrument than the ammeter.

§ (58) CALIBRATION OF WATTMETERS.—Practically all commercial wattmeters of the best quality are of the ironless dynamometer type. For small currents and for voltages of the order of 100 they can be calibrated by continuous currents, which should be reversed to detect and allow for the effect of the earth's or any stray field. The induction type is also used, chiefly for switchboard purposes, and must be calibrated by alternating currents.

The very great advantage, and in many cases the practical necessity, of using instrument transformers has led to the universal practice of designing wattmeters for use with 100 to 150 volts on the pressure circuit and five amperes for full-load rating in the current circuit. The instrument must be tested by

alternating currents to determine the error, if any, due to inductance in the pressure circuit or eddy currents in the metal work, which should be quite negligible in a properly designed instrument.

The five-ampere winding is of so small a cross-section that no error due to alteration of current distribution in it will be produced. Having once proved a given instrument by alternating currents, continuous currents may be used for routine calibrations.

When used with instrument transformers it is desirable to have the whole set of apparatus tested *en bloc* as one unit. The instrument transformers will retain their characteristics, unless subjected to serious short-circuits or, in the case of current transformers, to accidental opening of the secondary circuits when on load.

The best quality of both potential and current transformers for portable use are made with series-parallel connection, so that such ratios as 3300 to 110 and 6600 to 110 can be obtained with the same potential transformer, and 10, 20, 40 and similar ratios obtained for the primary currents of current transformers. Except for possible small errors due to capacity, in potential transformers for high voltages such as 20,000, the correction for ratio and phase angle for one ratio may be taken as applying to other ratios of the same instrument.

The calibration of instruments such as power factor meters is commonly done in a similar manner to wattmeters by alternating current.

§ (59) Alternating Current Potentiometer.—The potentiometer, which is the universal instrument by which currents are determined in terms of a difference of potential between the end of a known resistance, has been developed by C. V. Drysdale for the measurement of alternating potentials.

The main circuit of the potentiometer must be supplied with alternating current of exactly the same frequency as that in the circuit to be measured, which means in practice that they must be supplied from the same source.

Further, the phase relation between the circuit to be measured and that supplying the potentiometer may have any value from 0° to 360°. In order to obtain a balance, as indicated by the detecting instrument, it must be possible to give to the potentiometer current any phase displacement relative to that of the potential supplying it. This is accomplished by supplying it through a phase-shifting transformer which consists of a stator wound with a circuit (*Fig.* 49), which produces a rotating field in a closely-fitting rotor. The rotor has a winding on it which supplies the potentiometer current. A rotation of the rotor of the phase-shifting transformer through 360 has the effect of producing a phase shift of the same value, and a pointer on the rotor axis indicates the phase angle on a suitably divided scale.

The "balance" is obtained by successive approximation of the usual adjustment of the potentiometer contacts (dial and slide wire reading) and of the phase-shifting transformer until the indicator shows no deflection.

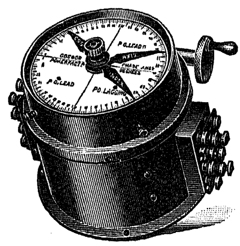

Fig. 49.

The indicator for low frequencies is a vibration galvanometer which must be closely tuned to resonate to the frequency of the circuit. For higher frequencies a telephone may be used.

The main potentiometer current must be kept at some known constant value. This is done by switching it over on to a continuous current circuit, which is adjusted until a balance is obtained at the proper setting, when a Weston cell is connected up in the usual manner. The reading of a sensitive dynamometer type ammeter in the main circuit is noted. This ammeter must read correctly with alternating and continuous currents. The potentiometer is then thrown on to the A.C. supply, which is adjusted so that the ammeter reads the same value. Arrangements are provided for reversing the ammeter in order to eliminate the effect of stray fields.

The phase-shifting transformer is usually supplied by single-phase current. To obtain the necessary field distribution a split-phase scheme is used, part of the excitation being provided by a circuit containing a condenser and a resistance in series. These are adjusted until the A.C. current in the potentiometer circuit is as nearly constant as possible, when the phase-shifting transformer is rotated to any position. As it is necessary to have the split-phase circuit somewhere near the resonating point, it must be adjusted for changes of frequency. As the vibration galvanometer has also to be adjusted for such changes, it is necessary to have a source of a very steady frequency and voltage for satisfactory working.

§ (60) Cathode Ray Oscillograph.—An apparatus for delineating the instantaneous value of the current or voltage in a circuit, by the deflection which a magnetic or electric field produces on a fine cathode stream passing through the field. The cathode stream [1] is generated by the influence of a high continuous-current voltage on a gas in a glass or similar tube at low pressure. The cathode

[1] See article "Piezo Electricity."

may be cold, or heated as in the thermionic valve.

The cathode ray oscillograph suggested by Braun [1] enables records of wave-forms up to many hundred thousands a second to be recorded by means of the most recent developments of this type of instrument.

A stream of cathode rays R is emitted by a cold or hot cathode K in glass tube (*Fig.* 50).

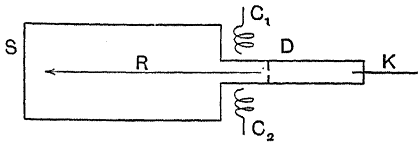

FIG. 50.

The stream falls on a metal diaphragm D with a small hole in it, and passes on to a sensitive screen S at the end of the tube, where its presence is indicated by a phosphorescent glow.

A divided coil, C_1 and C_2, has its axis transverse to the tube, so that a current in it produces a magnetic field across the path of the charged particles, deflecting them sideways at right angles to the field.

An alternating current in the coil C_1, C_2 produces the effect of a line of light on the screen, which, when observed in a rotating mirror, gives the usual effect of a periodic curve. The deflection of the ray can be made accurately proportional to the current in the coil.

The instrument therefore acts as an oscillograph, with the great advantage of having no inertia errors, at least up to a frequency of some millions a second.

A valuable feature is that a second magnetic field can be applied at any desired angle to the axis of C_1, C_2, so that combined effect of two fields can be produced. This can be extended to more than two fields. If in the case of the use of two fields at right angles one of them is given a value proportional to time,[2] the effect of stationary waves can be produced in a manner exactly analogous to the oscillating mirror mentioned in the description of the electromagnetic oscillograph.

The cathode should be excited by a steady potential of 10,000 to 20,000 volts. The higher the potential and the vacuum the faster the motion of the particles forming the stream, the finer the trace on the screen, and the less they are deflected by a given magnetic field. A high vacuum is necessary, which is not a difficult matter, even in large apparatus with modern "molecular" air-pumps.

Recent developments, however, have enabled much lower pressures to be used.[3]

[1] *Ann. der Phys.*, 1897, lx. 552.
[2] Zenneck, *Ann. der Phys.*, 1899, lxix. 838.
[3] *Physical Review*, March 1921, p. 420.

In early forms of this type of apparatus it was difficult to obtain photographs on account of the low intensity of the light after passing through the end of the tube.

By placing the photographic plate inside the tube, and allowing the rays to fall on it without such absorption, this disadvantage disappears, and records can be obtained of wave-forms up to a few million a second.

The diaphragm is commonly earthed, and it is important to have the coils C_1, C_2 at earth potential or to insert an earthed screen between them and the tube. Otherwise they will deflect the rays by the electric field.

§ (61) ELECTROSTATIC OPERATION OF CATHODE RAY TUBES. — In addition to using a magnetic field to deflect the cathode stream it is also possible to use an electric field.

For this purpose the stream is made to pass

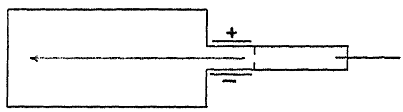

FIG. 51.

between two metal plates, which may be inside or outside the tube (*Fig.* 51).

These plates are connected to the conductors whose difference of potential is to be investigated. The negatively charged particles of the cathode stream are deflected towards the positively charged plate.

Two sets of plates at right angles may be used, or one set of plates producing an electric field and a set of coils producing a magnetic field.

§ (62) DUFOUR OSCILLOGRAPH.—Dufour [4] has added subsidiary details to the cathode ray oscillograph for facilitating the study of alter-

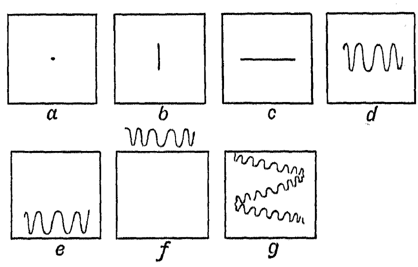

FIG. 52.

nating currents of frequencies up to a million and more a second.

Fig. 52, *a* represents the end view of the cathode stream, impinging on a screen or plate. If an alternating current is sent through a set of deflecting coils which have their axis horizontal, the ray will be drawn out into a band *b*.

[4] *Journal de Physique*, Nov. 1920, p. 146.

Suppose a second set of coils at right angles to the first has an alternating current in it, this alone will give the effect c. If b and c act together, and c is about 5 to 20 times as slow as b, the effect d will be produced if the exposure is of suitable duration. If the frequency b is of the order of 10^5 and that of c 10^4, it will be difficult to arrange a short enough exposure not to go over the same part of the plate many times and so produce the effect of general fog. To avoid this the ray is made to work near one edge e by the adjustment of a permanent magnet, if necessary. It is then pulled back across the field by a continuous-current electromagnet, so as to be near where the top of the photographic plate will be, or beyond it as at f.

After the plate is put in position the exciting circuit of the electromagnet is broken more or less rapidly according to the circumstances. As the field dies down the ray sweeps across the plate in a compound zigzag line g, often giving the appearance of a spiral wound round a cylinder. The value of the transverse frequency c will be commonly known, as it will often be obtained from an oscillating valve or arc with suitable inductance and capacity in circuit, and a wave-meter can be used to determine its frequency. The photograph will enable the frequency and value b and its over-tones to be measured. The instrument can be calibrated by continuous potentials.

§ (63) Ryan Oscillograph.[1]—This is a cathode ray oscillograph with the circuits arranged so as to give a power diagram.

The cathode ray describes a closed curve analogous to that of a piston engine indicator,

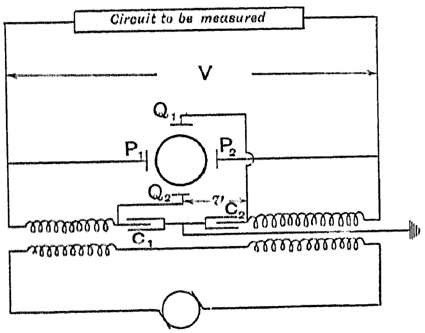

Fig. 53.

the area of which gives the energy in the circuit per cycle.

The same type of apparatus has been adapted by J. P. Minton[2] to the investigation of the energy absorbed by insulating materials under alternating electric stress.

The method devised by Ryan is to apply to two opposite plates, P_1 and P_2, the potential of the circuit V. In the case of a circuit of inconveniently high voltage some fraction of it is obtained by inserting series condensers in the circuit to form a potential divider.

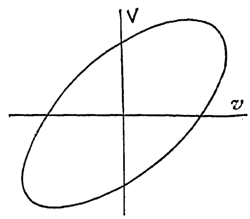

Fig. 54.

To the two plates Q_1, Q_2 (*Fig.* 53) at right angles to P_1, P_2 a potential v is applied by connecting them to two condensers c_1, c_2, which have their common terminal connected to earth.

The current through those condensers is the current i in the circuit to be measured.

The instrument describes the curve connecting V and v (*Fig.* 54). If $c_1 = c_2 = 2c$, then $c(dv/dt) = i$.

An elemental area of the curve $dA = V \, . \, dv$.

Thus $$dA = V\frac{i}{c}dt,$$

$$A = K\int V \, . \, i \, . \, dt.$$

Since $\int V \, . \, i \, . \, dt$ represents work, the area of the curve is equal to the work done per cycle.

The instrument has been specially applied to determining the power lost in high-voltage transmission lines, which is largely due to partial breakdown of the air at high electric stress.

§ (64) Technical Application of Cathode Ray Oscillograph.—The cathode ray oscillograph may be used to investigate transient phenomena which can be made to manifest themselves as changes of voltage or current.

An interesting development has been the measurement of pressure.

For this purpose the piezoelectric properties of such crystals as tourmaline or Rochelle salt can be used. When subjected to mechanical pressure in certain directions they develop a difference of polarity. If the parts at which difference of polarity is produced are connected metallically to the plates of the tube the spot of light will be deflected. To obtain the time-history of the pressure a magnetic or electric field may be applied so as to produce a deflection at right angles corresponding to some known function of the time, as in the Dufour oscillograph. From the curve described by the cathode stream the pressure-time relation can be deduced. It has been used in this manner to determine the intensity of pressure of under-water explosions.

ALTERNATING CURRENT WAVE FORMS, THE DELINEATION OF

§ (1) Point by Point Methods.—The method of determining the wave shape of an alternating P.D. which was first used, depended on the determination of each point of the P.D. curve. It was first employed by M. Joubert[1] and is generally called the Joubert point by point method. The alternator whose wave form it is desired to find is fitted with a contact maker which closes the circuit between the machine and a voltmeter, at a definite point on the wave. If the alternator is not accessible, a synchronous motor may be used to drive the contact maker.[2] The voltmeter shows the P.D. existing at the terminals of the alternator at the instant at which the contact is made. An electrostatic voltmeter is the most suitable instrument to use, but when one is not available an ordinary moving coil voltmeter may be employed, shunted by a condenser. The condenser gradually collects a charge proportional to the P.D. existing at the instant of closing circuit, and then discharges through the voltmeter. If the capacity of the condenser be suitably chosen, the voltmeter may be made to indicate to a high degree of accuracy the voltage actually existing at the time of closing circuit. It is evident that the voltage found is the average value of the P.D. at the instant of closing circuit of a large number of succeeding waves, and unless conditions in the circuit are steady the method of recording is not of very much use. A great deal also depends, in this method, on the form of contact maker that is used. If reasonably accurate records are to be obtained, the time of contact must be very short. The contact should not last more than $\frac{1}{50}$th of the duration of a half period, hence the time of contact allowable is only $\frac{1}{5000}$th of a second for a 50-cycle frequency.

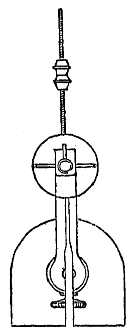
The construction of a contact maker, therefore, that will act with certainty is not an easy matter. The one which has been found most successful by the author consists of two pieces of watch-spring which are periodically short-circuited by a revolving brass plate. Having determined the P.D. at one point on the curve, the contact maker is moved round through a known distance, which can be measured on a scale attached to the alternator, and a series of records obtained of the P.D. of the machine, for different positions. The delineation of current may be effected by a similar arrangement. The voltage available for operating the shunted millivoltmeter, or whatever instrument may be used for the purpose of recording, is very much less than it is when wave shapes of potential difference are being measured, hence contact and thermo E.M.F.'s are apt to give trouble, and the readings of the instrument made much less steady. A great many experiments were made by Mr. Duddell and the author using a very sensitive electrostatic voltmeter of the quadrant type with the needle charged by a battery of small cells. The advantage of the electrostatic type of instrument for recording is that it does not require the use of the auxiliary condenser, and the quickness with which the instrument reaches its steady reading is much greater. Even under the most favourable conditions this method of delineating wave shapes is of no practical use except when circuit conditions are steady.

§ (2) The Ondograph.—In order to record wave forms more quickly, an instrument called the Ondograph was devised by M. Hospitalier.[3] In this apparatus the wave form is registered on a sheet of paper by a pen similar to that used in the ordinary barograph; it is an improvement on the original Joubert point by point method in that the point of contact is varied continuously by a gearing attached to the synchronous motor which is used to drive the contact maker.

The apparatus is shown in perspective and diagrammatically in *Fig.* 1. A synchronous motor A drives, on the one side, a contact maker D, and, on the other, a recording drum C through a series of gear wheels B. The recording instrument is shown at E, the needle of which, F, traces on the drum the wave shape which it is desired to find. The motor is driven directly from the alternating supply. The terminals H, H′ are connected to a condenser which serves the same purpose as that used in the point by point method, with a resistance in series with it of sufficient magnitude to prevent serious sparking. The terminals I and I′ are connected to the source of supply. When the contact maker D rotates, the series of connections is as follows. One terminal of the supply I is connected to the condenser H′ and to the recording instrument; the other terminal I′ is connected to the terminal of the contact maker *d* and so to the revolving cylinder D. When D is connected to *d* by the thin plate which projects from the surface of the cylinder, the condenser C is charged to a potential difference equal to that which exists at the instant at which the circuit is closed. At this time the brush *d″* rests on an insulating part of the cylinder D, but immediately afterwards *d″* makes connection with the cylinder, while *d* is insulated, with the result that the condenser C is discharged by the circuit H*d′d″*EH′C′ through

[1] Joubert, *Journal de Physique*, 1880.
[2] Fleming, *Electrician*, xxxiv. 460.
[3] *Journ. Inst. El. Eng.*, 1903–4, xxxiii. 75.

the instrument, producing a deflection corresponding with the instantaneous value of the voltage. The synchronous motor train B is arranged so that when A has made 1000 turns D makes 999 turns, and C has made $\frac{1}{3}$rd of a revolution. Thus during 1000 revolutions the contact maker will have made one revolution less than the synchronous motor, which will correspond with one complete alternation of E.M.F. in the circuit. The complete revolution of the drum, therefore, will correspond with three complete waves. The galvanometer E is of the ordinary moving coil type with special arrangements for setting the zero of the instrument and balancing the pointer. Some records obtained with this apparatus are shown in *Fig.* 2.



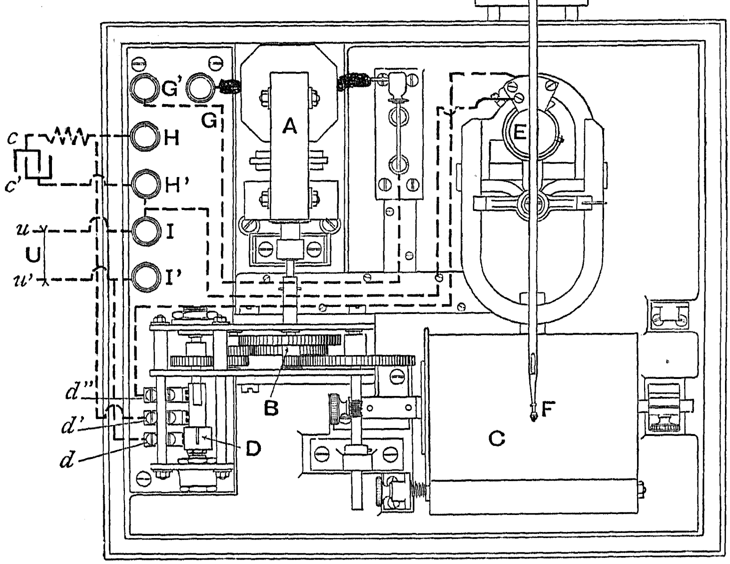


FIG. 1.

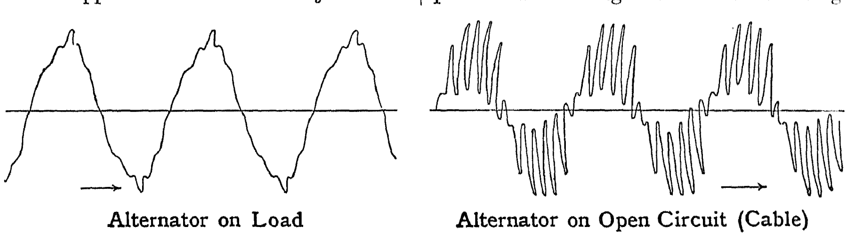

FIG. 2.

§ (3) EARLY HISTORY OF OSCILLOGRAPHS.—Instruments like the ondograph are obviously limited in their application, as they are restricted to making records of periodic phenomena which persist over several seconds; they cannot record transient phenomena. Attempts have been made, therefore, to design an instrument which would record instantaneously the current which was passing through it. Such an instrument was subsequently called an Oscillograph. The earliest type of apparatus proposed consisted of a telephone diaphragm, to which some arrangement was attached, by which its motion could be recorded. One of the first attempts of this kind was made by Frölich.[1] He attached either a plane or concave mirror to the diaphragm of an ordinary telephone through which was passed the alternating current to be recorded. The mirror was not attached to the centre of the diaphragm, but eccentrically, so that when the diaphragm was bent by the action of the current the mirror was tilted slightly. The light from an arc lamp was reflected from the mirror and focussed, so as to form a bright spot either on a moving photographic plate or a revolving mirror. In order to give opposite deflections of the mirror for opposite directions of flow of current, the telephone must be fitted with a permanent magnet, the strength of which is either weakened or strengthened by the current passing round

[1] Q. Frölich, *Elekt. Zeits.* viii. 210, x. 65 and 345.

the coil of the telephone. If the change in strength of the attraction of the diaphragm by the magnet is relatively small, the alteration in deflection of the diaphragm will be approximately proportional to the magnitude of the current passing.

There is, of course, one obvious disadvantage of this method of recording: the diaphragm of a telephone is relatively massive and undamped, which makes it distort the shape of any current curve it attempts to record.

Professor Elihu Thomson [1] modified this arrangement by introducing a system of magnifying levers between the diaphragm and the mirror, thus rendering a very small motion of the diaphragm sufficient to produce a record; he also used a second coil in his telephone instead of the permanent magnet. This coil carried a continuous current, and the other the alternating current which it was wished to record, the object of this arrangement being to ensure a stricter proportionality between current and deflection than is possible when the action of the instrument depends on the weakening and strengthening of a permanent magnet. Another arrangement used by M. Guyau [2] for observing the motion of a telephone diaphragm is to attach a plane silvered mirror to it, and place in front of this mirror a fixed reference mirror. Interference fringes are formed, by a monochromatic source, by interference between the beams reflected from these mirrors, and as the diaphragm moves these fringes alter. To observe their motion they are focussed on a horizontal slit behind which is a sensitised film driven by clockwork, and moving vertically. The fringes so photographed trace out curves corresponding with the motion of the diaphragm.

Other suggestions have been made, such as the use of the phonograph, for recording the motions of the diaphragm, the actual record being made subsequently by running the wax cylinder through a specially arranged receiver, with a pointer attached to the pin of the phonograph, which in turn is connected with a system of magnifying levers to produce the deflection of a mirror.

Among various suggestions that have been made for constructing oscillographs may be mentioned one of Professor Nichols, who constructed an instrument which consisted of a fine jet of mercury [3] through which the alternating current that it was wished to record was sent. This jet was passed between the poles of a powerful magnet and a shadow of the jet as it passed the magnet was thrown, by a beam of light, on a moving photographic film. The deflection of the jet is approximately proportional to the instantaneous value of the current. Another suggestion, worked out in some detail by M. Pionchon [4] and Professor Crehore,[5] is to make use of the property of a magnetic field of rotating the plane of polarisation of a beam of polarised light, which is passed through a solution of carbon bisulphide. If the coil producing the magnetic field carries an alternating current, the plane of polarisation will be rotated in one direction or the other according to the direction of the current passing. In the actual arrangement the light from a powerful source is first passed through a polarising Nicol prism, then in succession through a quartz plate, a solenoid containing a glass tube full of carbon bisulphide, an analysing Nicol and a slit; the light emerging from the slit is split up, either by a prism or diffraction grating, into a spectrum. The effect of the quartz plate is to produce a rotation of the plane of polarisation of the light which depends on the wavelength. The plane of polarisation of the blue light in the spectrum is rotated through a smaller angle than the red, and so on. When, therefore, no current is flowing through the coil, there will be a dark patch on the spectrum, which may be moved backwards and forwards by turning the analysing Nicol. By adjusting the position of the analysing Nicol, the dark band may be set near the middle of the spectrum. If now an alternating current is sent through the solenoid a rotation of the plane of polarisation is produced on the light as it passes through the carbon bisulphide in the solenoid, and the dark patch on the spectrum will move backwards and forwards across the spectrum in a direction depending on the direction of the current, and by an amount very nearly proportional to the strength of the current.

If, therefore, a photographic plate is moved so as to make a trace of the motion of this dark patch, a record will be obtained of the variation in strength and direction of the current flowing through the coil. This arrangement has many obvious disadvantages. As the dark patch is of considerable size, no very clear definition can be obtained on the photographic plate. The only advantage of this method is that the pointer consists of a beam of light which, of course, is weightless, so that the apparatus can be employed just as easily to measure a very high frequency current as it can one of the ordinary working frequency. It has not been developed, however, on a practical scale.

Another method of tracing out a wave form has been devised by Professor Janet.[6] This is a chemical method, and depends for its action on the fact that if an electric

current be passed through a paper soaked in a mixed solution of ferrocyanide of potassium and nitrate of ammonia, a coloured mark will be made on the paper, the intensity of which depends on the strength of the current. An improvement on this arrangement is to use a number of styles connected to a number of batteries arranged in series. The alternating P.D., which it is required to record, is connected between the drum and the middle style. At any instant there is a style for which the algebraic sum of the E.M.F.'s between it and the cylinder is approximately zero. By rotating the drum curves would be formed by the gaps in the series of parallel straight lines formed by the styles on the paper.

It has also been suggested that the capillary electrometer might be used for recording alternating wave forms.[1] The mass of the moving meniscus in the instrument is very small and its motion can readily be photographed; it responds very quickly to any varying force acting on it. This apparatus, however, has not been used to any appreciable extent for this purpose. Another method, originally suggested by F. Braun,[2] was to use as a recorder a pencil of cathode rays. These are deflected by a magnetic or electrostatic field, and if a coil carrying the alternating current or a pair of electrodes connected to the source of P.D. is so arranged as to influence these rays, the deflection produced will be proportional to the current which is passing through the coil. These rays may fall on a fluorescent screen contained within the tube, and produce a bright spot whose motion can be observed in a rotating mirror, or the moving spot may be recorded on a photographic plate. This method has lately been developed for high frequency measurement and will be described more fully.

§ (4) Modern Forms of Oscillographs.—Of the forms of oscillograph mentioned above there are two types, both originally suggested by Monsieur Blondel,[3] which have become practical instruments of great value. The first of these is that in which the record is obtained by the deflection of a pair of tightly stretched wires or strips arranged in a magnetic field.

(i.) *Duddell Oscillograph.*—Monsieur Blondel produced such an instrument, but the form of apparatus devised originally by Mr. Duddell[4] has been most generally employed in this country. In the original form, an electromagnet with poles N, S and with a small air-gap was made (see *Fig.* 3), with a pair of phosphor bronze strips stretched between them; these were passed round a pulley. They were tightly stretched by a spring balance attached to the pulley P. The ends of the strips were connected to two terminals. The alternating current passed up one of them and down the other. Thus the two strips are displaced in opposite directions, their deflection being observed by means of a mirror attached at their centres. The essentials of such an instrument are: (1) very short periodic time compared with the periods of the wave forms being recorded; (2) critical damping, *i.e.* the motion ceases to be oscillatory when the strips are deflected; (3) negligible self-induction; and (4) sufficient sensibility.

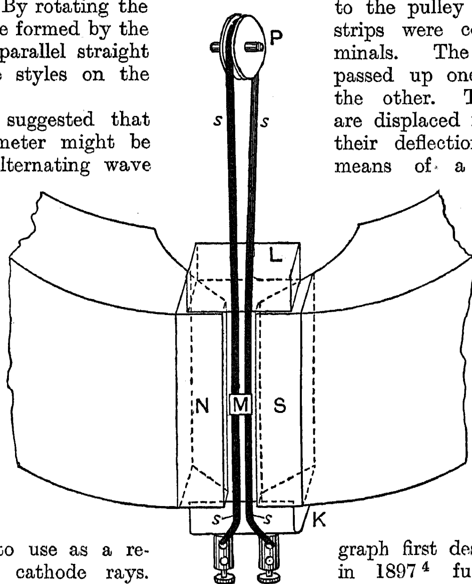

Fig. 3.

The Duddell oscillograph first described by Mr. Duddell in 1897[4] fulfilled all these conditions, the agreement between the curve traced out by it and the curve obtained by a point by point method being almost perfect (see *Fig.* 4). In a later form the vibrating system was designed so as to obtain a periodic time of less than 1/10,000 of a second. This was done by using strips of phosphor bronze stretched nearly to their ultimate tensile strength and using a very small mirror to indicate the deflection. In the first design of this instrument the greatest difficulty lay in securing critical damping.[5] In the Duddell instrument this was effected by using short strips and immersing the whole oscillograph system in an oil bath, the oil being of a very viscous kind. The oil was contained by a chamber of which the sides are formed by the pole pieces, the back by a brass plate, and the front by a lens.

In the later types the magnet was arranged with very narrow bridge pieces, placed so as

[1] Burch, *Electrician*, xxxvii.
[2] Braun, *Wied. Ann.*, 1897, lx. 552.
[3] Blondel, *La Lum. élect.* xli. 401.
[4] Duddell, *Electrician*, xxxix. 636, and *Journ. Inst. El. Eng.* xxviii. 1.
[5] See "Galvanometer," § (10) (iii.).

to make each strip vibrate in a little cell of its own. By these methods, critical damping was secured, and with critical damping the

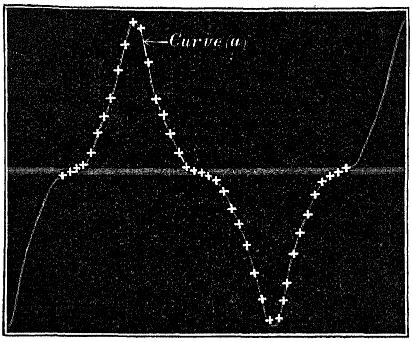

FIG. 4.

moving strip reaches its steady deflection in the shortest possible time.

The beam of light reflected from the mirror may be received on a screen or photographic plate, the instantaneous value of the current being proportional to the displacement of the spot of light. This spot moves backwards and forwards across the plate with great rapidity and gives the impression of a line of light. To obtain the wave form, the photographic plate must be moved in a direction at right angles to that of the line formed by the vibrating spot, or another mirror may be introduced in the path of the beam and this mirror rotated or oscillated so that it moves the beam uniformly (*i.e.* proportionally to the time) in a direction at right angles to the plane of vibration due to the varying current. The spot of light will then depict on a stationary screen the curve of variation of current with time. If the variations are periodic and the second mirror is synchronised, the spot of light traces out the wave form over and over again, and if it is thrown on a screen of ground glass the appearance is that of a continuous wave or line. Small fuses mounted in glass tubes are used to protect the strips from injury in case of excessive current.

The most recent form of the oscillograph is shown in *Fig.* 5; the same instrument

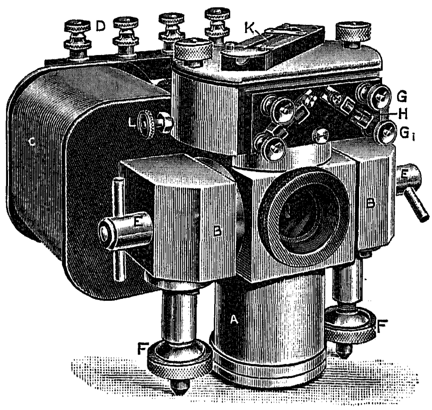

FIG. 5.

with permanent instead of electromagnets is shown in section in *Fig.* 6. A is the oil bath

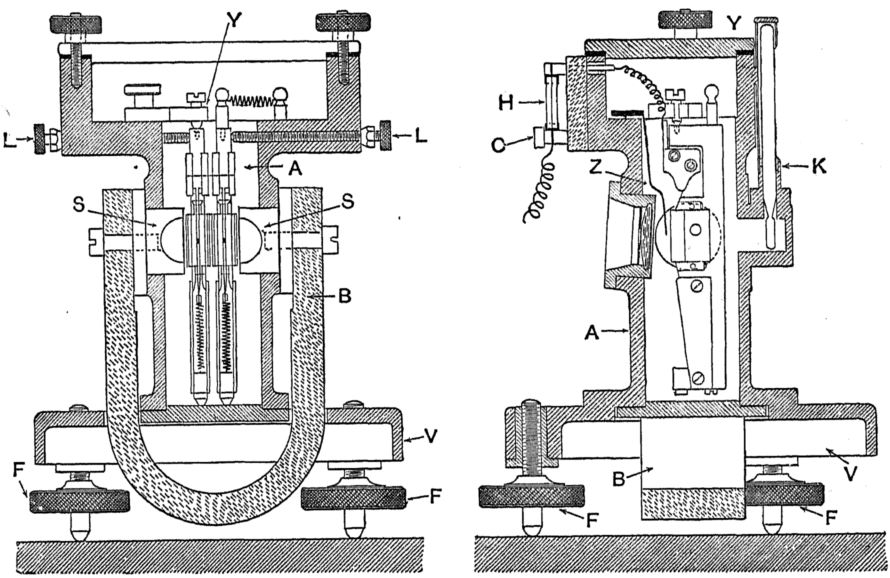

FIG. 6.

in which the two vibrators are fixed. The oil bath is formed of a brass box and is held

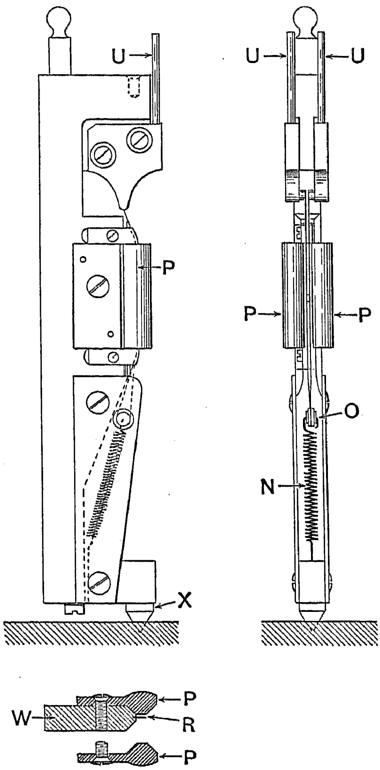

FIG. 7.

in position between the magnet poles by brass hand bolts EE (*Fig.* 5). The connections from one of the two vibrators are brought out to two terminals G and G_1. The fuse for protecting the vibrator is shown on the face of the terminal plate, and is arranged inside a glass tube fitted with brass caps which fit into two connecting clips. A thermometer is used for observing the temperature of the oil, this being the quantity on which depends the effective damping of the instrument. The vibrator itself is shown in *Fig.* 7. The brass frame W supports two soft iron pole pieces P. Between them is a long narrow groove divided into two parts by a thin soft iron partition R which runs up the centre. The current is led in by a brass wire U, passes from an insulated brass plate to the strip, which is passed over an ivory guide block down one of the narrow grooves, then over a second guide block and round the ivory pulley O and so back to the other terminal U; the spring N is used to adjust the tension on the strips. Half-way up the groove the centre partition is cut away so as to allow a mirror to be attached to the strips.

(ii.) *Recording Oscillographs.*—The simplest form of recording camera is that using a falling plate; in this arrangement a photographic plate is allowed to fall freely down a light tight slide,[1] past a horizontal slit through which the beam of light reflected from the oscillograph mirror passes. The normal speed of the plate is 400 cm. per second as it passes the slit. The speed of course gradually increases as the plate falls, so that the time scale is not quite uniform, but if the plate falls from a height of 3 or 4 feet, the variation is not enough to produce any sensible alteration in the wave shape. For recording transient phenomena, a modified cinematograph camera can be employed, in which the image of the wave is recorded on a revolving film, similar to that used in the ordinary cinematograph. When it is desired to observe the wave shape without taking a photograph, a revolving mirror, usually four-sided, is arranged inside the box containing the outfit, and is driven round, either by hand or by a small motor. If the oscillating spot of light is observed in this mirror, it is spread out into a curve which represents the wave shape.

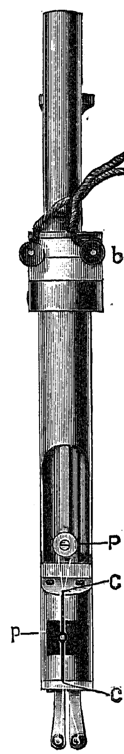

FIG. 8.

If it is desired to make tracings of the wave or to project them on to a screen, the beam of light, after it has been reflected from the oscillograph mirrors, falls on a vibrating mirror which gives it a deflection proportional to time in a direction at right angles to that produced by the oscillograph. This mirror is vibrated by a cam on the shaft of a synchronous motor, and makes a motion forward during a period corresponding to three half alternations of the current; during the next half period the mirror springs back to its original position, but in order to prevent the spot from showing on the screen during this motion, a shutter is arranged on the shaft which cuts off the light during this half period. The motor is of the attracted iron type, the rotor carrying four pieces of iron which are attracted by the alternating magnetisation of the iron horseshoes which carry the coils. The motor may be started

[1] See "Radio-frequency Measurements," § (4) (vi.).

up either by hand or by a contact maker on the shaft which makes and breaks contact to the magnet coils, and so enables the motor to be run up to speed.

(iii.) *Blondel Oscillograph.*—The oscillograph which has been constructed by M. Blondel is very similar in general design. M. Blondel uses a separate vibrator to carry the oscillating strips, *i.e.* a mounting for the strips which can be removed *in toto* from the instrument, in order to facilitate repairs. The form of his vibrator is drum which carries the photographic films is shown at E; the lens which focusses the beam on to the film is shown at F_{60}. The oscillating mirror, which gives the time motion for visual observation, is shown at M; the lens F_{150} focusses the light from this mirror on to a ground glass screen at the top of the cover. The lens F_{150} and the mirror M are carried on an arm *ch* which can be operated by the lever *m* when the instrument is to be used for photographic recording.

Another form of oscillograph developed by

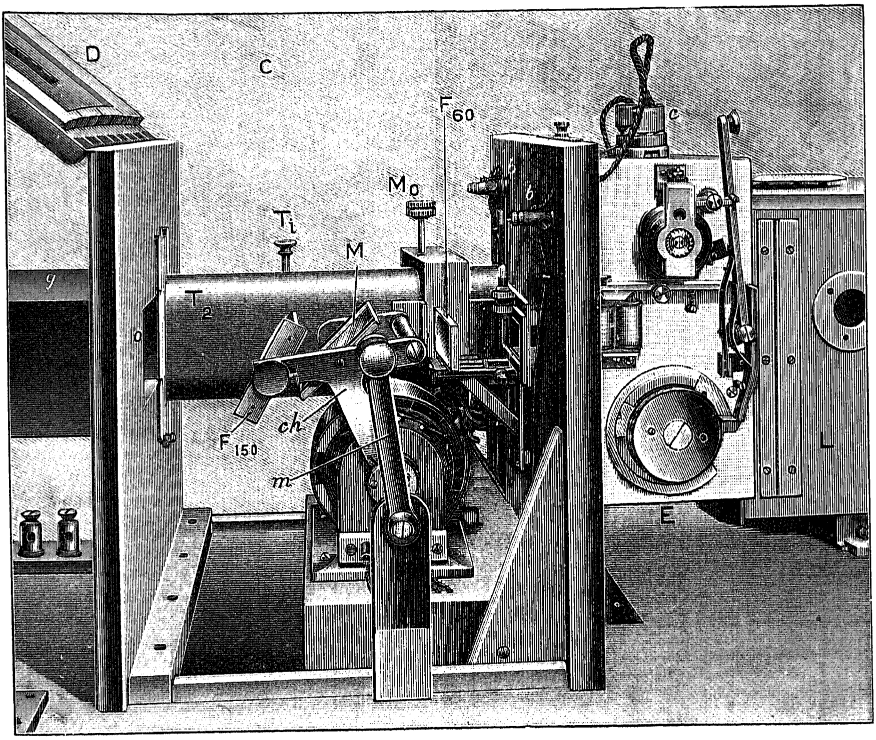

FIG. 9.

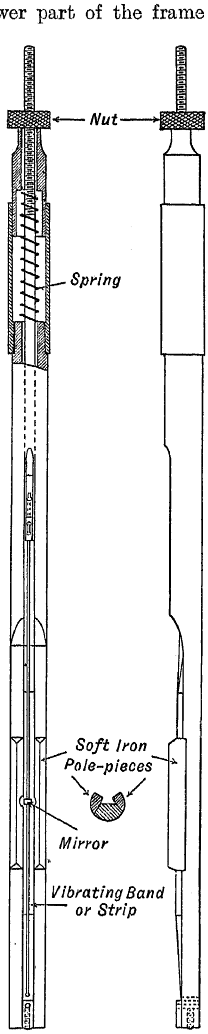
shown in *Fig.* 8. Instead of flat strips he uses round wires, as originally proposed by him in 1901, the advantage of the round wire being that a much narrower air-gap can be used in the magnet, and so a more powerful field obtained than if the flat strips, as used by Duddell, are employed. The damping is effected by oil, and the whole vibrator is immersed in an oil bath.

The most striking feature of the instrument, as compared with the Duddell, is the very powerful magnet. It is made with three vibrators so as to enable three records of wave form to be made simultaneously. The form of photographic recorder used by M. Blondel is shown in *Fig.* 9. The box containing the M. Blondel is one depending on the deflection of a band of iron strip stretched tightly in a strong magnetic field, its width being along the lines of force (see *Fig.* 10).

The tension of the band may be adjusted so as to have as short a period as 1/40,000 second. A powerful permanent magnet provides the necessary controlling force on the strip. The deflecting force due to the alternating current is provided by two small coils, with their axes at right angles to the direction of the magnetic field due to the permanent magnet. If a current is sent through these coils the field in the gap is correspondingly distorted and the band takes up a position with its width along the resultant field. A

small mirror is attached to the centre of the band which indicates its motion. The entire lower part of the frame carrying the band is put into a tube filled with castor oil. This gives the necessary damping; the front of the tube is fitted with a lens, just as in the Duddell oscillograph, and prevents distortion of the spot of light in its passage through the tube. The optical system



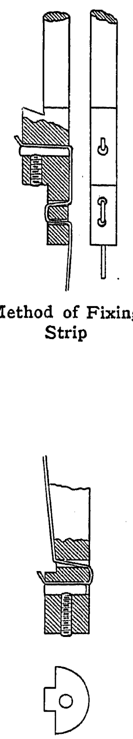


FIG. 10.—Details of Blondel Oscillograph.

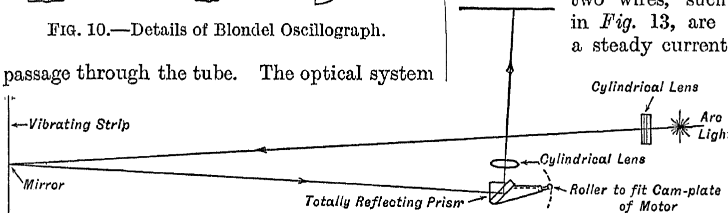

FIG. 11.—Arrangement for recording Vibrations of Oscillograph.

of this oscillograph is shown in *Fig.* 11, and is similar to that used in the Duddell instrument.

(iv.) *General Electric Company Oscillograph.*—A special type of oscillograph designed for use in works testing has been constructed by the General Electric Company of Schenectady. The form of this instrument is shown in *Fig.* 12. The vibrator consists of a separate unit which can be completely removed from the oil as in the later forms of the Duddell and Blondel oscillographs. Each vibrator is in a separate cell, and is placed between the poles of separate magnets, the arrangement for the three vibrators being shown in the figure. The tension on the strips is adjusted by the tension screw TS operating through a small spring balance. The vibrator terminals are shown at VT and the magnet coil terminals at MP. The tangent screw W is used

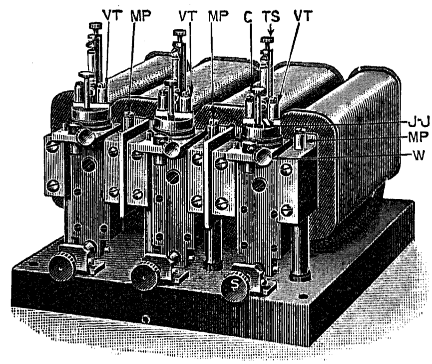

FIG. 12.

for adjusting the zero of the instrument. To obtain records with this instrument a special combined photographic drum and tracing attachment is used. The film roll is driven by a small synchronous motor, which is started automatically just before the shutter opens; the mechanism is so arranged that the shutter remains open for one complete revolution of the drum.

(v.) *Irwin Oscillograph.*—Another form of oscillograph has been suggested by Mr. J. T. Irwin,[1] and has been developed into a practical instrument. It depends on the fact that if two wires, such as CD and EF in *Fig.* 13, are so arranged that a steady current I_b flows through them from a battery B, in the direction indicated by the arrows *b*, *b*, and if there is superimposed on this a current I_a flowing from C to F in the direction indicated by the arrows *a*, *a*, the difference in the heating of the strips CD and EF will be proportional to the current

[1] *Proc. Inst. E.E.* xxxix. 617.

I_a. This may easily be seen algebraically. The heating of the strip CD is proportional to $(I_a - I_b)^2$ and that of EF to $(I_a + I_b)^2$, the difference between these quantities equals $4I_aI_b$, and, if I_b remains constant, is proportional, therefore, to I_a. The wires sag when the current passes, and if a mirror is attached to the mid points of CD and EF the deflection of the mirror will be proportional to the current I_a. The practical difficulty is to make certain that the two strips CD and EF and the sag in them are exactly the same. This is clearly very difficult to ensure when one considers that the motion, in some of these instruments, corresponding with sensible deflections is as small as 1/10,000 of an inch. The arrangement adopted by Mr. Irwin is shown in *Fig.* 14. The two wires C, D, *Fig.* 14, A, are each of the form shown in *Fig.* 14, B—*i.e.* they are passed round an ivory pulley which serves to give the necessary tension to the wires through the spring S. The wires are connected together by threads as shown in *Fig.* 14, C. If there is no current passing through C′C, D′D, or EE′, F′F, and if the wires are exactly similar at the same temperature, then their sag will be the same in each case. If a current is sent through the 4 portions in series then there will be an increase in length of all 4 wires, but no deflection. If the wire CC′, D′D is heated more than the wire EE′, F′F, the mirror M will be tilted by an amount which depends on the difference in the rate of heating of the two wires. With this arrangement, however, the objection is that the rate at which the wires will heat up is very slow. Mr. Irwin states that the instrument will not indicate accurately for frequencies much above 5 per second, even when the strips are immersed in oil so as to increase the rate of cooling and so make the instrument reach its steady deflection more rapidly. To make

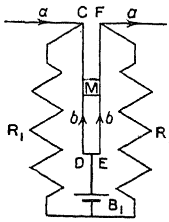

FIG. 13.

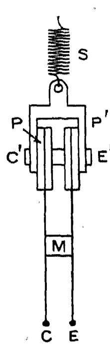
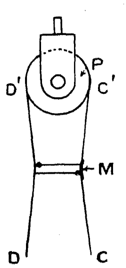
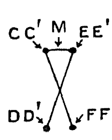


A



B



C

FIG. 14.

it practical for ordinary frequencies, the resistance R_4 (see *Fig.* 15) is shunted by a condenser K. The resistance of the instrument itself is low compared with R_4, being about 1/200 of it, for a voltage of 100 across AB. In this case the difference in temperature of the two wires of the instrument at any instant is proportional to the difference of potential across AB, *Fig.* 15. This may be shown mathematically as follows:

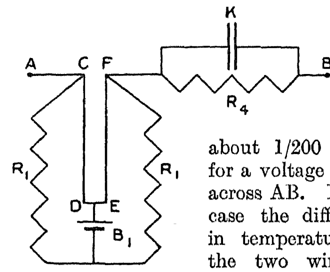


FIG. 15.

The temperature rise of the wires when heat is supplied to them depends on their mass and specific heat and on the rate at which they cool.

Thus $\qquad ms\,\dot{t}_1 = w - bt_1,$

where m is the mass of the wire,

s its specific heat,

$\dot{t}_1$ = rate of increase of temperature with time,

w = power supplied to wires,

bt_1 = heat lost per second by radiation, etc.

Writing $ms = a$ the equation becomes

$$a\dot{t}_1 + bt_1 = w = (I - i)^2 r$$

where I is the steady current and i is the varying current in one wire.

In the same way, for the other wire

$$a\dot{t}_2 + bt_2 = (I + i)^2 r,$$

where t_2 and $\dot{t}_2$ are the temperature and rate of increase of temperature for the second wire. Thus if

$$\theta = t_2 - t_1,$$

we have

$$a\dot{\theta} + b\theta = 4I\,ir.$$

Now the current i flowing through a condenser K shunted by a resistance R is given by

$$i = \left(\frac{V}{R} + \dot{V}K\right),$$

where V and $\dot{V}$ are the potential difference and rate of change of P.D. respectively.

Hence

$$a\dot{\theta} + b\theta = 4I\,ir\left(\dot{V}K + \frac{V}{R}\right).$$

If, therefore, a/b equals KR, θ is proportional to V, and the difference in temperature of the two strips will be proportional to the P.D. on the circuit. The deflection of a mirror attached to them, provided it is light, and the system has a sufficiently short periodic time, will, therefore, also be proportional to the P.D.

To record current, the instrument may be shunted by an inductance of suitable value and thus made to give deflections proportional to the current passing in the circuit. The form

adopted is shown in *Fig.* 16, the arrangement of the vibrating wires being similar to that in *Fig.* 14. The screws at the top of the instrument are used to adjust the tension on the strips, but this does not alter the natural period so much as varying the amount by which the wires are tied back in attaching the mirrors. In a particular case quoted by the constructor, the natural period was altered from 1/3,200 to 1/2,900 of a second by reducing the tension from 10 oz. to 6·6 oz. The natural period of the strips is, of course, rather longer when the strips are immersed in oil than when they are in air. It is possible to obtain critical damping with an oil slightly more viscous than paraffin, so that the damping difficulty does not appear to be so serious as in the other forms of oscillographs which have been described.

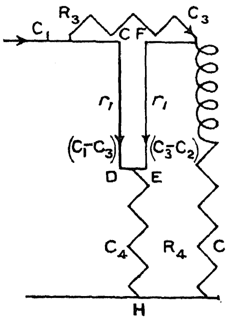

FIG. 16.

It has been shown that the indication of the hot - wire instrument depends on the product of the two currents I and *i*. If one of these currents, which Mr. Irwin has called the polarising current, instead of being constant, is proportional to the pressure which is applied to the circuit, and the varying current is the alternating current which is being observed, or a fraction of it, it is clear that the difference in heating of the two strips on which depends the deflection of the instrument, will be proportional to the power that is being expended in the circuit. When this oscillograph, therefore, is suitably connected it may be used to record variations in the power expended in a circuit. In order that the instrument may work satisfactorily, the resistances must be adjusted so that the power used in the instrument is a comparatively small fraction of the power being used in the circuit. Mr. Irwin has obtained some power diagrams which approximate very closely to those obtained by calculation from the pressure and current curves.

(vi.) *Cathode Ray Oscillograph.*—An oscillograph depending for its action on the deflection of a beam of cathode rays has been developed by Ryan.[1] The form of tube used by him is shown in *Fig.* 17. A cone of cathode rays *cr* is emitted by the disc-shaped negative electrode, it falls on an aluminium diaphragm *dd* in the centre of which is a small aperture, it then passes between the two plates Q′Q″, and falls on the fluorescent screen S. The rays are "focussed" by a coil MMF which produces a strong magnetic field along the axis of the cone. This has the effect of concentrating the beam and giving a smaller spot on the screen than is obtained without it. Ryan states that with the standard Muller-Uri-Ryan tube No. 2671 about 2500 ampere turns are required on this coil. The coil should be mounted in the first place axially to the beam, but should be capable of adjustment in any direction so that the resultant of its own field and the earth's field can be made to have the proper relation to the direction of the ray. The action of this magnetic field is explained by Ryan as causing the electrons in the cathode ray beam to move in spirals instead of allowing them to diverge, and the "focussing" is not therefore very accurate. The cathode ray discharge may be produced by an influence machine, or by a "diode" used in conjunction with a small high-tension transformer. After a time the cathode ray tube becomes "hard," as is found in X-ray work, and to soften it, that is, to reduce the vacuum, a small platinum tube *pt* is sealed into the cathode ray tube at one end, the other end, projecting outwards, is closed. Hydrogen may be passed through the tube by heating it in an alcohol flame, and the tube may be adjusted by having a spark-gap shunting it, so as to maintain such a vacuum that the discharge just passes through the tube, instead of across the spark-gap. In order to make a trace of the curve outlined on the screen *ss*, the whole tube may be put in a box and the screen observed through a smoked glass on which its shape may be

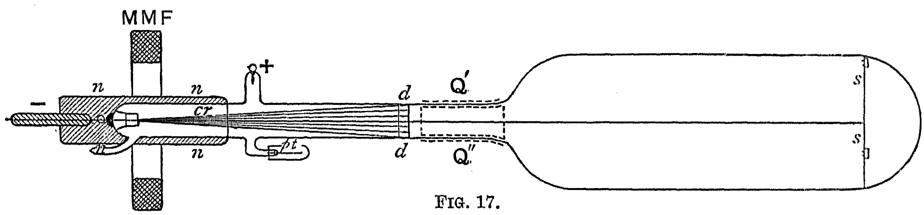

FIG. 17.

[1] Ryan, *Trans. A.I.E.E.* xxii. 539; *Proc. A.I.E.E.*, 1911, p. 532. See also "Piezo Electricity" and "Cathode Ray Manometer," Vol. I.

scratched. A better plan is to photograph the screen.

The arrangement shown in *Fig.* 17 is

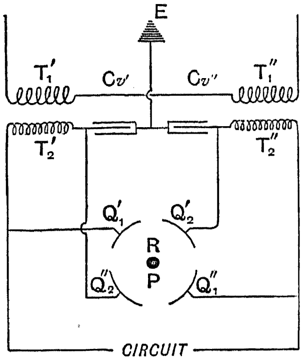

FIG. 18.

intended for taking oscillograph records of power. In the arrangement described two

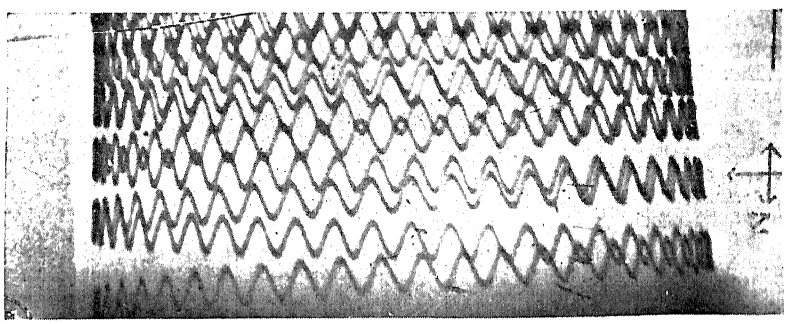

FIG. 19.

pairs of quadrants are shown, which are connected as shown in *Fig.* 18. The pressure between Q'_1 and Q''_1 will be equal to v, the potential difference applied to the circuit, and will produce a displacement y (say); the potential difference between Q'_2 and Q''_2 will be proportional to the current which is passing but will be 90° out of phase with it.

If x is the displacement of the cathode ray beam (which is proportional to the potential difference between the ends of the condenser $C_{v'}$ and $C_{v''}$) the current i which is passing may be written $c(dx/dt)$, where c is a constant depending on the capacity of the condenser and the size of the tube. The displacement of the pointer in the x direction, therefore, will be given by $dx=(idt/c)$, and the area of the curve formed on the screen by the cathode ray pointer, which will be equal to $\int_0^T ydx$, will be proportional to $\int_0^T vidt$, *i.e.* to the energy which is being expended in the circuit.

Not only can this instrument be used to delineate power curves, but, if the pointer is controlled, either by a magnetic field varying according to a sine law, or in some known way, it may be used to record wave shapes. One of the latest developments in the application of this form of apparatus has been the delineation of the wave shape of very high-frequency currents. The full details of this apparatus have not yet been published,[1] but the general scheme is evident from the oscillograms of an alternating current of 200,000 ~ per second that are given in *Fig.* 19. The "time" motion of the cathode ray beam is given by a magnetic field or electrostatic field of low frequency, while the current whose wave shape is required, produces a magnetic or electrostatic field in a direction at right angles to the time motion. For high-frequency wave delineation the cathode ray vacuum tube is by far the most promising apparatus that has been developed.

ARC LAMPS

§ (1) CHARACTERISTICS OF THE ARC.—The *Electric Arc* is used for illumination because its high temperature offers one of the most efficient means of generating useful light rays.

The name "arc" is given to a stream of hot gases carrying an electric current across a gap between two electrodes. The arc is usually started by first bringing the electrodes into contact and then slowly separating them to the required distance when the stream of vapour is generated and maintained by the evaporation of one or both of the electrodes by the action of the current.

The temperature of an arc stream is assumed to be the same as the boiling point or the vapour point of the negative electrode. Carbon is generally used for the electrodes because it has the highest vapour temperature, and because it passes directly from the solid to vapour (*i.e.* without becoming liquid) and therefore retains its shape up to the moment of transition.

The characteristics of the arc are greatly modified by the composition and physical properties of the electrodes, also by the current density and the distance between the electrodes. All these variables render the action complicated, and, because of its relative simplicity, it is advisable to approach the subject by a study of the pure carbon arc.

Previous to the modern development of the high efficiency "flame" arc the arc between pure carbon electrodes was usually employed, and its characteristics have been very fully recorded, notably by Mrs. Ayrton in her book *The Electric Arc.*

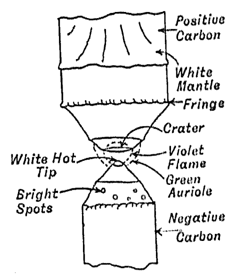

FIG. 1.

Fig. 1 (reproduced from *Electric Lamps* by Maurice Solomon) represents a typical direct-current open-type arc burning between carbon electrodes. The positive electrode is 18 mm. diameter and the negative 12 mm., these proportions giving even rates of consumption of the two carbons. The current through the arc is 10 amperes and the potential difference between the electrodes 40 volts. The vertical distance from the lowest point on the positive electrode to the top of the negative is 2 mm. The actual length of arc is greater

than 2 mm. because a hollow forms opposite the point of the negative. This hollow or crater in the positive electrode has a curvature of which the point of the negative is roughly the centre.

Between the surface of the crater and the point of the negative is an inverted cone of hot gases which carry the current from one carbon to the other.

The cone of gases in a pure carbon arc gives relatively little light, but an intense light is given by the surfaces that are being evaporated by the action of the current, viz., the crater of the positive carbon and the extreme point of the negative carbon. These two surfaces are of about equal intrinsic brilliancy, but the crater has much the larger area and is therefore the source of practically all the light.

Surrounding the cone of current-conducting vapour is a sheath of vapour which has escaped from the cone and has ceased to be part of the electrical circuit. This sheath resembles an ordinary flame. It gives practically no light.

The cone of conducting vapour is not constant in resistance and of itself it is unstable, but it can be kept constant by suitably varying the voltage across the electrodes, also by varying the length of the arc. The first is done by connecting a resistance in series with the arc, and the length of arc is controlled by an automatic mechanism which is fitted to each lamp.

This mechanism usually consists of an electromagnet carrying the arc current and having its armature arranged to pull the carbons farther apart when the current is above normal and retrace its movement when the opposite conditions prevail. It may have another magnet with a high-resistance winding connected as a shunt to the arc and with its armature arranged to pull the carbons nearer together when the voltage across the carbons

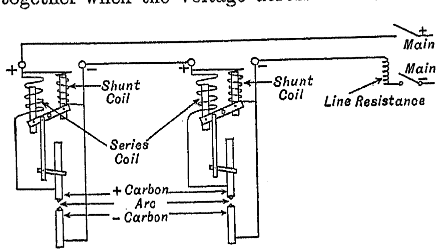

FIG. 2.

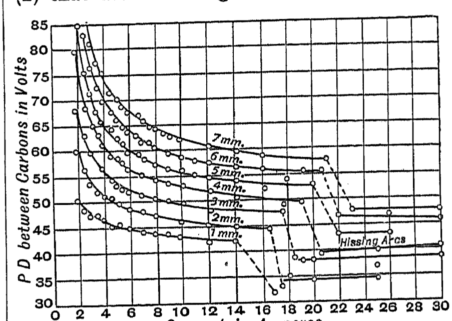
is above normal. Arc lamp mechanisms are described in more detail farther on in this article. The details of a typical arc lamp circuit are shown in *Fig.* 2.

The three zones in the arc, namely, the crater, the current-conducting vapour, and the bright point of the negative, have each their particular electrical characteristics. The crater of a pure carbon arc has a potential drop of 30 volts on, or very close to, its surface. The bright point of the negative electrode has a drop close to its surface but only of about 5 volts. Both these voltages are nearly independent of the amount of current passing. The areas of these two terminal regions vary directly as the current. If the current is increased quickly, the bright patch will be enlarged proportionally and will overlap the rim of the crater. If the current decreases the bright patch will cease to cover the whole of the crater, but in each case the crater ultimately burns to a diameter equal to the new diameter of the bright patch.

The cone of conducting gases also varies in area in such a manner that it is always approximately proportional to the current passing, but the voltage drop per unit of length *decreases* as the total current increases.

Summing up, it will be seen (1) that the terminal regions do not affect the value of the current, *i.e.* they cannot prevent it varying, and (2) that the cone of gases causes an unstable



P.D. and Current for Different Lengths of Arc.
Carbons: Positive 11mm.; negative 9mm.

FIG. 3.

condition. For instance, the current through an arc of fixed length and constant voltage will not remain constant at any value. If such an arc is above a critical length the current dies down and the arc goes out, and if it is below that critical length the current increases indefinitely. A line resistance is therefore connected in series with the arc, so that should the current increase the resulting rise of voltage across the resistance causes a decrease of voltage across the arc equal to the natural decrease of voltage along the cone of gases.

Mrs. Ayrton gives several sets of curves showing the relations between current and voltage and length of arc. *Fig.* 3 is one which illustrates the unstable feature very clearly, that is the fall of voltage which occurs when the current is increased and the length of arc is kept constant. The length of arc is

measured in the way described above and the full length of the vapour column is greater by a distance equal to the depth of the crater. For the present, attention is called to the inverse current-voltage characteristic for readings below 16 amperes. The sharp drop which occurs with higher currents, *i.e.* when the arc hisses, is of somewhat different character and will be dealt with later on.

§ (2) Arcs in Series or in Parallel.—Each series of lamps requires its separate steadying device, because if two series were connected in parallel and if they run on a common line resistance the current would grow in one series and die out in the other.

The mechanism which adjusts the length of arc does to some extent steady the arc and long series of lamps are easier to control than short series, because the variation in volts caused by a variation in any one arc is only a comparatively small part of the whole voltage drop and can be counteracted by the mechanism.

Ten " open type " arc lamps in series with 16 per cent of line resistance will burn more steadily than two lamps in series with 20 per cent. The arcs in both cases take about 40 volts each. " Enclosed " arc lamps having 70-75 volts across each arc require a larger proportion of line resistance, 20-30 per cent, because the long arc has a larger inverse-voltage factor. The effect would be more marked if the arc were not enclosed and so shielded from draughts.

A choke coil on an A.C. circuit and the self-induction in the open coil armature of the Brush Arc Lighter D.C. generator (a machine used in the early days of arc lighting for series constant-current lamps) act in the same way as a line resistance and do not absorb energy. The modern steadying device, which depends on the demagnetising of the field of the generator, is not quite so satisfactory because it does not answer instantly, but it has many advantages to set against that.

§ (3) Conditions of Steadiness. (i.) *The Continuity of the Arc.*—Another important characteristic which adds to the difficulty of maintaining a steady arc is the fact that if the current is interrupted for only a very short time it is impossible to restart the arc except by bringing the carbons together or by applying sufficient voltage to jump the gap. It is best explained by considering what goes on with an alternating current arc. This arc dies out at each half cycle and the current does not start to flow in the reverse direction until the voltage has risen sufficiently to jump the gap. The proportion of the cycle which must elapse before this critical voltage is reached depends on the temperature of the gases left in the gap, hence low periodicities will cause a greater lag, because the gases have more time to cool off before the voltage rises sufficiently. Again, electrodes having low vapour temperatures and low voltage per unit length of arc stream will not restart at all. Thus it is impossible to maintain an alternating current arc with such electrodes. In this respect pure carbon should make the best electrode because it has the highest vapour temperature, but in practice a carbon cored with a mixture of soft carbon and potassium silicate gives the steadiest arc with alternating current.

The explanation of this depends on various properties of the arc such as the resistances of the gases with and without the coring materials, the rates at which they cool, and the extent to which evaporation is continued during the break from one half cycle to the next.

Since the temperature of the carbon is above the vapour point of the other materials a fairly constant supply of gas is maintained. The noise with cored carbons is more musical than with uncored carbons—the crackling sound typical of the hissing D.C. arc is absent, but this may only show that the arc follows the same path at each half cycle and not that there is any marked difference in the continuity of evaporation.

When current ceases to flow at the end of each half cycle the full instantaneous E.M.F. of the circuit is then impressed on the electrodes, consequently the larger the steadying device (line resistance or choke coil) the earlier is the instant when there is sufficient pressure to jump the arc gap. A choke coil gives better results than a line resistance for two reasons : (1) it takes less energy than a resistance, and (2) it makes the arc current lag behind the E.M.F. of the supply, consequently when current ceases to flow through the arc the line E.M.F. has already reversed and has risen to an extent depending on the time during which the current lagged behind the E.M.F. With sufficient choke voltage it is possible to make the current restart immediately and so bring the " power factor " of the arc itself very close to unity. A.C. arcs with a low " power factor " (*i.e.* long idle period) are less efficient than when there is no idle period. " Power factor " of the arc itself must be considered apart from the overall power factor. When the latter is low, the former is high.

(ii.) *The Path of the Arc.*—Having provided for the continuity of the arc, either A.C. or D.C., the next thing is to fix its path and after that to supply it with a stream of vapour unchanging in quantity and composition. Position of the stream is influenced by draughts, by magnetic fields (including that of the arc itself), and by variation of the materials (physical and chemical) round the margin of the crater, or at any other point on the positive electrode to which the arc may take a new path through the hot gases which surround it. As regards the negative electrode the arc can

slide over it, but cannot jump from one point to another.

Even if a conductor more negative in potential than the negative electrode is introduced into the arc stream near the negative end, the arc will not at once transfer to it. A cold carbon of small diameter connected in this way may be passed across and through the arc stream without causing the arc to transfer to it. If the point is held in the arc stream until it becomes white-hot then the arc may transfer to it, but even this is probably due to a momentary disturbance of the original arc and to a static spark jumping from the point of the third carbon, which, according to the present theory, starts a new arc.

At the positive electrode, however, the arc stream can and does choose the path of least resistance if it is not otherwise influenced by draughts or magnetic fields.

Positive carbons are usually cored with materials which have been found to tend to keep the arc central on the carbon. The action appears to depend on these materials throwing off a stream of vapour of lower resistance than that which comes from the body of the carbon. The lower resistance may result from the physical condition of the core or from its chemical composition. For instance, carbon in a powdered form, loosely held together, will not have the heat-conducting property of the solid carbon body, and consequently will more quickly rise in temperature when exposed to the heat of the arc. As regards chemical composition it may be assumed that practically all substances, including those used for colour radiation, give off vapours having a lower resistance than carbon vapour.

Disturbance may occur through changes in the condition of the carbon body—for instance, the binding material may be burnt away by contact with the air and leave a layer of finely divided carbon on the surface. If the arc should leave its central position and so touch this layer of dust, then the resistance of the resulting vapour is less than the original stream, and the arc shifts bodily on to the layer of dust and generally takes a circular path round the cone before returning to the core. Somewhat similar disturbances are caused by layers of material which have condensed on the cone or the sides of the positive carbon. In open-type arcs the carbon passes away as CO_2, but some of the materials used for coring as well as some impurities from the body of the carbon condense and settle down as dust after they leave the arc stream. These layers of dust will lead the arc up the sides of the carbon, assisted by draughts and by magnetic effects, until the arc is so lengthened that it goes out or until the carbons are brought together by the controlling mechanism and a new arc thus started in the correct position.

Impurities in the body of the carbon are evaporated when the arc reaches them, and as they are generally of materials which give a much lower resistance stream than carbon the result is a sudden increase of current.

The foregoing are all disturbances due to variations of materials. Another set of disturbances can be said to be due to errors of position, that is, the positions of the various surfaces of the positive carbon in relation to each other and to the point of the negative carbon. The ideal conditions for steady burning are: no effects from draughts or magnetic fields, carbons exactly on a common axis, a true formation of the ends of the carbons and an arc stream of constant resistance and having its greatest conductivity at its centre and on the axis of the carbons.

(iii.) *Diameter of the Carbons.*—There are practical limits to the diameter of the carbon for a given current.

The arc will only remain central so long as the shell of the carbon is burnt away as quickly as the core. With open-type lamps the greater part of the shell just burns away and the resulting gases do not get into the arc stream, but if this burning does not take place fast enough the crater becomes deeper and its edge gets nearer to the point of the negative carbon, thus offering a path of less resistance, and the arc wholly or partly leaves the core until it has burnt away the over-prominent rim of the crater. It is necessary to avoid this wandering because the effect on the light is noticeable, and also the arc may touch a fringe of loosened or of deposited material as explained above.

There are also limits to the reduction of the diameter of the carbon for a given current. In practice it is the quick rate of consumption and the great length that would be required, but beyond that is the necessity of maintaining sufficient area at the end of the carbon to prevent the arc overlapping, and this is particularly so with a pure carbon arc. Overlapping in this instance may cause the arc to hiss.

In the foregoing it has been assumed in every instance that owing to its higher temperature the centre of the arc stream has less resistance than any other path open for the current. This supposition has also been made for the terminal regions, but it is probably not true of the positive terminal region in some instances. This region has the greatest voltage drop per unit of length, and the drop is greater the higher the vapour temperature of the electrode; this is highest with pure carbon. If the surface of the carbon becomes irregular, and if one of the projecting points is bathed in the hot gases which immediately surround the arc stream, the voltage between that part of the stream near the terminal region and the point on the positive carbon may be sufficient to cause a discharge through the

gases; the arc shifts bodily to this new position. It will be understood that this discharge occurs between two parts of the positive terminal region, and does not pass direct from the negative electrode.

For picture projection work it is necessary to displace the negative carbon from the axis of the positive so that the negative does not throw a shadow on to the picture. The axes of the two carbons may be kept parallel or may be placed at an angle to each other. In both cases the ends of the carbons assume shapes which are not symmetrical with the general line of the arc stream, and there is consequently a tendency for the arc to shift to the "high" points. This is usually counterbalanced by a magnetic field arranged to bend the arc stream, so that it starts in a direction normal to the cone of the negative and ends as a normal to the crater of the positive carbon.

§ (4) The Hissing Arc.—Under certain conditions the positive end of the arc stream will travel over the carbon at a high speed—too quickly for all its movements to be followed by the eye. There is a distinct falling-off in light, and a loud noise which has given it the name "hissing arc."

An ordinary carbon arc burning in air will always hiss when the current density in the positive carbon exceeds the critical value for that particular carbon. Hissing will begin below this value with a short arc. It may also start if a sudden increase of current causes the arc stream to expand beyond the rim of the crater, or if one of the carbons is moved sideways or the arc is blown sideways.

When hissing starts there is always a sudden fall in the arc voltage, and this fall practically all occurs near the positive crater region. This drop is shown by the dotted parts of the curves already given in *Fig.* 3. Mrs. Ayrton gives the results of a long series of tests on hissing arcs. Her conclusions are that the hissing and the fall of potential are due to the oxygen of the air getting to the crater surface, because an arc will not hiss if surrounded with nitrogen or carbon dioxide. The explanation suggested for the quick movements is that air first combines with the carbon on part of the crater surface, then the products of combustion temporarily shield the surface but afterwards disperse, and a fresh supply of air rushing in the action is repeated.

As an alternative theory the present writer suggests that the skin of unoxidised gases immediately surrounding the arc stream near the positive crater is disturbed when the arc grows in area beyond the rim of the crater and coming in contact with the air undergoes a change which reduces its resistance and so *attracts* the arc. The arc then continues its movement as the layer of gas on its forward side is changed in its turn. This presumes an orderly movement, and it would account for the humming which precedes the hissing when the current is slowly increased. The hissing may be started when air rushes in to fill the vacuum caused by the gases cooling in the rear of the moving arc. A strong rush may catch up the arc and, acting on its rear surface, may reduce the resistance at that point, and by making the direction of travel erratic cause a hissing instead of a humming sound. The foregoing all refers to arcs with ordinary carbons. Flame-cored carbons work at much higher densities before hissing, and this fits in with the theory now put forward because flame arcs require less voltage drop per unit of length and work at lower temperatures, and therefore are not so easily short-circuited by the surrounding gases. The theory that the crater region of a pure carbon arc may be short-circuited by the surrounding gases will account for many of the difficulties experienced with pure carbon arcs and explain why coring with substances other than carbon overcomes these difficulties.

§ (5) Effect of Magnetic Fields.—Magnetic fields acting on the arc are of three classes: (i.) From external sources, (ii.) from the current-carrying parts of the lamp, and (iii.) from the current in the carbons and in the arc itself.

The effect of a magnetic field on the arc is to force the arc in the direction which will cause the greatest increase in the number of lines of magnetic force linked with the circuit of which the arc forms part.

Generally speaking, the carbon arc works best when not influenced by any magnetic field, but one is often used to counteract the effect of draught and also for bending the arc stream to alter the direction the crater faces as already explained. Pure solid carbon arcs do not work satisfactorily with a curved arc stream, but cored carbons work well enough if the arc is long, say one requiring 60 volts or more. Flame carbons work well with a curved arc stream at as low a voltage as 38 volts.

With regard to the three classes of field, (i.) the external fields do not often cause trouble, but it is advisable to bear the question in mind both when designing and when erecting lamps—particularly lamps with long arcs such as those used for photographic work. Alternating current arcs are only influenced by A.C. fields in synchronism. The effect of the Earth's field is distinctly noticeable on D.C. lamps. In north latitude its vertical component causes a horizontal arc to curve to the left, looking from positive to negative. The effect is seen in the type of flame lamp which has converging carbons with the arc at the lower ends, and lamps with long iron frames or cases show it more than others. It is usually counterbalanced by making one pole of the blow magnet (used for bending the arc downwards) stronger than the other or by the stray field from one of the operating

solenoids. Lamps for use south of the equator require the opposite effect.

The horizontal component of the Earth's magnetism cannot be counteracted permanently unless the lamp is always hung one way round. It causes a vertical arc to curve towards the east if the upper carbon is positive. Its intensity varies with the latitude but its direction is constant.

When lamps are hung close together the field from the operating solenoid in one lamp may act on the arc of another lamp, although it will not affect the arc of its own lamp if the arc is vertical, because the field is vertical in that region and therefore in line with the arc stream.

(ii.) *Fields from Parts of the Lamp carrying Current.*—These include those from operating solenoids and magnets, which, however, can usually be so placed that the resulting field is in line with the arc stream and therefore does not influence it. Parts carrying the main current near the arc itself are not so easily dealt with. When possible the current should be split and carried equally on each side of the arc. This is not always practical in a searchlight, and with currents of 100-200 amperes the field is relatively strong. If the carbons are horizontal and the connections to the holders come from below there will result a strong field which curves the arc upwards. There will also be the up-draught caused by the heat of the arc. It is usual to counteract these forces either by an electromagnet (or a solenoid with or without an iron core), or by so placing a piece of iron that it attracts the arc by virtue of the magnetic field generated by the current in the carbons and in the arc itself.

The usual form for the last mentioned is a "C"-shaped piece of iron concentric with arc and with the gap at the top.

With heavy current searchlights, say 100 amperes and upwards, it is possible to get the necessary control by passing the main current through one or more conductors placed parallel with the arc. If the current passes in the same direction as through the arc the conductor attracts the arc and *vice versa.* Better results are obtained by repulsion because, as the arc retreats from the conductor, it passes into a weaker field and the forces thus tend to balance. On the other hand, if the arc is attracted towards a conductor it enters a stronger field and so tends to move nearer to the conductor. The same is true of pieces of iron arranged to attract the arc, such as the "C"-shaped iron mentioned above.

(iii.) *Magnetic Fields produced by the Current in the Carbons and in the Arc itself.*—These act in the same way as those of Class (ii.) for any definite position of the arc, but the arc may take up a new position and so change the conditions. A full consideration of this point will explain why small-diameter, coppered-core, negative carbons were developed for searchlights and cinema projector work and why they give so much better results than the earlier types.

First consider an arc, say of 100 amperes, with carbons on a common axis and the arc for the time being on this axis. If the conductors leading to the carbons are so arranged that they do not produce a field near the arc or that their field is in some way counteracted, then there will only be the usual circular field round the carbons and the arc typical of a long straight conductor.

Now consider what happens if the arc moves bodily sideways, say to the edge of the carbon, but still keeping its axis parallel with that of the carbons. The current will still flow evenly along the carbon most of the way, but near the end it will be crowded over to the point from which the arc starts, and thus for a short distance the mean path of the current is not axial and the current at this point will therefore have a magnetic effect on the arc. The result is a curved arc stream, the amount of curvature depending on the distance the arc is displaced from the axis. Large diameter carbons will show this disturbance much more than those of small diameter. When the arc has been curved in this way each part of the arc will then have a magnetic influence on the remainder, thus tending to enlarge the loop, but at a position beyond the tangent to the mean path in the carbon a balance is obtained between the two forces —the current in the carbon now acting as a

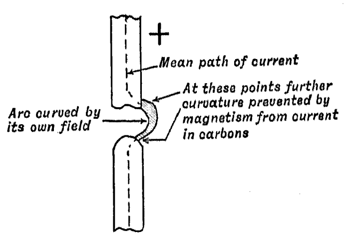


FIG. 4.

restraining force to prevent further curvature (see *Fig.* 4).

The modern negative carbon for searchlights and cinema projectors is made small in diameter and has also special means for keeping the current-path central. It is provided with a high conductivity core of hard carbon and the core is heavily coated with copper. This core is virtually the electrode proper—the use of the outer shell is chiefly to support the core and to protect it from oxidisation. The positive carbon is also made small in

diameter, the current density being increased until it is as near the hissing point as is practical.

The magnetic forces acting on the arc have to be considered in conjunction with draughts due to the heat of the arc. With horizontal carbons the forces are very similar in their effects when both are acting in an upward direction. With vertical carbons the draughts do not play a part until the arc has first been displaced by other forces, but then the effect may become serious, particularly with long arcs such as those used for photographic work. An arc for this purpose is 2 in. or more in length, and is enclosed in a relatively small globe, but sufficient air remains in the globe to cause considerable convection currents. If the up-draught gets full control of the arc stream the latter takes a shape like the figure 7, the horizontal limb starting from the side of the positive carbon. The magnetic effect of the current in the positive carbon restrains the arc from over-curvature in the manner already explained, but this force is greatest next to the carbon. The up-draught acts on the horizontal limb of the 7 and the two forces together are the cause of the elbow in the arc stream (see *Fig.* 5). In practice

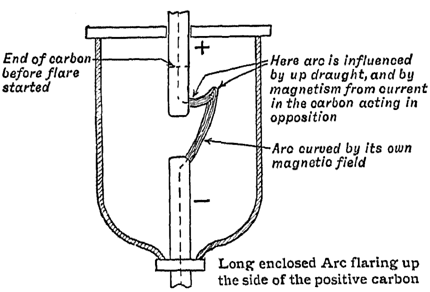

Fig. 5.

successful operation is attained by using small diameter carbons of good quality—if there is nothing to cause the initial disturbance the up-draught does not get a chance to displace the arc.

§ (6) Best Forms of Arc for Projectors.—In the foregoing it has been assumed that an arc stream maintained on the axis of the carbons gives the best results for projectors. This is true of a pure carbon arc because it will not burn steadily unless the stream is maintained on that line. When flame carbons are used the current density in the positive carbon may be increased considerably without causing hissing, and then the greatest brilliancy for that type of carbon is obtained by forcing the negative stream away from the positive, so that there are then two streams distinctly visible, the true electrical discharge coming from the negative, and a stream of evaporated material coming from the positive. These streams cross each other and so complete the electrical circuit. The negative carbon is set at an angle to the positive and below it so that its shadow does not fall on the mirror. Magnetic and draught effects are such that the two streams meet near the positive carbon but well above a line joining the point of the negative and the centre of the positive crater (see *Fig.* 6). The positive stream is considerably diverted above the axis of the positive carbon and passes so close to the upper lip

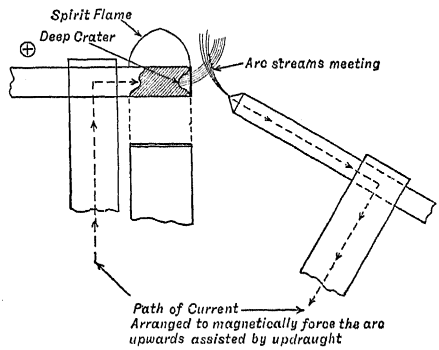

Fig. 6.

of the crater that the arc is inclined to transfer itself to the lip.

The Beck Arc.—The crater formation is preserved by rotating the positive carbon slowly, and in the "Beck" arc this action is supplemented by surrounding the carbon (but not the arc stream) with a flame of methylated spirit. If the spirit flame plays on the arc stream the latter makes a whistling noise and becomes very unsteady.

The action of the spirit flame on the positive crater appears to be twofold. It preserves the edge of the crater by preventing air getting to it and it reduces the conductivity of the vapours in that region; possibly this is also because the air is kept away. The crater becomes very deep because the arc cannot transfer itself to the lip. At the bottom of the crater there is an area of the greatest brilliancy that has been obtained so far. However, there are several objectional features to set against it. For instance, flame carbons generate fumes which may condense on the mirror, and they also give a long luminous flame, the image of which is inverted and thrown on the foreground.

It has not been determined how many of the special features are necessary to get this increased brilliancy, but it is certain that if, other things being unaltered, the negative stream is allowed to impinge straight into the crater, the voltage across the carbons drops and the brilliancy decreases very considerably.

§ (7) Flame Arcs.—A flame arc is more efficient in illumination than a pure carbon arc because the former gives "coloured" radiation, *i.e.* gives a larger proportion of the wave-lengths to which the eye is sensitive. The light from the crater of a pure carbon arc gives "black body" radiation corresponding to its temperature, which is the vapourising temperature of carbon. All wave-lengths are given in the visible range, and for a considerable range on either side of it, so that a large proportion of the energy is wasted in invisible radiation or in wave-lengths to which the eye is not very sensitive. The carbon arc is converted into a flame arc for coloured radiation by feeding into the arc stream materials which radiate a larger proportion of useful wave-lengths, notably calcium salts, which as gases heated to the temperature of the arc stream give off a preponderance of yellow rays, the colour to which the eye is most sensitive. Such materials are usually introduced into the core of the carbon. They are insulators when in the solid state, but become conductors when evaporated, and in that way they modify the electrical condition of the arc stream besides modifying the light.

The electrodes themselves, as well as the means of controlling the arc, have been developed mostly by experiment, and it has been only during the last ten years that theory has assisted to any extent, notably in the selection of materials to give coloured radiation and the method of carrying them into the arc stream.

In a paper on Yellow Flame Arcs read before the I.E.E. in 1912 Mr. Solomon gave the following figures:

	Watts per Candle Power.	
	Mean Spherical.	Lower Hemispherical.
1. Converging carbon flame lamps	0·276-0·313	0·145-0·159
2. Enclosed flame lamp	0·458	0·374
3. Open type with Blondel carbons (end on)	0·178	0·095

Other things being equal, the efficiency of a yellow flame lamp increases with the proportion of flame materials in the arc. When these are above a certain proportion they cause flickering.

Class 1 contains a high proportion, but the carbons are of small diameter and therefore work steadily. Class 3 contains a larger proportion, the carbons, however, are relatively large in diameter, and the steadiness not so good as in No. 1.

The effective proportion of flame material in the arc No. 2 was low, moreover the wattage of this arc was 357·5 as against 435-450 for No. 1, and 396 for No. 3. The efficiency, therefore, was reduced in consequence. Since that date considerable improvements have been made in carbons for enclosed flame lamps. See "Carbons for Arcs, the Manufacture of."

§ (8) Characteristics of Arcs in Air, in Inert Gases, and in Vacuum. *Enclosed Arcs and Economisers.*—Arcs burning in vacuum or inert gases are of no use for illumination, mainly because it is necessary to carry away from the arc all the material which is evaporated. If any of it condenses on the carbon unsteadiness results. Even in air a short arc will "mushroom"—that is, carbon will build up on the negative, destroy its symmetrical shape, and cause unsteadiness, besides blocking the light. However, in "enclosed" lamps and lamps fitted with economisers advantage is taken of gases less active than pure air. In enclosed lamps the oxygen becomes exhausted by combustion of the carbon, also the heat in the enclosure rarefies the gases. The inlet for fresh air and the size of the globe are adjusted until the burning away of the carbon is just fast enough to keep the ends clean. The carbons become practically flat on the burning ends and the arc is continually moving about burning each part in turn—the area of the carbon being much greater than the area of the arc.

When flame carbons are used in enclosed lamps it is necessary to deposit the fumes on surfaces other than the enclosing globe. This is done in several ways, but all depend on convection currents carrying the gases into additional chambers and over large cool surfaces on which the fumes are deposited, the gases returning to the globe after they have been clarified. It is necessary to keep the globe hot to prevent condensation on its surface, and therefore it is generally surrounded by another globe which keeps the cool outer air away from the inner globe.

Economisers retard the consumption of the carbon by restricting the circulation of air in the neighbourhood of the arc. They are principally used for open-type flame arcs, both those with vertical carbons end on and those with converging carbons. They are usually bell-shaped and the carbon (or carbons) pass through close-fitting holes at the top of the bell, the arc being located in the mouth of the bell. The air in the bell is rarefied by heat and is also robbed of oxygen to a certain extent, so that the higher the arc is in the bell the slower is the burning of the carbon which is above it. With end-on carbons the bell therefore counteracts uneven burning of the top and bottom carbons and keeps the arc fixed (focussed). The same is true with converging carbons—if one carbon burns slower than the other its point stands lower down

and, coming in contact with less heated and denser air, is burnt away faster. This property of the economiser is essential to the success of the converging carbon lamp. Without it the points of the carbons would not remain level with each other—the smallest difference in their rates of burning would soon put them right out of balance because in unrestricted draughts the lower point burns slower than the higher one. Even if the points remained level the unrestricted draughts would make the arc very unsteady.

Some economisers are made of fireclay and some of iron—the latter are used for magazine lamps; they collect a layer of white deposit from the arc gases and reflect as much light as the fireclay type. The iron bell is also used as a shield from a strong magnetic field located above a slotted horizontal partition in the bell. This field is used to blow out the arc which is formed at the carbon grips when the stumps of carbon are ejected. The field also extinguishes the arc on the last pair of stumps for which there is no means of ejection, and it is used for lamps with one pair of carbons for this latter purpose.

§ (9) Automatic Arc-controlling and Carbon-feeding Mechanism.—The function of the automatic mechanism is to start the arc and to maintain it at the desired current and voltage, also to feed the electrodes as they are consumed.

The mechanisms may be divided broadly into two classes—(i.) those which strike an arc of definite length and afterwards feed the carbons step by step, and (ii.) mechanisms with a floating adjustment.

(i.) *Step by Step Mechanism.*—In this class the usual arrangement consists of a series magnet which separates the carbons to strike the arc by moving over a fixed distance, and a shunt-controlled mechanism which feeds the carbons when the voltage of the arc exceeds a certain value. Some of the large searchlight lamps are built on this principle—the moving parts being too heavy to control with a floating adjustment. With the non-floating mechanism there is no retrace—that is to say, if through some irregularity in the supply voltage or in the electrodes the voltage across the carbons rises momentarily the carbons will feed until the voltage drops. After this feed has occurred the cause of the disturbance may be removed, in which case the carbons would need to be pulled apart to a certain extent to bring the arc back to its normal condition, but as there is no retrace in the feed mechanism the arc has to burn at the reduced length until some of the carbon has been consumed and normal length of arc regained in that way.

The general effect on the arc of a mechanism which has no retrace is to reduce the average voltage and increase the average current passing through the arc when the conditions of the circuit are unstable from any cause. This characteristic has its good points. The increased current causes an increased drop in the line resistance and thus a natural increase of the steadying effect given by the line resistance. Therefore, with a mechanism having no retrace the lamp will burn at a higher current and lower voltage across the arc when the circuit conditions are unsteady, whilst with everything under the best conditions the average voltage of the arc will approximate the voltage to which the feeding mechanism is set. An unsatisfactory feature of this mechanism is its inability to bring the carbons nearer to each other quickly when conditions are unstable, thus allowing the arc to go out frequently when it might have been maintained.

Owing to the unstable nature of the arc, it is advisable to counteract the variations in the composition of the electrodes and any effects due to the arc wandering over the surface of the carbons, also those which occur due to the supply voltage not being constant, and to other lamps in the circuit not functioning properly.

(ii.) *Floating Mechanism.*—With a floating mechanism any reduction of the arc current immediately brings the carbons nearer to each other. It may also cause a feed in the same way as with a non-floating mechanism, but when the circuit conditions return to normal the mechanism retraces the carbons all or part of the way and brings the conditions in the arc to normal. Generally speaking, it is not advisable to have a floating mechanism adjusted to a straight line characteristic. It gives better results if it makes the lamp take a little more current when the mechanism is above the feeding point. This gives the floating mechanism a somewhat similar characteristic to that of the non-floating mechanism, namely, an unsteady circuit tends to make the lamp take more current and thus increase the steadying effect.

The same may be true of the dash-pot arrangement which is used for preventing quick movements of the mechanism. It is advisable to have a valve in the dash-pot which retards movements which separate the carbons and allows quick motion in bringing the carbons together.

§ (10) Forces used for controlling the Mechanisms.—With mechanisms of the non-retracing type electromagnets are generally used. It is of very little consequence whether the pull of the magnet is constant over the length of the movement, because it is only necessary to move the mechanism over a definite distance and then to arrest it.

Again, as regards the shunt-controlled feed gear the usual thing is to release a detent controlling a train of wheels and a retarding

fan, and this detent can be operated practically as well with a magnet as with a solenoid.

Another type of feed gear for this class of lamp consists of a shunt magnet and vibrating armature on the same principle as the ordinary electric bell, the vibration of the armature being used to operate a ratchet-wheel step by step and so feed the carbons. The armature is controlled by a spring which is adjusted so that the armature begins to vibrate when the feeding voltage is reached and ceases to vibrate when the voltage drops below the critical amount.

In mechanisms of the floating type solenoids give better results because the pull is more even, also there is very little side pull, and, if the solenoids *lift* the cores, a minimum of friction on the pivots. Magnets have been used for operating floating mechanisms, but it is necessary to shape the pole pieces and arrange the armature so that it has an oblique approach, so as to give an approximately constant pull over the working range. All this, however, means very close adjustment and strong construction; because if the parts become worn or displaced the characteristic of the pull is altered altogether.

The controlling windings for the various types of lamp are as follows:

(i.) *Lamps in Parallel.*—For lamps to burn in parallel a series-wound solenoid is sufficient. The lamp then takes an approximately constant current, the voltage of the arc being controlled by the voltage of the supply and the amount of line resistance in the circuit—that is to say, if a lamp is burning on a 100-volt circuit and the solenoid is wound to balance a gravity or spring controlled mechanism when 6 amperes are passing through the solenoid, and if the line resistance is 5 ohms, the result will be an arc of 70 volts. If now the supply voltage is increased to 110 without other conditions being altered, the arc voltage will go up to 80, because the current will remain constant and the absorption in the line resistance is therefore constant, hence the extra voltage has to be absorbed in the arc.

Series windings have also been used with fair success for short series of what are known as "shuntless" lamps, but in that case the solenoid is constructed to depart considerably from a straight-line law. The system will be best explained by considering what would happen if a number of ammeters, say 4, are connected in series, the ammeters being identical in construction and calibration. If 5·5 amperes pass through these meters all the needles will stand at a certain position on the dials, and if the current is increased to 6 amperes they will all move a definite distance and take up a 6-ampere position, and so on to another position if the current is increased to 6·5 amperes.

Now imagine that the distance between the 5·5 ampere and the 6·5 ampere position is equal to the length of a 6·5 ampere arc of say 70 volts, then imagine the "ammeters" are strong enough to operate 4 lamp mechanisms attached to the points of the needles so that when the four needles reach the 5·5 ampere positions they engage the clutches of the carbons and when moved further up 4 arcs are struck, the arcs being in series with the ammeter windings. With such an arrangement the four lamps will strike up and burn at 6·5 amperes until the carbons have been consumed to some extent. Then as the current drops the needles will sink back gradually, until when the mechanisms have retraced their movements half-way all the arcs will be burning at 6 amperes and, providing the carbons have been consumed evenly in the four lamps, the four arcs will still be of equal length although slightly longer than they were when taking 6·5 amperes.

This action goes on until the mechanisms further retrace their paths and get near to the 5·5 ampere positions where the clutches originally gripped the carbons. At this position, however, a further consumption of the carbons and a further reduction of the current would make the clutches lose their grips of the carbons, and as this may occur in one and not happen in the other three, it would be impossible to ensure an even feeding of the carbons, therefore a mechanism is added which extinguishes all the arcs just before the clutches would be opened say at the 5·75 ampere position. This arc-extinguishing mechanism may consist of an additional magnet capable of arresting the mechanism even when say only 50 per cent of the normal current is passing, and fitted with a pin and slot device which is free at the 5·75 ampere position and upwards, or it may be that the solenoid core is made in two parts, also with a pin and slot device, or again it may be simply a mechanical stop which temporarily arrests the mechanism on the downward stroke when it falls to the 5·75 ampere position.

It is essential that the arcs are extinguished and all pairs of carbons brought together, so that when each clutch takes a fresh grip of its carbons all arcs are restarted evenly and the sequence of motions repeated.

With enclosed lamps, for which type this shuntless mechanism was designed, the sequence of operation need not occur more than once an hour, and the momentary blink due to the resetting action is not objectionable at this long interval.

(ii.) *Lamps in Series.*—Series enclosed arc lamps have been controlled by the expansion of a stretched wire which carries the main current. When an excess current passes it allows the carbons to be separated either by a spring or counterweights, and when the current decreases the wire cools, contracts, and pulls the carbons nearer until a balance is attained. The action is the same as if the above-mentioned "ammeters" were hot-wire meters instead of electromagnetic. The heating and cooling of the strip is slow, so no dash-pot is necessary, also no restarting gear is necessary because the movements are so

sluggish that the arcs go out much more frequently than is required to stop individual feeding; in fact, that is where the system fails —too frequent extinctions and long periods of darkness whilst the wires are cooling down sufficiently to open the clutches.

Arc lamps fitted with shunt control only have been made for working in series, but they give very poor current regulation except when there is a large proportion of line resistance. On a typical circuit, say two open-type arcs on 110 volt with 42 volts on each arc, assuming the shunt control follows a straight-line law and has only a 5 per cent lag due to friction, then the current will vary in proportion to the variation of voltage across the line resistance. Five per cent of the arc voltages is 4·2, so the current will drop as 30·2 : 26 or 14 per cent.

With two 40-volt arcs on 100 volts the current will drop 17 per cent. Variations of the supply voltage have a similar effect. An increase from 110 to 115 volts will increase the current as 26 : 31 = 19 per cent, and in the second circuit an increase from 100 to 105 volts as 20 : 25 = 25 per cent.

The pull of the shunt solenoid or magnet is counterbalanced by gravity or a spring, therefore the carbons separate when the circuit is switched off, and are pulled into contact when switched on, afterwards separating until the rise of voltage across the arc and across the shunt circuit increases the pull enough to cause a floating balance.

(iii.) *The Differential Control.*—A differential control for a floating adjustment combines the best features of the simple series- and shunt-wound types, and the great majority of modern arc lamps are controlled in this way. The typical arrangement consists of two solenoid cores attached to the opposite ends of a lever, one being pulled upwards by a solenoid carrying the arc current and the other is pulled upwards by another solenoid wound with fine wire and connected as a shunt to the arc (see *Fig.* 2). The solenoid carrying the arc current is usually the stronger. The carbons are brought together by gravity when the lamp is switched off, and the difference of power between the two solenoids is used for balancing this gravity effect. A common relation between these forces is main coil 3 balancing the shunt coil 2 and gravity 1, but when the length of arc is adjusted by moving the points of the carbons in a line at right angles to the direction of feed, as in converging-type flame lamps, the proportion of gravity effect may be reduced and the coils made equal in strength or nearly so.

The characteristic of a lamp with shunt and series coils equal in strength is such that current and voltage across the arc rise and fall together and equally as the line resistance or the line pressure is varied.

When the forces are respectively 3, 2, and 1 as explained above, then a 2 per cent increase of current will cause approximately a 3 per cent increase of the voltage across the arc.

In another type of differential control the shunt coil is placed below the series coil, the one iron core serving for the two coils. This arrangement works at its best when the two coils magnetise the core in the same direction. With coils magnetising in opposite directions one coil will repel the core when it is mainly in the other coil.

A third type of differential control consists in putting the shunt and series windings on the same bobbin, winding one over the other and connecting them in opposition. Regulation is obtained by the shunt weakening the pull of the series, but it must not be possible for the shunt to become the stronger, else it will separate the carbons when its proper function is to allow them to be brought together. This arrangement will work well enough for say 2 lamps in series, where the full circuit voltage on one of the shunt coils would not be strong enough to lift the iron core, but even then the shunt has to be made relatively weak and that gives poor balancing of the two arcs.

(iv.) *Magnetic Control.*—Magnetic deflection of the arc has been tried as a means of maintaining the current at the desired value, but because it disturbs the natural alignment of the arc it tends to cause unsteady burning. However, the current in the converging carbon flame arc is momentarily controlled by the blow-magnet to some extent, but that is because the blow-magnet is instantaneous in its action. At the most it only smooths out the ripples which the floating regulation cannot deal with because it is too sluggish.

§ (11) Types of Control Mechanism.—There is an endless variety of mechanisms for operating arc lamps, but the differences are mostly in detail. They can be classified by the type of feeding gear used, and generally success depends on the efficiency of the feeding gear. A differentially controlled floating regulation can fully control the arc whilst it retains a hold on the carbons. As the carbon burns away the mechanism returns to the point where it first gripped the carbon, or some part attached to it, and there, at what is called the feeding-point, it must be possible for the carbon to slip through the grips. In open-type lamps, on account of the short arc and the rapid consumption of the carbons, the feed must be so gradual that it does not cause a blink in the light.

A train of wheels with a retarding fan or an escapement controlled by a detent gives

excellent results, but needs more care than a clutch or a brake.

(i.) *Clutches and Brakes.*—These are generally applied in such manner that the grip increases as the resistance to movement increases. This is a precaution against slipping when the lamp is pumping.

With only 16 to 20 per cent of line resistance and the self-induction of the series coils to limit it, the instantaneous current may be four times the normal and at a time when there is no voltage on the shunt coil. Dash-pot action cannot be increased because it would retard recovery after a feed, hence the clutch or brake must be very positive in its action.

Clutches are very simple, the simplest of all being the washer clutch, which is a plain washer having a hole very slightly larger than the rod it grips. When lifted at a point near the rim it tilts and grips the rod. The heavier the rod the harder it is gripped. On returning to the feeding-point the lower end meets a stop which reduces the angle of tilt and allows the rod to slip. The strength of the grip depends on the ratio between the horizontal distance from rod to lifting-point and the vertical distance between the two gripping-points. Therefore when the hole wears, or if a smaller rod is used, the tilt is increased and the grip weakens.

The above-mentioned ratio must not be less than 4 to 1, and this is true of most clutches and brake gear.

Improvements on the washer clutch consist in extending the leverage of the lifting-point and in applying a spring both to assist in gripping and to bring the clutch back to the gripping angle quickly when the lamp is pumping. With a suitable spring the clutch may even gain on the rod, *i.e.* the rod is jerked upwards by the rush of current and when the mechanism is checked by the dash-pot the rod travels through the clutch, but is caught directly it begins to fall.

Developments of the washer clutch consist in a long sleeve through which the rod slides and a horizontal lifting lever pivoted to the sleeve. A short extension of this lever just above the pivot engages with the rod and grips it. The leverage can be kept constant independent of wear.

Some brake wheels are operated by what is virtually a clutch acting on the inner and outer surfaces of the rim of the wheel or between a central boss and one of these surfaces.

Flexible band brakes are used in two ways. The two ends may be attached to a lever at points which compare with the two gripping-points of the washer clutch, in which case the grip is proportional to the resistance it meets, or one end may be connected directly to the operating gear and the free end of the band attached to a spring, which pays out on the "strike" and takes up the slack on the return movement until the feeding-point is reached, when the band is loosened to let the wheel slip.

(ii.) *Feed Control.*—Fineness of feed depends on the nature of the gripping surfaces and on the rods or brake rims being parallel and true. Rubber grips give a creeping feed but lose their resilience, also they wear and alter the feeding-point. Metal chains used as band brakes give the best metal to metal feed. Metal clutches on parallel rods do not give a creeping feed, but will do so if the rod is made taper. Most excellent results are obtained with a rod having not more than $\frac{1}{8}$ per cent taper. Feed rods with a number of $\frac{1}{8}$ per cent slopes and steps cause a severe blink once every five hours, but during those intervals the feed is so good that the rod has to be marked to show its movement. Such slopes necessitate not more than a 15 per cent increase in the range of the striking gear, *i.e.* the feeding-point varies 15 per cent of the total movement of the clutch.

Rotary motors are used to control the feed in some lamps. The motor may be wound differentially and so control all movements of the carbon, but they are usually too slow when shortening the arc, and let it go out when a quicker movement would keep it going. In a modern searchlight burning flame carbons, a shunt-wound motor is used for feeding only. The field cores work at high density so that speed varies with the voltage, and this automatically keeps the arc volts constant.

Reciprocating motors (an elaboration of the vibrating armature already mentioned) are used for magazine flame lamps for feeding the converging carbons. Arc adjustment is done by swinging one of the carbons laterally. The motor is stopped and started by variation of voltage (in which case the fall of the core does the work) or by an arrangement similar to the "feeding-point" control of a clutch. In the latter arrangement, when the carbons have been swung towards each other to the desired limit, a shunt make-and-break gear is released and continues acting until the feed allows the carbons to be swung apart again. The make-and-break gear controls a shunt-wound solenoid whose core operates the feeding gear. The carbons are of small diameter, but are gripped near their lower ends and current is led through the grips. Therefore it has only a short distance to go along the carbons, and it is not necessary to copper them or use metal cores.

The magazines hold up to twelve pairs of carbons, each 15 inches long, giving 120 to 150 hours' burning and the option of retrimming at any time without waste. The small diameter carbons give the steadiest flame arc

obtainable and average seven candles per watt over the ordinary lighting angles.

The carbons are either forced down by two dredger chains with "buckets" engaging the top ends of the carbon or by two fingers which are carried up and down by a cross bar. The cross bar is racked up and down by a reciprocating rack rod engaging reversible pawls, a second (fixed) rack being used to support the bar during the idle part of the stroke.

Each pair of carbons pushes down the burning stumps of the previous pair and finally ejects them. There is an interval of darkness not exceeding two seconds in the latest type of lamp. This is attained by gripping the carbons at a point not more than ¼ in. above their highest apex and allowing a long swing inwards from the feeding-point, so that the new carbons first touch high up in the bell and the arc is struck whilst they are feeding down to the normal burning position.

In another type two sets of magazines are used and carbons fed alternately from each set, the arc changing over from one to the other without an interval of darkness.

In all converging carbon flame lamps, and particularly in magazine lamps, there is a chance that some of the deposit on the economiser will become dislodged and get wedged between the carbons and insulate them. In the rack-fed lamp mentioned above, this trouble is overcome by oscillating one of the magazines, at right angles to the line of the arc, each time the carbon feeds. This rubs the carbon points together and dislodges anything that gets between them.

A very simple type of feed control which has been used for converging carbon flame lamps works on the same principle as the candle feed in a carriage lamp. The burning end of the negative carbon rests on a metal abutment, and as it burns away the part resting on the abutment crumples up and so lowers the carbon. The positive carbon may be supported from the negative so that the two are lowered together. The abutment cannot be used on the positive carbon or for alternating current because of danger of the arc transferring to it.

Unsatisfactory features are the distortion of the end of the negative and the excessive condensation of flame material on it, both of which cause the arc to wander.

§ (12) PROTECTIVE DEVICES.—Lamps working more than two in series require their shunt coils protected against the chance of the full voltage of the circuit being maintained on one lamp. This will happen if one lamp has no carbons or if they are held apart by some mechanical fault. The carbons in the other lamps are brought together and allow the full voltage to get through to the faulty lamp. The usual protection is an automatic switch which connects a resistance across the carbons of the faulty lamp. The switch may be operated by the differential floating regulator gear, being closed when the mechanism falls well below the feeding-point. Alternatively an extra shunt magnet has been used to close the switch when the arc voltage rises say 50 per cent above normal, but this has the disadvantage that the auto switch is open at the instant of switching on the series of lamps, so that full voltage may get across a faulty lamp for the short time taken to close the automatic switch. All insulation is better protected by a switch controlled by shunt and series solenoids differentially arranged, the series being the stronger so that the auto switch is closed by gravity when the main switch is opened. When the current is again switched on the equivalent resistance is already in circuit, and remains in circuit until sufficient current passes through the carbons and the series solenoid to open the auto switch.

A. E. A.

ARMATURE: that part of a dynamo machine in which the E.M.F. of the machine arising from electromagnetic induction is generated. In D.C. machines it is usually the rotating part, in alternators it is generally stationary. See "Dynamo Electric Machinery," §§ (4), (9).

ARMATURE REACTION: the effect on the magnetic field of a dynamo machine due to the current carried by the armature. See "Dynamo Electric Machinery," § (5).

ARMATURES, MAGNETO:
- Cores of. See "Magneto, The High-tension," § (11) (ii.).
- Windings of. See "Magneto, The High-tension," § (11) (iii.).

ARNÒ'S ELECTROMETER METHOD: a null method of capacity measurement. See "Capacity and its Measurement," § (39).

ARTICULATION, TELEPHONIC, TESTS OF: tests of the capability of a telephone system for transmitting fundamental speech sounds. See "Telephony," § (11).

ASTATIC COILS: coils so wound that their currents produce no external magnetic field, and that a uniform alternating magnetic field induces no voltage in them.
- Use of, for inductance standards. See "Inductance, The Measurement of," § (58).

ATMOSPHERE, CONDUCTING LAYERS IN, SITUATION OF. See "Magnetism, Theories of Terrestrial and Solar," § (24).

ATMOSPHERICS: irregular disturbances picked up by the receiving apparatus in wireless telegraphy. See "Wireless Telegraphy Transmitting and Receiving Apparatus," § (10).

BATTERIES, PRIMARY

§ (1) HISTORICAL INTRODUCTION.—The primary cell in its simplest form arose from a chance observation of Galvani, who noticed that recently skinned frogs' legs, hung by a copper wire to an iron balcony, were convulsed whenever they touched the iron. It was found that these movements could be reproduced by connecting the nerves and muscles by a piece of metal, and Galvani therefore supposed that a separation of positive and negative electricity occurred at the junction of nerves and muscles.[1] This idea was disproved by Volta, who showed that movements could equally well be produced by connecting two parts of the same muscle by an arc of two metals instead of one—for example, by iron and copper—the important point being that a junction of dissimilar metals should form part of the circuit. This condition was, of course, fulfilled in Galvani's original observation. Thus Volta introduced his contact theory, according to which an electric force arises on placing two dissimilar metals in contact; and in support of this theory he constructed in 1799, and described in 1800, the form of dry battery known as Volta's pile, consisting of discs of zinc, wet cloth, and copper piled upon one another in that order, so that a disc of cloth was always encountered in passing, say, upwards from zinc to copper, but not in passing from copper to zinc. By this means a large number of cells were obtained in series, with a high total E.M.F., but having the disadvantage of high internal resistance.

Thus the terms "galvanic electricity" and "voltaic electricity" arose and denoted what may be called low potential electricity as opposed to the high potential, frictional, or electrostatic electricity which had so far been available.

It was a comparatively short step to replace the wet cloth of Volta's pile by free electrolyte. This was done by Volta[2] in his "crown of cups," which consisted of a series of cups containing salt water in which stood zinc

[1] Volta, *Roy. Soc. Phil. Trans.*, 1793, Part i. 10.
[2] *Roy. Soc. Phil. Trans.*, 1800, Part ii. 403.

and copper plates, the zinc of each cell being connected to the copper of the next, so as to form a number of simple cells in series.

In 1801 Davy tried acid electrolytes, but they do not appear to have come readily into favour. Progress then became slow. An important advance was made in 1830, for Kemp, followed by Sturgeon, then introduced amalgamation of the zinc when used in acid solutions.

Polarisation also received serious consideration. Probably Becquerel was the first to have a true understanding of this subject, for in 1829 [1] he described cells of the Daniell type, but they were not of a very practical nature. It was in 1836 that Daniell [2] described his well-known cell, and three years later Grove [3] described the cell with which his name is still associated.

with the tops projecting. The plates are then found to be at different potentials, so that the cell thus formed has an E.M.F.

The value of the E.M.F. depends largely on the materials or metals used for the plates. When two metals, such as zinc and copper, are placed in contact it is found by electrostatic tests that the zinc is at a higher potential than the copper, and zinc is therefore said to be electro-positive to copper. By this and other means all the chemical elements can be arranged in a series, known as the electro-chemical series, such that each element is electro-positive to all those that follow it and electro-negative to those above it. The following series (reading down each column in succession) is given by G. Gore, but it should be noted that the exact order may vary slightly according to the conditions.

Electro-chemical Series

Electro-positive

Caesium	Magnesium	Nickel	Hydrogen	Rhodium	Selenium
Rubidium	Aluminium	Thallium	Mercury	Platinum	Phosphorus
Potassium	Chromium	Indium	Silver	Osmium	Sulphur
Sodium	Manganese	Lead	Antimony	Silicon	Iodine
Lithium	Zinc	Cadmium	Tellurium	Carbon	Bromine
Barium	Gallium	Tin	Palladium	Boron	Chlorine
Strontium	Iron	Bismuth	Gold	Nitrogen	Oxygen
Calcium	Cobalt	Copper	Iridium	Arsenic	Fluorine

Electro-negative

The Smee cell appeared in 1840. In the same year J. T. Cooper modified the Grove cell by substituting carbon plates for the platinum, but this cell is usually known by the name of Bunsen, to whom we owe the popular bichromate cell.

No further progress appears to have been made until 1868, when the Leclanché cell appeared. This cell is remarkable, not only on account of the extent to which it has been applied, but also on account of the dry cell, which is now used to the extent of many millions per annum, and which is simply a modified form of Leclanché cell so far as fundamental principles are concerned.

I. The Simple Voltaic Element and its Defects

An appreciation of the physics underlying primary cells is most easily gained by first considering the simplest form of cell and the defects from which it suffers.

§ (2) Fundamental Principles. — A primary cell may be defined as a device for the direct transformation of chemical energy into electrical energy. In its simplest form it is obtained by standing two plates of dissimilar conducting material in an electrolyte,

[1] *Ann. de Chim. et de Phys.*, 1829, xli. 5.
[2] *Roy. Soc. Phil. Trans.*, 1836, Part i. 109.
[3] *Phil. Mag.*, 1839, 3rd Series, xv. 287.

It has been found that if a high E.M.F. is desired, the elements used for the plates should be as far apart on the electro-chemical series as possible. Thus zinc may be used on the one hand and copper on the other, but it is better to use platinum or carbon rather than copper, because these conductors are further away on the series. Some metals are not very suitable owing to special reasons. For example, iron is seldom employed, because oxides of iron are liable to be thrown down and are troublesome.

The terminals on the plates for connection to the external circuit are called the poles. The current is found to flow in the external circuit from the electro-negative plate. Consequently the terminal on the electro-negative plate (*e.g.* carbon) is the positive pole and the terminal on the electro-positive plate (*e.g.* zinc) is the negative pole.

It is the electro-positive plate that tends to pass into solution in the electrolyte, and that usually supplies most of the energy by combination with the negative ion of the electrolyte.

A reasonably high E.M.F. is naturally regarded as one of the essentials of a commercial primary cell. A second essential is that chemical action in the cell should only take place (at least to a serious extent) when the external circuit is closed. Unfortunately this condition rules out some of the most

electro-positive elements when an aqueous solution is used as an electrolyte. For example, potassium and sodium cannot be used, as they decompose water vigorously.

The E.M.F. also depends on the electrolyte. Solutions of salts may be used, but dilute acids have a lower resistivity and generally give higher E.M.F.

A cell consisting of two plates standing in an electrolyte is often termed a "simple voltaic element." Such a cell is shown dia-

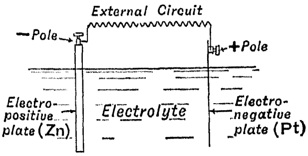

FIG. 1.

grammatically in *Fig.* 1, the plates being platinum and zinc.

§ (3) ACTION OF A SIMPLE CELL.—We may now consider what takes place in this simple cell when it supplies a current. Suppose that the electrolyte is dilute sulphuric acid, and that the plates are platinum and zinc; then the current in the external circuit flows from the platinum to the zinc, but in the electrolyte it passes from the zinc to the platinum, as indicated in *Fig.* 2. When a current flows through an electrolyte by means of electrodes, electrolysis necessarily takes place, and thus the electro-chemical changes which ensue in a cell when it supplies a current are subject to the laws of electrolysis. It follows, therefore, that the positive ion (in the present instance hydrogen) will be deposited on the platinum (the electro-negative plate) since the current flows from the zinc to the platinum.

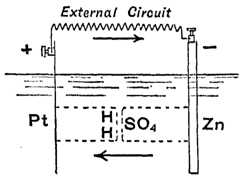

FIG. 2.

The negative ion, or acid radicle (SO_4), will be deposited on the zinc plate and will be exactly equivalent in amount to the hydrogen. Moreover, it will proceed to combine with the zinc, forming zinc sulphate. It may be said, as a general statement, that the electro-positive element of a cell is the one that is attacked, and hydrogen or an equivalent metal ion is deposited on the electro-negative element.

The electro-positive element is commonly called the negative plate (corresponding to its negative pole) and the electro-negative element is frequently called the positive plate; and we shall now adopt this nomenclature, though these terms are not strictly correct.

The above action is represented in *Fig.* 2. It is not intended to give the impression that the SO_4 deposited on the zinc and the hydrogen deposited on the platinum belong to the same molecule of acid; they certainly do not, but it is convenient to represent the main reaction in the simplest manner.

§ (4) POLARISATION.—Now, although the SO_4 combines with the zinc, the hydrogen has no such effect on the platinum. If the hydrogen were freely given off there would be little objection thereto, but unfortunately it remains on the surface of the platinum to a considerable extent. This has the effect of changing the character of the platinum plate, so that it is more in the nature of a hydrogen plate, and since hydrogen is much more electro-positive than platinum the E.M.F. becomes correspondingly reduced. This change is known by the name of polarisation. It gradually passes off when the current is interrupted, because the hydrogen diffuses into the electrolyte. *Polarisation* may be defined as a temporary reduction in E.M.F., due to an alteration of the plates or of the electrolyte brought about by the action of the cell. Polarisation may also occur at the zinc plate, but as it is chiefly noticeable at the electro-negative plate, the term generally has reference to that plate.

Polarisation is one of the difficulties encountered in all primary cells. It is particularly noticeable in the simple cell above described, because in such a cell no means are adopted for its elimination, and it is for this reason that the simple cell is generally of no value in practical work. The only simple cells that have proved commercially useful are the cell due to Smee and a recent cell due to Féry (described later). The former consists of zinc and platinum standing in dilute sulphuric acid, just like the cell we have been considering, but there is this fundamental difference, that the platinum plate, instead of having an ordinary bright surface, is platinised—that is, it has received an electrolytic deposit of platinum upon it. The effect of this is that the surface, instead of being smooth, is very finely roughened, and consequently the hydrogen is much more easily evolved. It appears that any finely roughened surface is effective in this way. For example, specially prepared carbon has been so used and has proved effective. The great advantage of the Smee cell is its simplicity, but it has the considerable disadvantage of a low E.M.F., under 0·5 volt.

§ (5) OVERVOLTAGE.—The extent of the polarisation for different electro-negative plates depends upon what is termed "overvoltage."[1] Theoretically, the evolution of hydrogen in electrolysis should take place when the applied electric pressure exceeds a certain value. The

[1] See "Electrolysis, Technical Applications of."

minimum value, with suitable electrodes, is about 1·1 volts, and if the pressure required is found to be higher with a given pair of electrodes the excess pressure beyond 1·1 volts is termed the overvoltage for the combination. It is found that platinised platinum as a cathode has the lowest overvoltage among the elements commonly available. On the other hand, some metals, such as mercury, have a very high overvoltage. Thus the extent to which polarisation may interfere with the action of a simple cell depends considerably upon the electro-negative element that is used.

II. Local Action and Amalgamation

§ (6) Local Action.—When impure zinc is placed in dilute acids it dissolves rapidly. If the zinc is pure the action is slow, but pure zinc is too costly for use in batteries. Consequently the ordinary commercial zinc is used, and if the electrolyte is an acid the solution takes place irrespective of whether the cell is supplying a current unless some preventive means are adopted. This solvent action, which thus serves no useful purpose, is known as *local action*, and is due to the impurities forming local voltaic circuits.

This will be understood on reference to *Fig.* 3. Here Z represents a rod of zinc in dilute sulphuric acid. Suppose N to be a metallic impurity, such as lead. Since lead is electro-negative to zinc we have a small short-circuited cell consisting of the particle of lead in contact with the zinc, both being in contact with the acid. Consequently local currents will flow from the zinc through the acid to the lead, and hydrogen will be evolved at N. The same thing will happen at every point where there is an electro-negative impurity on the surface, and consequently the zinc dissolves rapidly.

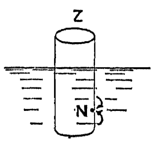

Fig. 3.

Local action is most evident in acid electrolytes, but it also takes place in others, though generally so slowly as to be comparatively unimportant.

§ (7) Amalgamation.—The remedy that is always adopted is the amalgamation of the zinc. This is readily effected by bringing the zinc plate into contact with mercury in dilute acid and rubbing the plate so as to spread the film until a perfectly bright surface is obtained throughout. The zinc is then found to be free from attack by local action even in an acid electrolyte, but the protective effect wears off in time.

This protective action has not been satisfactorily explained. On theoretical principles it might be expected that such treatment would be ineffective, because mercury is markedly electro-negative to zinc, and thus it would be thought that the zinc in contact with mercury would be readily dissolved through local action. The mercury may possibly act as a filter so far as the ordinary impurities are concerned, only permitting the zinc to pass through, and thus the mercury would remain effective until it became too thin, but this does not explain the lack of local action by the mercury itself.

Overvoltage might be supposed to afford an explanation because the overvoltage of mercury is high. Thus hydrogen would not be evolved readily from a mercury surface. But against this explanation is the fact that the overvoltage of lead is almost equally high and lead is one of the most common impurities of commercial zinc. As hydrogen is evolved readily from the lead impurities it should not experience much greater difficulty in the case of mercury.

It is found that mercury assumes the electro-positive position of zinc by addition of the latter with remarkable readiness. Hockin and Taylor [1] found that even one-millionth part of zinc was sufficient to cause this change.

III. Depolarisation and Internal Resistance

In what follows we shall deal only with polarisation at the positive plate, as it is there much more important, and the term usually refers to that plate. What is required is the more or less complete removal of the polarising ion, which in practice is hydrogen.

§ (8) Depolarisation by Substitution.—The most effective method of depolarisation is to substitute a harmless ion in place of the harmful hydrogen ion. This is the method adopted in the Daniell cell. In this cell the zinc and sulphuric acid are contained in a porous pot; the latter stands in an outer jar containing a copper plate in a solution of copper sulphate. The effect of this arrangement will be appreciated on reference to *Fig.* 4. The left-hand part of the diagram shows

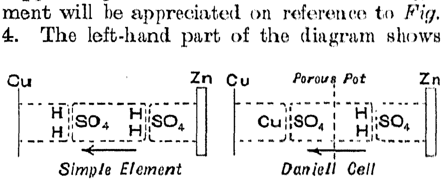

Fig. 4.

the action of a simple element consisting of zinc and copper standing in dilute sulphuric acid. When the circuit is closed the current flows through the electrolyte in the direction of the arrow, the SO_4 ion attacks the zinc, and the hydrogen ions are deposited on the copper, where they form gaseous hydrogen molecules. On the right-hand side of the diagram the

[1] *Soc. Tel. Eng. J.*, 1879, viii. 282.

corresponding action of the Daniell cell is indicated. Here the current in the sulphuric acid is carried by the SO_4 and H ions as before, but when the current passes to the copper sulphate it is then carried by the SO_4 and Cu ions, and it is copper that is deposited upon the electro-negative plate. In other words, copper has been substituted for hydrogen, and there is no polarisation, because copper is deposited upon copper. This is the most effective means of depolarisation that can be adopted, but it is not generally available, because it necessitates using an electrolyte containing, as the positive ion, the metal of which the electro-negative plate is formed.

§ (9) Depolarisation by Oxidation.—Much the most usual method is to remove the hydrogen by oxidation. For this purpose various oxidising agents have been used, and they may be classified broadly as (1) solid, (2) liquid, and (3) gaseous.

In regard to solid depolarisers, it may be said that the choice is somewhat circumscribed, partly because solid oxides do not always give up their oxygen with sufficient rapidity, and partly because of their low conductivity. For example, manganese peroxide is used extensively in Leclanché and dry cells, but its action is slow, and since it is practically non-conducting it must be mixed with a considerable proportion of carbon or graphite to obtain the necessary conductivity. Thus the liberated hydrogen is not necessarily in contact with the oxidising agent, and the net result is that a depolariser made up with manganese peroxide is not very effective, though for many purposes it is sufficient for the intermittent use to which such cells are usually applied.

Cupric oxide is an oxidising agent which is sometimes employed. This is more effective than manganese peroxide, because it is sufficiently conducting to be formed into plates without the admixture of some conductor; moreover, it gives up its oxygen readily. Thus it is found to be quite an effective depolariser, but unfortunately, owing to other properties, its use is very restricted.

Solid depolarisers also have the disadvantage that the reducing action is confined to the outer layers. In that way they may be inefficient, because only a small proportion of the depolariser is used up by the time the cell becomes exhausted for practical work unless the material is finely divided.

Liquid depolarisers have the general advantage that, as a rule, a gas acts more readily upon liquids than upon solids at ordinary temperatures. On the other hand, the whole of a liquid suffers through any change, on account of the diffusion of those parts which have been reduced, and therefore all the liquid gradually loses its effectiveness; whereas in the case of a solid the parts not immediately exposed form a sort of reserve which are attacked later. Thus, when a liquid depolariser has been diluted beyond a certain point by the products formed as the result of reduction, the depolarisation becomes continuously less effective, and this deterioration is generally more marked than in the case of solid depolarisers. It must be understood, however, that depolarisers, both solid and liquid, vary considerably in their effectiveness, and, therefore, no very general statement can be laid down.

Sometimes the liquid depolariser is simply mixed with the acid, as in the bichromate cell. In other cases it is necessary to separate the depolariser from the acid by means of a porous pot. This is so in the Grove cell, which consists of a sheet of platinum standing in nitric acid, which is separated by a porous pot from the dilute sulphuric acid surrounding the zinc. The effect of the nitric acid acting as a depolariser may be represented by *Fig.* 5. The hydrogen ions are deposited upon the platinum from the nitric acid, and there form hydrogen gas, which reacts chemically with the nitric acid, or more probably it acts in the nascent state. The nitric acid deteriorates in this process through dilution by the water and nitrogen oxides so formed. A porous pot is necessary, because the nitric acid must be concentrated to be effective, and if this concentrated acid were allowed to come in contact with the zinc, local action would take place, even if the zinc were amalgamated.

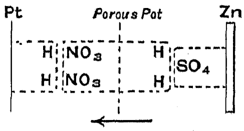

Fig. 5.

Gaseous depolarisers need not be seriously considered. Atmospheric oxygen has the advantage of being inexhaustible, and can be used free of cost, but it necessitates the exposure of the positive plate to the atmosphere, and this usually cannot be accomplished at all easily. The only cells in which this method seems to have been applied usefully to a limited extent are the "R. and R." dry cell, by Rylander and Rudolphs of Sweden, and Féry's cell. Jungner has also worked in this direction.

Depolarisation by physical means has also been attempted. The finely roughened surface of the platinum plate in a Smee cell may be looked upon as a physical method. Again, attempts have been made to give a certain motion to the positive plates of a cell, so that continually varying portions are exposed to the air, any deposited hydrogen being thus removed by the oxygen on the surface of the plate, but such a method is too complicated to be of commercial value.

§ (10) Internal Resistance.—When a cell supplies current to an external circuit the P.D. is lower than the E.M.F. on account of the internal resistance of the cell. Representing the resistance of the external circuit by R, and the internal resistance by r, the current I is given by $I=E/(R+r)$, in which E is the E.M.F. of the cell. Equally, if the P.D. is represented by V, then $V=E-Ir$.

Assuming there is no polarisation, and that the internal resistance is constant, then the value of the current would be determined for a given E.M.F. simply by the external resistance. According to experiments by Carhart,[1] however, the internal resistance decreases as the current supplied by the cell increases. But there is some doubt whether this apparent variation may not be due to polarisation. This latter view has been supported by K. E. Guthe.[2]

Generally speaking, polarisation is not absent, and therefore, at the moment when the external circuit is broken, the E.M.F. does not return at once to the value which it had before the circuit was closed. In time the original value is regained, but the recovery is more or less gradual according to the effectiveness of the depolarisation. For this reason it is difficult to determine accurately the value of the internal resistance by voltmeter readings on opening the external circuit. A somewhat more reliable result is obtained at the moment of closing the circuit.

IV. Theories of the Voltaic Cell

In the space available for the present article it is only possible to glance very briefly at the theories which have arisen in connection with the voltaic cell.

§ (11) The Chemical and Contact Theories.—The contact force, or E.M.F. of contact, when two dissimilar metals are brought together is considerable. For example, in the case of zinc/copper it has been found to be about 0·75-0·85 volt. In the absence of the law of conservation of energy, it was therefore not surprising that Volta should attribute the E.M.F. of a voltaic cell to the contact force of the two elements forming the plates. Volta's method of observation consisted in forming a condenser of two plates of the particular metals, which were then metallically connected for an instant. On separating the plates the leaves of a gold-leaf electroscope connected to one of them diverged, giving a measure of the charge and, consequently, of the force giving rise thereto. As the result of this work Volta enunciated what is known as Volta's law, namely, that if a conductor is made up of a number of metals so that there are several junctions, the contact forces are additive. For example, if the conductor consists of copper at one end and zinc at the other, with a number of metals, M_1, M_2, M_3, between them, as in *Fig.* 6, the contact force between the ends is given by $Cu/M_1+M_1/M_2+M_2/M_3+M_3/Zn$, where M_1/M_2 is the contact force between M_1 and M_2, etc. Also, since there is no E.M.F. in a closed circuit of this kind so long as all parts are at the same temperature and varying magnetic fields are absent, it follows that the contact force of such a series is simply equal to the contact force of the two end metals, for, if the total E.M.F. is zero, we have $Cu/M_1+M_1/M_2+M_2/M_3+M_3/Zn+Zn/Cu=0$. But $Cu/Zn=-Zn/Cu$, which demonstrates the statement.

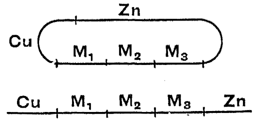

Fig. 6.

Other physicists soon discovered that chemical action invariably occurs when a cell generates a current, and thus a very prolonged controversy sprang up between the followers of Volta and those who held that the E.M.F. was purely chemical.

§ (12) Difficulties in investigating Contact Force.—There is considerable difficulty, however, in the quantitative investigation of contact force and in determining its cause with any certainty. For example, Sir Oliver Lodge[3] has expressed the view that when two metals are in contact they are at the same potential, but differently charged, forming practically an air battery, the charges resulting from oxidation. Thus each metal may be regarded as possessing a certain E.M.F. proportional to the heat evolved on oxidation, and the contact force would thus be equal to the differences of these two E.M.F.'s. In this way the contact force of zinc/copper would be about one volt. Experimentally, the contact force in this case has been found to be 0·71 volt by Pellat, 0·75 volt by Ayrton, and 0·85 volt by Clifton. This is sufficient to show that the results by different observers vary considerably and that they are only roughly of the same order as the figure derived from oxidation.

A brief examination of the work in this subject is sufficient to afford ample explanation of the variable results so often obtained. All such measurements really depend upon the charge of a very small condenser. Consequently the quantity of electricity involved in the measurement is extremely small, and the quantity of oxygen or other gas so involved is infinitesimal. It is not easy, therefore, to say whether the contact force is being measured between two metals or between their oxides,

[1] *Phys. Rev.*, 1894–95, ii. 392.
[2] *Phys. Rev.*, 1898, vii. 193.
[3] *Brit. Assoc. Report.*, 1884, p. 464.

for a film of oxide is not necessarily detected easily or removed with ease when detected.

Bottomley[1] found that the contact force of zinc/copper remained unchanged when the air pressure was reduced to 2½ millionths of an atmosphere, and also when the air was replaced by hydrogen, but such an experiment does not necessarily prove that contact force is independent of the oxygen in the air. An experiment of greater interest is that by Brown,[2] who found that when air was replaced by hydrogen sulphide the contact force of iron/copper was reversed. In this case we are dealing with a gas which forms sulphide films with great ease, and, therefore, some marked change would be expected, but it would not be reasonable to suggest that the contact force so measured was that of iron/copper in hydrogen sulphide gas. De Broglie[3] has found that the greater part of the contact force vanishes on drying the atmosphere. This would point to voltaic action.

Not only is contact force varied by chemical action, but it may vary also with the physical state of the metals, such as polishing. Experiments of this kind have been carried out by J. R. Erskine-Murray[4] and by N. Hesehus.[5] In considering such experiments, however, it must be borne in mind that chemical action of the air or other gas on such surfaces is not easily excluded, and that gas films, in one form or another, are often very difficult to remove.

Q. Maiorana[6] has found that contact force is greatly reduced by low temperatures, obtained by dropping liquid air on the junction. This again may possibly be regarded as supporting the idea that the force is due to the voltaic action of moisture.

This brief account is sufficient to indicate the extreme difficulty in devising satisfactory experimental methods in this subject so that a definite theory may be formulated. So far as the voltaic cell is concerned, contact force is not now regarded as the most important constituent of the E.M.F., because, as will be seen later, the transformations of energy take place at other points.

§ (13) Seat of the E.M.F.—There has been almost as keen a controversy over the precise location of the E.M.F. in a voltaic cell as there was over the rival theories of contact force and chemical action. At first sight it would not be unnatural to suggest as the seat of the E.M.F. either the metallic junction (of, say, zinc to copper) or the area of contact of the zinc with the electrolyte, according to the point of view. There is at once a difficulty, however, in accepting the first alternative, because, as already stated, the contact force is distinctly smaller than the E.M.F. of the cell. There are also the contact forces of the metal/liquid junctions, but these are much smaller, and Ayrton and Perry[7] showed that the E.M.F. is equal to the sum of all the contact forces in the cell.

In considering this part of the subject it becomes necessary to define exactly what is meant by a seat of E.M.F., as otherwise a discussion may mean very little. If the term is restricted to any point in a circuit where energy is transformed, then we have a definition which appears reasonable, provided that such points can be found. In many electrical circuits no such point or points could be suggested, as, for example, in the electromagnetic production of E.M.F. Accepting this definition, however, it is found that when a current flows across a copper/zinc junction heat is absorbed or evolved according to the direction of the current, thus indicating the presence of an E.M.F., but this is quite small, corresponding with the well-known Peltier effect.

The view is sometimes taken that the E.M.F. is due to the sum of the contact forces at the junctions, and that the current is maintained by chemical action.

If, on the other hand, it is considered that the E.M.F. arises where the chemical action takes place, then there is no legitimate reason to restrict attention to the zinc/electrolyte contact alone. Voltaic action differs from ordinary chemical action in that it takes place in equivalent amounts at both the plates of the cell and not merely at a single surface. Consequently both the zinc/electrolyte and copper/electrolyte contacts (in the case of a zinc and copper cell) should be considered.

§ (14) Thermo-chemical Considerations.—Considerable light is thrown upon the production of E.M.F. by considering the thermochemical changes which take place. But before we pass to this subject it may be well to state generally the essential conditions which must be fulfilled by the constituents of a voltaic cell. They may be stated to be as follows:

(i.) At least three elements are necessary.

(ii.) One of these must be a conductor of the first class (*i.e.* not decomposed by the passage of a current), one must be of the second class (*i.e.* an electrolyte), and the third may be of either class.

(iii.) Two of these constituents must be capable of chemical interaction. It must be borne in mind, however, that this interaction need (and indeed should) only take place when the circuit is closed. Ordinary chemical action is quite a different matter.

(iv.) Finally, it follows from the above that the liberation of an ion is necessary; or, in other words, separation of the electro-positive from the electro-negative ion must take place.

All commercial cells consist of two different conductors of the first class together with one or more electrolytes.

Now, although the chemical reaction taking place in any cell is split up so that half of it occurs at one plate and half at the other, yet from the energy point of view the chemical action may be considered as a whole. It is a common observation that when chemical changes take place heat is either absorbed (endothermic reactions) or evolved (exothermic reactions). Voltaic cells depend generally upon exothermic reactions.

Assuming that the reaction only takes place when the circuit is closed, then the whole of the heat due to the chemical reaction, and which would otherwise be liberated, should appear as electrical energy. For example, if zinc sulphate is the compound formed by the action of a cell, then in the production of, say, one gramme of zinc sulphate the cell should generate a quantity of electrical energy equivalent to the heat evolved in the formation of one gramme of zinc sulphate. Since the electrical energy is given by the product of the quantity of electricity into the E.M.F. under which it flows, it follows that for a given quantity of electricity the E.M.F. will vary according to the heat that is evolved.

It remains to choose a suitable unit of weight of the compound under consideration, and here the laws of electrolysis come to our assistance. We know that if a quantity of electricity q liberates one gramme of hydrogen in the electrolysis of a solution of, say, HCl, it will decompose one gramme molecule of HCl. Equally this quantity q will decompose a gramme molecule of any other salt of which the molecule contains only a single atom of a monovalent metal, such as NaCl. If the metal is divalent, or if the molecule contains two atoms of a monovalent metal, such as $ZnCl_2$ or Na_2SO_4, the gramme molecule requires $2q$ of electricity for its decomposition; and so on for higher valencies. Consequently, if we take q, the quantity of electricity which liberates one gramme of hydrogen, as our unit of electricity, then the gramme molecule of the compound will be a convenient unit of weight.

Assuming that all the heat of the reaction is converted into electrical energy and that the E.M.F. depends only upon this heat, then we may equate the electrical energy to the heat H_c in the chemical reaction, expressed as work, or $qE = H_c$, or, if the heat is expressed in calories, $qE = JH$, in which E is the E.M.F., H is the heat of formation in calories of a gramme molecule of the compound that is formed in the case of a monovalent metal (since q is the quantity of electricity necessary for the liberation of *one* gramme of hydrogen), and J is the mechanical equivalent of heat. Since q is 9654 C.G.S. units (96,540 coulombs) and J is 42×10^6 ergs, we have

$$E = \frac{42 \times 10^6}{9654} H \text{ in C.G.S. units,}$$

or

$$E = \frac{4 \cdot 2}{96{,}540} H \text{ volts}$$

$$= \frac{H}{23{,}000} \text{ volts (monovalent metal).} \quad (1)$$

Usually the metal is divalent, and in that case q becomes $2q$, the final result being

$$E = \frac{H}{46{,}000} \text{ volts (divalent metal).} \quad (2)$$

This equation is due to Kelvin.

Helmholtz saw the possibility of the E.M.F. being dependent on thermal E.M.F.'s in the cell in addition to the heat of reaction, and that consequently the simple equation of Kelvin might be incorrect. This proved to be the case, and we shall now consider briefly by an approximate proof the modification that is necessary.

If the E.M.F. is due not merely to the chemical heat H_c but also to heat of a purely thermo-electric character, which we may call H_t, then we must write $qE = H_c + H_t$ in place of our original expression. In order to find a value for H_t we may put a theoretically reversible cell through a sort of Carnot cycle. A reversible cell is one in which the chemical reactions are completely reversed by passing a reverse current, or charging current, through the cell. This condition is very approximately fulfilled by a Daniell cell containing zinc sulphate and copper sulphate solutions. Let such a cell, having an E.M.F. E at the absolute temperature T, be put through the following cycle of operations: (1) raise its temperature slightly above T, say to $T + dT$, in which case its E.M.F. will generally change to $E + dE$; (2) allow it to generate q coulombs of electricity at this temperature, giving electric energy equal to $q(E + dE)$; (3) allow the cell to cool down to the original temperature T; and (4) pass q coulombs of electricity in the reverse direction (*i.e.* in opposition to the E.M.F.), the electrical energy in this case being equal to qE.

The cell is now in its original state. The heat that was required to raise it to the temperature $T + dT$ has been recovered upon cooling. The chemical changes which gave rise to the current at the higher temperature have been reversed by the charging current at the lower temperature, the cell being by hypothesis reversible. It is true that any I^2R loss due to the current flowing through the resistance of the cell is not reversible, but this may be made negligibly small by making the

current I very small. As a net result of these operations, however, a certain amount of energy has nevertheless been gained, for the energy given out at the higher temperature was $q(E+dE)$ and that returned at the lower temperature was qE. Consequently there has been a gain of qdE, and this can be supplied continuously by repeating the operation. This energy has not been supplied by the chemical reactions, because these have been reversed; it must, therefore, be due to the term H_t.

Here it is necessary to remember that if one body is at absolute temperature T and a second body at temperature $T+dT$, work can be done by the flow of heat H from the hotter to the cooler body. But only a fraction of this heat H can be transformed into work, the amount of work so obtainable being given not by H but by HdT/T.

Thus the energy obtainable from H_t in the cycle of operations is not equivalent to H_t but to $H_t dT/T$. We may therefore write

$$H_t\frac{dT}{T}=qdE,$$

or

$$H_t=qT\frac{dE}{dT}.$$

Making use of this value of H_t we can now write

$$E=H_c+T\frac{dE}{dT},$$

or numerically, as before,

$$E=\frac{H}{46,000}+T\frac{dE}{dT}\text{ volts (divalent metal).} \quad (3)$$

This is the Helmholtz equation, and it shows that the simpler Kelvin equation holds only if the temperature coefficient of a cell is zero.

Some interesting conclusions can be drawn from this equation.

If the E.M.F. rises with rise of temperature, then dE/dT is positive and the E.M.F. is greater than that due to the heat H. Since the additional electrical energy must be derived from some source, this further supply of heat is derived from the surroundings. In such a case the cell cools when it generates a current so as to absorb the required heat. Since the amount of heat in question is never large, this cooling can only be observed when the current is small; otherwise the effect is masked by the heat resulting from the internal loss in the cell due to internal resistance.

If the E.M.F. falls with rise of temperature, then dE/dT is negative and the E.M.F. is smaller than that due to the heat H. The cell then heats up on generating a current, irrespective of the internal loss.

The application of these principles will be rendered clear by taking two examples. Suppose we have a simple cell consisting of zinc and platinum in dilute sulphuric acid. The body that is formed is zinc sulphate. The heat of formation of a gramme molecule of zinc sulphate, using zinc and dilute sulphuric acid, is 37,730 calories, and therefore the E.M.F. is

$$\frac{37,730}{46,000}=0{\cdot}82\text{ volt,}$$

assuming that the temperature coefficient is zero.

In the case of the Daniell cell we have not only the formation of zinc sulphate but the decomposition of copper sulphate. Now the formation of copper sulphate is endothermic, absorbing heat. Consequently its decomposition results in the evolution of heat, and this heat is added to that resulting from the heat of formation of the zinc sulphate. Thus we have

Heat of formation of zinc sulphate . .	37,730
Heat of decomposition of copper sulphate	12,400
Total heat	50,130

In the Daniell cell the temperature coefficient is negligible, and therefore the E.M.F. is given simply by

$$\frac{50,130}{46,000}=1{\cdot}09\text{ volts.}$$

This calculated value is very close to that which is actually observed, and which varies somewhat with the strength of the solutions.

It will be noticed that the use of the copper sulphate in the Daniell cell not only maintains the E.M.F. through efficient depolarisation, but increases it considerably beyond that of the simple cell in which the copper sulphate is absent.

As an instance in which the temperature coefficient is considerable we may take what is known as Grove's gas cell, or the oxygen-hydrogen cell. If two strips of platinised platinum stand in dilute sulphuric acid, and so that the exposed part of one plate is surrounded by hydrogen and the exposed part of the other plate is surrounded by oxygen (the gases being contained in inverted cylinders dipping into the acid), the combination is found to act like a cell of which the plates are hydrogen and oxygen respectively. The active part is the surface of the platinum near the surface of the electrolyte, and here no doubt the gases are absorbed, so that when the cell is allowed to generate a current they combine voltaically to form water. Now the heat of formation of a gramme molecule of water is 68,300, and therefore, if the temperature coefficient were negligible, we should expect the E.M.F. to be $68,300/46,000=1{\cdot}48$ volts (the figure 46,000 being used because, although hydrogen is monovalent, there are two hydrogen atoms in the molecule of water). But Smale [1] found

[1] *Zeits. physik. Chem.*, 1894, xlv. 577.

the temperature coefficient to be negative, equal to 0·00141 volt per degree C. Therefore we have, at 17° C. (or 290° absolute),

$$E = \frac{68{,}300}{46{,}000} - 290 \times 0{\cdot}00141,$$
$$= 1{\cdot}48 - 0{\cdot}41,$$
$$= 1{\cdot}07 \text{ volts.}$$

This is about the value observed experimentally and differs seriously from that due to the heat of formation of water alone.

Although the application of thermo-chemical data in this way appears simple, it is often difficult through lack of knowledge of the exact chemical conditions and reactions. Moreover, such data are often of doubtful accuracy and may have been obtained with materials which are not precisely similar to those taking part in voltaic changes.

From the Helmholtz equation it will be realised that it is impossible to obtain a voltaic cell having a high E.M.F. (such as 10 volts), because the heat of formation of most compounds that can be utilised is equivalent to about 2 volts or less.

§ (15) The Osmotic Pressure Theory.—Thermo-chemical data give an insight into the action of a cell from the point of view of energy, but if it is desired rather to look into the mechanism of voltaic action we may turn to the Osmotic Pressure Theory. This depends upon the idea of "electrolytic solution pressure" as put forward by Nernst. Neither theory excludes the other.

A case analogous to solution pressure, commonly accepted, is the evaporation of a liquid into an atmosphere above it in a closed vessel. The evaporation continues by means of molecules leaving the liquid until the stage is reached when as many molecules return from the atmosphere into the liquid as leave the liquid and pass into the atmosphere. This is the state of equilibrium, and it arises when the partial pressure of the vapour is equal to the vapour pressure of the liquid. Similarly, if a solid is in contact with a solvent, we may consider that, when the solution is saturated, as many molecules return from the solvent to the solid as escape from the solid into the solution; or, if we may regard the solid as having a solution pressure, we may say that equilibrium occurs when the osmotic pressure of the solute becomes equal to the solution pressure of the solid.

In this connection it must be remembered that osmotic pressure is a measure of the number of molecules in solution in unit volume, at least in the case of dilute solutions. In such solutions the laws of Avogadro, Boyle, and Charles all apply as they do in gases, and the constant which occurs in those laws is the same for solutions as for gases. The investigations of van't Hoff led to the striking conclusion that the osmotic pressure exerted by the molecules of a given weight of substance in solution is equal to the pressure which an equal weight of the substance would exert at the same temperature if it occupied a volume in the gaseous state equal to that of the solution.

The analogy of evaporation of a liquid into a gas and the passing of a solid into solution thus becomes very marked. But, in order to account for the E.M.F. between a metal and any electrolyte in which it is immersed, Nernst went a step further and introduced the idea of *electrolytic* solution pressure of the metals as distinct from ordinary solution pressure, to which reference has just been made. Electrolytic solution pressure is taken to be a measure of the tendency of a metal to pass into free ions when placed in an electrolyte. Suppose that such free ions are formed. They will be positively charged, and the electrolyte containing them will therefore also be positively charged; but since both kinds of electricity must be formed simultaneously, it follows that the metal will be negatively charged and will therefore attract the positive ions back towards itself again. As soon as the attraction of the metal for the positive ions is equal to the electrolytic solution pressure, equilibrium is established and no more ions can pass into solution. A very few ions are sufficient to bring about this equilibrium, because the ionic charges are large.

If for any metal the electrolytic solution pressure be P and the osmotic partial pressure of the metallic ions already in solution be represented by p, then three cases are possible according as $P > p$, or $P = p$, or $P < p$. If $P > p$, more metal ions pass into solution and the metal becomes negatively electrified until equilibrium is produced; but the E.M.F. is smaller than it would be if no ions were already present, because there is already an osmotic pressure to oppose the electrolytic solution pressure. If $P = p$, nothing happens; in other words, the metal does not become charged and there is no potential difference. Lastly, if $P < p$, some ions are precipitated upon the metal and give up their charge, so that the metal becomes positively charged, the solution being negative.

We thus have what is called a "double layer" at the surface of separation between the metal and the electrolyte, the metal being, say, negatively electrified, and close to it a layer of positive ions. Here the ions may be looked upon as being under a pressure P equal to the electrolytic solution pressure, whereas any ions in the body of the electrolyte are under a pressure p equal to the osmotic partial pressure of these ions. If a current flows, due to the E.M.F., the ions pass from the pressure P to the pressure p, and in this change a certain

amount of work must be done by the ions. This we can proceed to calculate and thus arrive at a value for the E.M.F.

First let us take the ordinary case of work done by an expanding gas. Suppose a certain quantity of gas is held in a cylinder by a piston, the length of the cylinder up to the piston being x and the area of the piston (or cross-section of the cylinder) being A. Let the pressure of the gas be p and its volume v. Then the total pressure outward on the piston is pA. If the gas causes the piston to move outwards through a small distance dx, then the work done by the gas in this movement is $pAdx$. But since Adx is the variation in volume, or dv, this expression becomes pdv, and the work done in a change of volume from v_1 to v_2 is thus $\int_{v_1}^{v_2} pdv$. Further, in gases we have the relation $pv = \mathrm{RT}$ (R being a constant and T the absolute temperature), so that the

$$\text{work done} = \mathrm{RT}\int_{v_1}^{v_2} \frac{dv}{v},$$

$$= \mathrm{RT} \log_e \frac{v_2}{v_1} = \mathrm{RT} \log_e \frac{\mathrm{P}_1}{\mathrm{P}_2}.$$

It becomes necessary to define R by taking a definite quantity of gas, and here again, for this particular purpose, the gramme molecule is a convenient unit. Now the gramme molecule of a gas occupies a volume of 22·38 litres at normal temperature and pressure, and if this is taken as a basis the value of R, expressed as heat, becomes 2 calories.

In the case of an electrode in an electrolyte, when a current flows the ions pass from the electrolytic solution pressure P to the osmotic partial pressure p, and we may apply the result just obtained to evaluate the work done by the ions. On the other hand, if the metal is monovalent, 96,540 coulombs will be required to decompose one gramme molecule, and if E (in volts) is the value of the single E.M.F. of the metal/liquid junction, the work done is also equal to 96,540E, so that we may write

$$96{,}540\mathrm{E} = \mathrm{RT} \log_e \frac{\mathrm{P}}{p},$$

if R is suitably expressed. As already stated, R is equal to 2 calories, or to $2 \times 42 \times 10^6$ C.G.S. units of work (the mechanical equivalent of heat being 42×10^6 ergs). Since a coulomb is one tenth of the C.G.S. unit, and a volt is 10^8 C.G.S. units, we have

$$\mathrm{E} = \frac{2 \times 42 \times 10^6}{96{,}540 \times 10^{-1} \times 10^8} \mathrm{T} \log_e \frac{\mathrm{P}}{p} \text{ volts}$$

$$= 0{\cdot}000087\mathrm{T} \log_e \frac{\mathrm{P}}{p} \text{ volts}$$

$$= 0{\cdot}0002\mathrm{T} \log_{10} \frac{\mathrm{P}}{p} \text{ volts},$$

or, generally,

$$\mathrm{E} = \frac{0{\cdot}0002}{v} \mathrm{T} \log_{10} \frac{\mathrm{P}}{p} \text{ volts}, \quad . \quad . \quad (4)$$

in which v is the valency of the metal, T is the absolute temperature (expressed in degrees centigrade), P is the electrolytic solution pressure, and p is the osmotic partial pressure of the ion in solution. This is the Nernst equation of E.M.F.

If the temperature is 15° C., T is 288 and the equation becomes

$$\mathrm{E} = 0{\cdot}0575 \log_{10} \frac{\mathrm{P}}{p} \text{ volts}, \quad . \quad . \quad (5)$$

for a univalent metal. If the valency is v, then

$$\mathrm{E} = \frac{0{\cdot}0575}{v} \log_{10} \frac{\mathrm{P}}{p} \text{ volts}. \quad . \quad . \quad (6)$$

This expression applies to a single plate or electrode. Such a single E.M.F. cannot be measured by ordinary means. For this purpose the dropping mercury electrode has been developed, and by this method the value of the E.M.F. between zinc and normal zinc sulphate solution has been deduced as 0·52 volt. If the zinc sulphate is sufficiently dilute to regard it as completely ionised, then the osmotic partial pressure p of the metal ions due to a gramme molecule of the salt in a litre of solution is 22·38 atmospheres. These values of E and p may now be substituted in the expression for E, and the value of P, the electrolytic solution pressure, may be calculated. The figures so obtained are often enormous or very small. Thus the electrolytic solution pressure of zinc is $2{\cdot}7 \times 10^{19}$ atmospheres, but that of lead is $1{\cdot}1 \times 10^{-3}$ atmospheres.

In every ordinary cell we are concerned with two such expressions as the one just given, one for each plate. Thus, in the case of a reversible cell, of the Daniell type, if we neglect the small E.M.F.'s at the metal/metal and liquid/liquid junctions, we have two metal/liquid junctions contributing to the E.M.F. of the cell. At both these junctions the metal ions tend to pass into solution, but this can only occur at one of the plates, deposition occurring at the other. Thus one plate will be positive and the other negative in respect to the solution. The E.M.F. at 15° C. will be the difference of the two potentials and will be given by

$$\mathrm{E} = \frac{0{\cdot}0575}{v}\left(\log_{10} \frac{\mathrm{P}}{p} - \log_{10} \frac{\mathrm{P}'}{p'}\right) \text{volts},$$

assuming that both the metals are of the same valency. In the simple case where the two solutions have equal concentrations we have $p = p'$ and the formula becomes

$$\mathrm{E} = \frac{0{\cdot}0575}{v} \log_{10} \frac{\mathrm{P}}{\mathrm{P}'} \text{ volts}. \quad . \quad . \quad (7)$$

As an example we may take the Daniell cell with zinc and copper plates. Here $v = 2$, $\mathrm{P} = 2{\cdot}7 \times 10^{19}$ atmospheres for zinc, and $\mathrm{P}' = 4{\cdot}8 \times 10^{-20}$ for copper. Hence, substituting in (7),

$$\mathrm{E} = \frac{0{\cdot}0575}{2} \log_{10} \left(\frac{2{\cdot}7}{4{\cdot}8} \times 10^{39}\right) \text{ volts}$$

$$= 0{\cdot}02875 \times 38{\cdot}7502 \text{ volts}$$

$$= 1{\cdot}11 \text{ volts}.$$

This is approximately the value observed.

It follows from equation (7) that so long as

the two solutions are of equal ionic concentrations the E.M.F. is independent of their strength. This is found to be approximately the case.

Conversely, we may have two solutions of different ionic concentrations but with both plates of the same metal. We then have $p = p'$ and the formula becomes

$$E = \frac{0{\cdot}0575}{n} \log_{10} \frac{p'}{p} \text{ volts.} \quad . \quad . \quad (8)$$

Such cells are termed concentration cells. For example, we may have the cell, silver/(N/100) silver-nitrate-solution/(N/10) silver-nitrate-solution/silver. The E.M.F. is then given by

$$E = \frac{0{\cdot}0575}{1} \log \frac{100}{10},$$
$$= 0{\cdot}0575 \text{ volt,}$$

assuming that the ionisation is complete in both the solutions. Actually the E.M.F. is affected also by the ionic velocities, and the exact expression is more complicated than that just given. The rate at which cells of this kind can generate electrical energy is small, because they depend upon diffusion instead of upon chemical energy, and thus the currents so obtainable are small compared with those from the more usual type of cell, even when regard is had to the low E.M.F.

V. Examples of Practical Cells

§ (16) One-fluid Cells.—The simplest type of cell is that in which only a single electrolyte is employed, and, as simplicity is desirable, many such cells have been developed. The so-called "simple cells" belong to this type, but they are not commonly used, as the E.M.F. is low and the depolarisation is generally poor.

(i.) *The Bichromate Cell.*—With regard to depolarisers, there is a choice between liquids and solids, as already mentioned. The simplest form of one-fluid cell with a liquid depolariser is the Bichromate cell. The electrolyte here consists of dilute sulphuric acid with a bichromate or chromic acid dissolved therein. One plate is of carbon and the other of zinc, which, owing to the electrolyte being acid, must be amalgamated. The E.M.F. is 1·9-2·0 volts. Potassium bichromate is often used as the depolariser; sodium bichromate, however, not only gives a better result, but is much more easily soluble and gives less trouble in the formation of alum crystals, which are liable to form if the cell is used over a considerable period and evaporation is allowed to take place. A still more easy depolariser to use is chromic acid, as it is very quickly dissolved and a smaller weight is required. A suitable formula for general use is as follows:

Water	1 litre	35 fluid oz.
Sodium bichromate .	70 grammes	2·5 oz.
Sulphuric acid (conc.)	100 c.c.	3·5 fluid oz.

The sodium bichromate may be replaced by about 45 grammes or 1·8 oz. of chromic acid in the respective formulae. The sulphuric acid may be added to the water, and the depolariser dissolved therein subsequently, or the acid may be added to the solution of the depolariser.

The depolarisation is not very satisfactory in such cells; it falls off rather rapidly owing to the decomposition of the depolariser and its dilution, not merely with its own products but with the zinc sulphate formed by the action of the cell. A considerably better result is obtained by introducing a porous pot, as seen in *Fig.* 7. The zinc is placed in the porous pot which alone contains the depolarising solution, sometimes mixed with a little acid or zinc sulphate to reduce the internal resistance. When the cell is not in use the zinc should be removed if the electrolyte is acid. If a porous pot is used it should contain a little mercury to help in maintaining the amalgamation of the zinc. Porous pots should be kept in water when out of use, to prevent crystallisation of salts in their pores and consequent splitting.

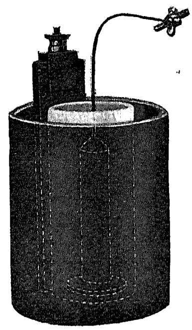

Fig. 7.

Constant polarisation can only be secured by removing and replenishing the depolariser as rapidly as it is used. This method has been successfully applied in the Benkö cell, which has been described in detail by the present writer.[1]

(ii.) *The Lalande Cell.*—When we come to solid depolarisers we find that two main types have been developed. One of these depends upon the use of cupric oxide. This is a convenient depolariser, for it can be made up in the form of slabs fitted into a framework of copper, thus forming the positive plate. The necessary conductivity is given to this plate by reducing the surface. The electrolyte is a solution of caustic soda (one part of soda to three of water by weight), and therefore the zinc does not require amalgamation, as appreciable local action is absent except at the surface of the electrolyte, where it slowly takes effect. Very good results are given by these cells, the depolarisation being excellent and permitting a considerable current, but the E.M.F. is low. At first this may be 1·0 or 1·1 volts, but the effective value is only about 0·75 volt.

This form of cell was originally devised by De Lalande, but has been modified in detail by others, particularly by Edison. Such cells remain effective a considerable time without attention and have therefore been used on a

[1] *Inst. El. Eng. J.*, 1911, xlvi. 741.

considerable scale for track-signalling on railways.

(iii.) *The Leclanché Cell.*—The most notable example of a single-fluid cell with solid depolarisers is the one that was introduced by Leclanché in 1868. In this case the positive consists of a carbon surrounded by manganese peroxide, or some equivalent combination, and the electrolyte is a solution of ammonium chloride (2 oz. to 4 oz. to the pint). Since the electrolyte is neutral or alkaline, local action is negligible, but the zincs are usually amalgamated. A certain amount of local action slowly takes place, more particularly (as is always the case) near the surface of the electrolyte. The E.M.F. initially is about 1·5 volts, but as the depolarisation is not very perfect this value falls somewhat, and when on closed circuit for any length of time the value may be more nearly 1 volt. For this reason Leclanché cells are employed only for intermittent work, and generally where the current required is comparatively small. They can be left without attention and therefore have become very popular in such applications as electric bells.

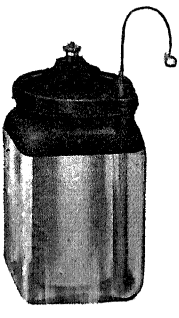

FIG. 8.

The reaction may be roughly described by saying that the chlorine of the ammonium chloride attacks the zinc and that the NH_4 ion passes to the manganese peroxide. Here it splits up into NH_3 and hydrogen, the latter reducing the MnO_2 to Mn_2O_3.

The original and most usual form of Leclanché cell is that shown in *Fig.* 8. Here the manganese peroxide is mixed with broken gas carbon and is held against the carbon plate by being packed into a porous pot. The latter is sealed up with pitch in which there is a small glass vent tube to allow the liberated ammonia to escape. The effectiveness of the depolarisation must depend to no small extent on the intimate mixing of the carbon and the manganese peroxide, because the hydrogen will be deposited upon the carbon (owing to its high conductivity) and must find its way to the manganese peroxide before its oxidation can result. For this reason it has become customary to use both manganese peroxide and carbon in the powdered form. The British Post Office specify that the manganese ore shall pass through a sieve having 40 meshes to the inch, but shall remain on a sieve having 60 meshes to the inch. It is found that sharp crystalline grains of the ore are more effective than rounded grains.

The objection to this construction of the cell is that the porous pot introduces resistance and that the cell is open, so that evaporation takes place. For the former reason, agglomerate blocks, made up of carbon and manganese peroxide held together by some binding material, have been used. These are generally held against the carbon plate, one on each side, by india-rubber bands. In this way the porous pot becomes unnecessary, but the depolarisation is not so satisfactory as with a porous pot properly charged. By adding graphite the agglomerate block may be used to take the place of the carbon. This method is used in the Leclanché-Barbier cell, made by the Silvertown Co. (*Fig.* 9), which has the advantage of being closed and therefore free from evaporation.

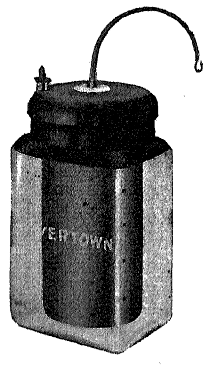

FIG. 9.

The disadvantages of the porous pot have been overcome by using what are known as "sack elements." It may be said that these are obtained by replacing the porous pot by canvas. The carbon is surrounded by the depolarising mixture, which is then bound round tightly in canvas. A suitable top and bottom are fitted as seen in *Fig.* 10, which shows an element by Siemens Brothers & Co. Such elements have been found to be very satisfactory, and cells on this principle have been made in comparatively large sizes so as to be capable of giving much larger currents. The Post Office form of Leclanché cell with sack element, as made by Siemens Brothers & Co., is shown in *Fig.* 11.

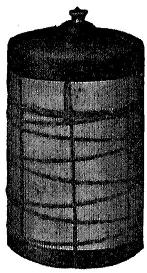

FIG. 10.

Some other depolarising materials have been used to a limited extent in single-fluid cells. Of these, mention may be made of lead peroxide, silver chloride, and acid mercuric sulphate.

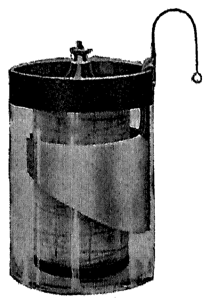

FIG. 11.

(iv.) *Cells with Gaseous Depolarisation.*—Attempts have been made to use atmospheric oxygen as the depolariser, but the difficulty is to bring it into action. The latest cell of this kind is that due to Prof. C. Féry. In this cell the zinc, instead of being of the usual vertical type, is a horizontal plate at the bottom of the cell. If a vertical zinc passing through the surface of the electrolyte is employed in the usual way it becomes attacked at this point by the atmospheric oxygen in the electrolyte, and basic salts are thus formed, which are troublesome. This is avoided by placing the zinc at the bottom of the cell. Any crystals that are formed remain in the lower half of the cell, and the upper part of the solution remains as a store-house of dissolved oxygen. The carbon is in the form of a vertical cylinder with a large surface, and depolarisation is effected by the oxygen in solution coming in contact with the carbon. Such a cell is capable of maintaining a current through 50 ohms for months, the P.D. falling from, say, 0·87 to 0·81 volt.

§ (17) TWO-FLUID CELLS.—In cells of the two-fluid type a liquid depolariser is used and is of such a nature that it cannot be mixed with the electrolyte employed to attack the zinc. The depolarisation is usually very effective, but porous pots are often troublesome.

(i.) *The Daniell Cell.*—There are various modifications of Daniell cell, the simplest consisting of a jar containing a porous pot. In the latter is placed the zinc, and in the space between the porous pot and the outer jar is placed a cylindrical sheet of copper. The zinc stands in dilute sulphuric acid, or preferably in a solution of zinc sulphate, and the copper plate in a saturated solution of copper sulphate. The E.M.F. varies from 1·07 to 1·14 volts, the value depending on the densities of the solutions. The reactions involved have already been described.

The sulphuric acid may be of the strength obtained by mixing one volume of concentrated acid with 10 volumes of water. The zinc sulphate may vary considerably in concentration. If a quarter of a pound is dissolved in a pint of water this will generally be sufficient. The copper sulphate, on the other hand, should be concentrated, and therefore crystals of the salt are often placed in the cell; also the area of the copper plate should be as large as possible. By the nature of the cell the internal resistance is rather high.

It is essential that the copper sulphate should not reach the zinc, as it would then be immediately deposited thereon and local action would ensue. With the arrangement just described diffusion is inevitable after a time and therefore the cell cannot be left for long periods, particularly if not in use.

This defect is somewhat remedied in the gravity form (*Fig.* 12). Here the copper plate is placed at the bottom of the jar, with crystals upon it, and the zinc plate is suspended above. In a cell of this kind diffusion is not so marked, provided the cell is kept in use. Also the porous pot is avoided; but the cell is not so portable, for any shaking tends to increase the diffusion of the copper sulphate. Kelvin's tray battery, which is a form of gravity Daniell, has been largely used in submarine telegraphy. In other modifications, such as that by Siemens and Halske, Minotto's and Meidinger's, various methods have been adopted with a view to greater permanence, at the same time eliminating the porous pot.

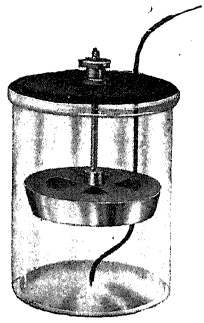

FIG. 12.

(ii.) *The Grove Cell.*—In this cell the depolariser is strong nitric acid. The form usually adopted is illustrated in *Fig.* 13, and the principle of the cell has been already described. The positive plate, which is a sheet of platinum, is placed in a flat narrow porous pot holding the nitric acid. The zinc, which stands in dilute sulphuric acid, is in the form of a heavy casting extending round both sides of the porous pot, so that the internal resistance is low. The E.M.F. is 1·9 to 2 volts, and thus such cells are capable of giving considerable currents provided they are required only for, say, one day. An objection to nitric acid is that nitric and nitrous oxides are formed, giving rise to corrosive fumes.

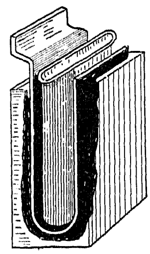

FIG. 13.

(iii.) *The Bunsen Cell.*—Owing to the high cost of platinum, a carbon rod or plate has been used as the positive, thus converting the Grove cell into what is known as the Bunsen. The cell generally takes the form of a cylindrical porous pot which stands in an outer jar. The porous pot contains the nitric acid and a square rod of carbon, and the zinc takes a cylindrical form surrounding the porous pot. Otherwise, what has been said in regard to the Grove cell applies equally to the Bunsen.

§ (18) DRY CELLS.—The term "dry cell" is strictly a misnomer, as no cell can generate current if it is really dry; but the term is conveniently used to denote cells in which the electrolyte is in the form of a paste or otherwise held so that there is nothing to be spilt if

the cell is inverted. Such cells are now used in enormous quantities.

(i.) *Typical Construction.*—So far, dry cells have been based upon the principles of the Leclanché cell, *i.e.* they consist of zinc and carbon plates with manganese peroxide as the depolariser, ammonium chloride being the electrolyte held in some convenient manner. The construction commonly adopted is shown in *Fig.* 14. The container is made of zinc and this is used as the zinc plate. At the bottom of the container is placed a layer of insulation, such as cardboard. The carbon is surrounded by a mass of black depolarising paste, and between this and the zinc container is a white paste which may be regarded as the electrolyte. Above the depolariser and the white paste is a layer of sawdust or similar porous material, and above this the cell is completed with a bituminous seal provided with a vent tube through which any gases may escape. The E.M.F. is about 1·5 volts, as in the Leclanché cell.

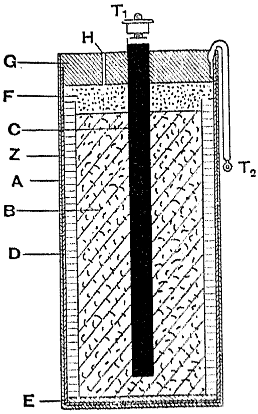

FIG. 14.

A, cardboard case; B, depolarising paste; C, carbon; D, white paste; E, insulating layer; F, sawdust; G, bituminous seal; T_1, positive terminal; T_2, negative terminal; Z, zinc; H, vent.

The exact compositions used are regarded as trade secrets, but the depolarising paste is stated to be of the following character:

Manganese peroxide	10 lb.
Carbon or graphite, or both . . .	10 lb.
Sal-ammoniac	2 lb.
Zinc chloride	1 lb.

Sufficient water is added to make this mixture into a suitable paste. The zinc chloride is necessary to prevent the contents of the cell becoming too dry and it also appears to prevent local action and takes up free ammonia. This paste is rammed into a mould round the carbon, the two being then removed and placed in the container. The white paste is then run in and allowed to set. The latter may be made up of flour, plaster of Paris, sal-ammoniac, and zinc chloride in suitable proportions, with water to form a paste. Sometimes a gelatinous paste is used.

Since the depolarising paste contains electrolyte, the white paste need only be thick enough to keep the black paste from touching the zinc container. The process can be carried a step further by abolishing the white paste, and substituting for it a layer of blotting-paper. This course is often adopted in America. It has the advantage of reducing the internal resistance to a minimum, but the paper is more fragile from the point of view of preventing the depolariser from touching the zinc.

The carbon with the surrounding depolarising paste is often made up in the form of a sack element, in which case a gelatinous electrolyte is used. This is particularly the case in small flash-light cells.

(ii.) *Desiccated Cells.*—Dry cells, although very convenient, suffer from the defect that they dry up in course of time, particularly if not in use. This may be due partly to evaporation and partly to the "setting" of the ingredients. Thus the internal resistance, which may be very low initially, slowly increases. Sometimes, also, gases are formed which cannot escape, or expansion takes place from other causes, and the cell bursts.

In order to eliminate the deterioration which may take place on merely keeping such cells in stock, cells have been developed which may be termed "desiccated cells," as they are truly dry and will not generate a current until water has been added to them.

In these cells the positive element is generally made up in the sack form, and this is placed in the container along with a sufficient supply of sal-ammoniac crystals. Thus the cell becomes practically a Leclanché wet cell on adding the necessary water. In the cell made by the General Electric Co., however, a hollow perforated carbon is used, surrounded by a dry depolarising mixture together with sal-ammoniac crystals, the mixture being kept away from the zinc by absorbent paper. The cell is rendered active by adding water through the carbon.

§ (19) STANDARD CELLS.—Standard cells are of the greatest importance in electrical measurements and much research has been carried out in this direction.

(i.) *The Weston or Cadmium Cell.*—This cell, which is due to E. Weston of the United States, was recommended as a standard of electrical pressure by the International Conference on Electrical Units and Standards which met in London in 1908. The construction of the cell, which can only be very briefly stated here, will be understood by reference to *Fig.* 15. It is set up in a glass vessel consisting of two tubes closed at one end and connected by a cross tube, giving what is called the H-form. The positive electrode is mercury and the negative electrode is a cadmium amalgam containing 12·5 per cent of cadmium. Above the mercury is a layer of paste made by mixing mercurous sulphate with powdered crystals of cadmium sulphate and a saturated aqueous solution of

cadmium sulphate. A layer of cadmium sulphate crystals is then introduced into each limb, and finally the cell is filled to a convenient level with a saturated solution of cadmium

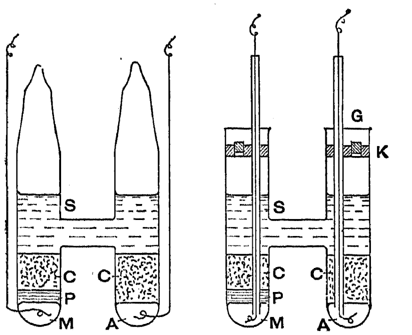

FIG. 15.

M, mercury; A, amalgam; P, paste; C, cadmium sulphate crystals; S, saturated solution of cadmium sulphate; K, cork; G, marine glue.

sulphate. Connection to the mercury and amalgam can be made by means of platinum wires sealed into the glass as shown on the left, in which case the tops of the tubes may be sealed off by heating in the flame of a blowpipe; or platinum wires protected by glass tubes can be used as shown in the right-hand figure, in which case the cell is sealed by means of corks and marine glue. The preparation of the materials must be carried out with great care if the highest accuracy is desired. The methods to be followed will be found in various papers.[1]

The E.M.F. of the cell (as agreed by the National Physical Laboratory, the Bureau of Standards at Washington, and the Reichsanstalt) is 1·0183 volts at 20° C. The variation of E.M.F. with temperature between 0° C and 40° C. follows the formula (recommended by the International Conference in 1908):

$$E_t = E_{20} - 0{\cdot}0000406(t-20) - 0{\cdot}00000095(t-20)^2 + 0{\cdot}00000001(t-20)^3.$$

Thus the temperature coefficient is very small and may generally be neglected. Such cells can be made to a high degree of accuracy. For example, it was found that the mean of 13 Weston cells made by H. L. Bronson and A. N. Shaw differed from the mean of those at the Bureau of Standards by less than 4 micro-volts and from the mean of those at the National Physical Laboratory by less than 5 micro-volts.

(ii.) *The Clark Cell.*—This cell, which was due to Latimer Clark, was the first successful standard of electrical pressure. It is obtained by substituting zinc sulphate for cadmium sulphate in the Weston cell. If made in a similar manner and with suitable precautions in the preparation of the zinc sulphate very satisfactory results are obtained. The E.M.F. is 1·433 volts at 15° C. The great objection to the cell is its high temperature-coefficient. According to W. Jaeger and K. Kahle the variation of E.M.F. with temperature is given by the following equation:

$$E_t = E_{15} - 0{\cdot}00119(t-15) - 0{\cdot}000007(t-15)^2.$$

This means that the variation per degree C. is 0·0012 volt, which is a serious amount, whereas the corresponding figure for the Weston cell is only 0·00004 volt. W. R. C.

[1] See Reports of the Electrical Standards Committee of the B.A., 1907, etc. The more important work is summarised in *Primary Batteries* by W. R. Cooper. See also "Electrical Measurements," § (45).

BATTERIES, SECONDARY

§ (1) INTRODUCTION.—There is no essential electro-chemical difference between the secondary cell and the primary cell when either is used as a generator of electrical energy. In the case of the primary cell, however, the interacting bodies must be mostly thrown away and replaced after a certain discharge has taken place if an efficient result is desired. On the other hand, the interacting bodies in a secondary cell are not replaced, but are brought back to their original condition by passing a current in the reverse direction to that of the current on discharge. A secondary cell may thus be defined as a voltaic cell which is reversible; that is, a cell in which the chemical changes can be reversed by the action of a reverse current.

Secondary cells are sometimes called "accumulators" or "storage cells," but these names are misnomers. Such cells do not accumulate or store electrical energy like a condenser; they are more in the nature of converters, for they change electrical energy into chemical energy and *vice versa.*

Many primary cells are more or less reversible, and some of them have therefore been used as secondary cells. As an example of a cell which is irreversible we may take the simple cell consisting of zinc and platinum in dilute sulphuric acid. In its discharge this cell gives zinc sulphate at the zinc plate (which salt passes into solution) and hydrogen on the platinum plate, this gas being slowly evolved. Although a reverse current may re-deposit some of the dissolved zinc it can never replace the hydrogen that has been lost, and therefore such a cell is useless as a secondary cell, being irreversible. A Daniell cell, on the other hand, is fairly reversible; the zinc will be re-deposited and the copper will pass into solution as copper sulphate when a reverse current is passed, so that the original state is reproduced. But the conditions must be suitable for these changes to take place with regularity; also

diffusion leads to deterioration, so that the Daniell cell has not been seriously used as a secondary cell. Many other primary cells, such as Reynier's zinc/sulphuric-acid/lead-peroxide cell, Sutton's copper/sulphuric-acid/lead-peroxide cell, and the Waddell-Entz zinc/potassium-hydrate/copper-oxide cell, have been tried, but none of them have proved to be commercially successful.

An excellent example of a reversible cell is the well-known gas cell due to Sir W. Grove. If two inverted tubes, with platinum electrodes (preferably platinised), stand in dilute sulphuric acid, and are filled with the acid, the passage of a current will decompose the water so that hydrogen will collect in the cathode tube and oxygen in the anode tube as indicated in *Fig.* 1. If, now, the cell is closed through a

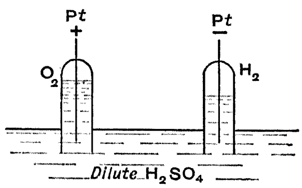

FIG. 1.

resistance it will generate a current until the hydrogen and oxygen have all re-combined to form water, and thus the initial condition will be completely reproduced. The electrodes act as though they consisted of oxygen and hydrogen. Although this cell is in many ways ideal, it suffers from the fact that the action depends upon the area of contact of the platinum with the electrolyte just at the surface of the latter, and consequently the rate at which the combination takes place is low; in other words, the current obtainable is small compared with that

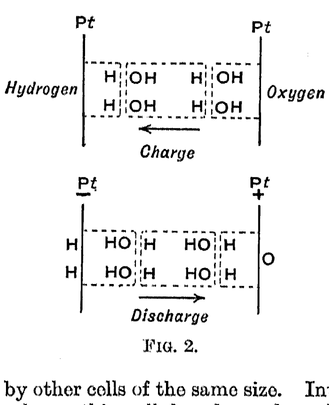

FIG. 2.

given by other cells of the same size. Interesting work on this cell has been done by K. Siegl.[1] The reactions of the gas cell are shown diagrammatically in *Fig.* 2. Here the water is

[1] *Elekt. Zeits.*, 1913, xxxiv. 1317.

looked upon as conducting. The electrolysis, or charging current, causes liberation of hydrogen at the cathode and two hydroxyls at the anode, but the latter combine to give water and oxygen.

Commercial secondary cells are of two general types, namely, (1) the lead cell, and (2) the much more recent iron/nickel cell. The former is acid and the latter is alkaline.

A. Lead Cell

I. General Principles

§ (2) Planté's Work.—The lead cell arose from the work of Gaston Planté on the polarisation of metals in electrolysis. Planté noticed that any voltameter, after the passage of a current, would act as a generator, no matter what the metal of the electrodes, so long as the cathode was polarised, but that lead was particularly active in this respect. He then proceeded to increase the capacity. Lead differs from some metals in that if this metal is used for both electrodes, the hydrogen evolved at the cathode produces no effect upon the lead plate so used, beyond cleaning it; on the other hand, the oxygen evolved at the anode forms a colloidal film of lead peroxide. This film soon stops the oxidising action. Planté found that if the voltameter is then allowed to stand for a sufficient time, or if the cell is short-circuited, the peroxide becomes converted into sulphate, after which the process can be repeated, when not only will the lead sulphate be converted into lead peroxide but more peroxide will be formed than existed previously, because the lead plate can be further attacked until it becomes again protected. By repeating the process a sufficient number of times an adherent and crystalline coating of lead peroxide is obtained of considerable capacity.

The capacity of the other electrode, however, which has been subjected merely to the action of hydrogen, is still negligible, not being appreciably attacked by the acid on discharge. But if a peroxidised plate is made a cathode (that is, if the peroxide upon it is not merely converted into sulphate but the current is still continued in the same direction so as to obtain further reduction) the lead sulphate becomes wholly reduced to lead in a finely divided or spongy form. This lead can then be acted upon by the acid voltaically so that when it is opposed to a peroxidised plate in dilute sulphuric acid a cell is formed capable of supplying a considerable current. When a discharge thus takes place both the spongy lead and the lead peroxide are converted into lead sulphate. A charging current brings back the lead sulphate to spongy lead on the one plate and to lead peroxide on the other, so that the original state is reproduced.

II. Theory of the Lead Cell

§ (3) The Elements.—It has been shown in the article on "Primary Batteries" that the two metals in a cell should be selected so as to be far apart in the electro-chemical series if a high E.M.F. is desired, and thus it might be thought that the use of the same metal, lead, for both the plates would lead to a very poor result. It must be borne in mind, however, that the active material is lead on only one plate, being lead peroxide on the other. It is a well-known fact that if a metal is combined with a very electro-negative body such as oxygen, the resulting compound is electro-negative to the original metal, and the higher the percentage of oxygen the more electro-negative is the compound. Lead peroxide has a high percentage of oxygen, and consequently this compound is very electro-negative to lead, with the result that if lead and lead peroxide are used as the plates of a cell a high E.M.F. is obtained. In this case the lead of the peroxide plate merely acts as a support for the active material.

The lead peroxide plate is commonly called the positive, though electro-negative in character. Similarly the lead plate is usually called the negative, though electro-positive in character. Whatever the method of manufacture, the lead cell is simply a lead/sulphuric-acid/lead-peroxide combination. On discharge, the lead and lead-peroxide are both more or less converted into lead sulphate, whilst on charging the reverse changes take place.

§ (4) The Double Sulphate Theory.—It is rather remarkable that the discharge should result in the same compound at both plates, and this fact has given rise to much controversy. Generally electrolytic reactions give different products at the two electrodes because the ions are different, and therefore the view has often been taken that the formation of lead sulphate on the positive plate could merely be a secondary reaction and could not contribute to the E.M.F., more particularly as it does not depend upon the ion. According to the supporters of the "double sulphate theory," on the other hand, the formation of this sulphate is to be regarded rather as a primary reaction, contributing directly to the E.M.F., and this view is now very generally accepted. The theory is due to Gladstone and Tribe.

The electro-chemical changes that take place can be shown most readily by considering the effect of the ions H and SO_4 of sulphuric acid upon the individual plates.

On discharge, the SO_4 ion attacks the lead of the negative plate, forming lead sulphate. The hydrogen at the positive plate finds a ready depolariser in the lead peroxide, and the reduced oxide is converted into lead sulphate by the sulphuric acid.

On charging, the lead sulphate on the negative is reduced to spongy lead, sulphuric acid being re-formed. This is quite a simple reaction. At the positive plate the lead sulphate is attacked by the SO_4 ion in the presence of water (the acid being always dilute) with the result that the sulphate is converted into lead peroxide and sulphuric acid is re-formed.

These changes are shown in the following equations:

Discharge.

Negative plate . . . $Pb + SO_4 = PbSO_4$.

Positive plate $PbO_2 + H_2 + H_2SO_4 = PbSO_4 + 2H_2O$.

Charge.

Negative plate . . $PbSO_4 + H_2 = Pb + H_2SO_4$

Positive plate $PbSO_4 + SO_4 + 2H_2O = PbO_2 + 2H_2SO_4$.

Or on both plates:

$$Pb + PbO_2 + 2H_2SO_4 \rightleftarrows 2PbSO_4 + 2H_2O.$$

On combining the changes that take place at the two plates, bearing in mind that H_2 and SO_4 are together equivalent to H_2SO_4, we obtain the final equation—a chemical equation as distinct from one that is electro-chemical—for the discharge. It will be noticed that if the terms of the pair of equations for the charge be similarly collected together, the molecule of H_2SO_4 which appears on both sides being omitted, the same final equation is obtained, but written backwards. Consequently this equation is conveniently written with arrows indicating that it may be read either way, forwards for discharge and backwards for charge.

§ (5) Experimental Evidence.—We can here only briefly consider the evidence upon which this theory rests.[1]

First, there is the question of the actual bodies involved. Chemical analysis in such cases is often difficult of application. Moreover, when bodies are formed electrolytically it is conceivable that they may differ somewhat from apparently the same bodies formed by ordinary chemical means. The measurement of E.M.F., however, affords a method of detecting differences. There has not been so much question about the spongy lead on the negative; it is rather the lead peroxide on the positive that has given rise to controversy, as it was felt that some other oxide might be involved, or an hydrated form of the peroxide. It is found, however, that a plate made up with chemically prepared PbO_2 gives the same E.M.F. as that

[1] A concise account of the double sulphate theory and others will be found in *The Theory of the Lead Accumulator*, by F. Dolezalek.

observed with the positive plate of a lead cell formed in the ordinary way. The peroxide might be hydrated, but Strecker [1] found that the E.M.F. due to a positive plate is unaffected after the plate has been heated to 170° C., at which temperature the hydrate, if present, would be decomposed. Analysis of the active material at various stages of charge and discharge have been given by Ayrton, Lamb, and Smith.[2] These various investigations are sufficient to prove that PbO_2 is the active material on the positive plate.

It will be realised that if the equations are true, and are due to the actions of the ions as distinct from ordinary chemical changes, the various bodies formed or decomposed must be formed or decomposed in proportion to the quantity of electricity that passes on charge or discharge. Here the lead sulphate is the only body about which there has been much discussion. The formation of sulphate on the negative plate has been found on analysis to agree satisfactorily with that required by the theory. But on the positive plate the agreement (for example, in the work of Mugden [3]) has not been so satisfactory. If the change from a reduced oxide to sulphate is a secondary reaction, agreement would not be expected. On the other hand, a definite divergence from the theoretical figure could hardly be expected, because the conversion to sulphate must be proceeding continually so long as a lower oxide is present. Here then the evidence is somewhat weak, and it is necessary to fall back on thermo-chemical considerations, which will be given later.

The other changes shown in the equations affect the electrolyte, and consist in the formation of water and the using up of H_2SO_4 during discharge and the converse reactions on charge. These changes are found to be strictly proportional to the quantity of electricity that has passed, and since they affect the strength of the sulphuric acid it follows that the variation of the specific gravity of the electrolyte affords a measure of the quantity of electricity that passes. For this reason the specific gravity is the most simple means of determining the state of a cell in regard to charge and discharge. This variation in the amount of H_2SO_4 is often taken as a measure of the amount of $PbSO_4$ formed on the plates, and correctly so, but it throws no light upon the question whether some of the $PbSO_4$ on the positive plate is formed by a secondary reaction.

A final test of the assumed reactions is to ascertain whether the E.M.F. calculated from thermo-chemical data is in agreement with the observed figure, as explained in the article on "Primary Batteries." The E.M.F. is given by the equation

$$E = \frac{H}{46{,}000} + T\frac{dE}{dT},$$

in which H is the heat in calories of the assumed reactions and TdE/dT is the temperature coefficient of the E.M.F. multiplied by the absolute temperature in degrees C. In this case the heats of formation of lead sulphate from lead and from lead peroxide cannot be found directly, so that indirect methods must be adopted. Both Streintz [4] and Tscheltzow [5] have made determinations of this kind. Taking Tscheltzow's results, the calculation may be set out briefly as follows:

Heat of reactions, taking *very* dilute acid	88,800 cal.
Less heat of dilution for acid of sp. gr. 1·150	1,600 „
Heat of reactions . .	87,200 cal.
E.M.F. (omitting $TdE/dT = \frac{87{,}200}{46{,}000} =$	1·89 volts.
Add TdE/dT ($T=290$, $dE/dT=0{\cdot}4 \times 10^{-3}$) = ...	0·12 „
Corrected E.M.F. . . .	2·01 volts.

The first figure given above is true for only very dilute acid, and as sulphuric acid gives out heat on dilution it is necessary to make the correction here shown if the figures are to apply to acid of a specific gravity of 1·150, which is nearer that used in practice. The value of the E.M.F. based on the work of Streintz is somewhat lower, being 1·96 volts. The observed E.M.F. is 1·99 to 2·01 volts, so that the calculated values must be regarded as reasonably satisfactory evidence in support of the reactions assumed in the double sulphate theory. Perhaps the only serious objection that can be taken to this part of the evidence is that many thermo-chemical data are far from accurate.

An interesting light is thrown on the equation of the reactions taking place in the lead cell by the consideration of reversibility. It has been pointed out that the equation may be read in either direction. In other words, the reactions are completely reversible, and therefore it follows that the E.M.F. on charge should be the same as that on discharge, at least when the plates are in the normally charged condition. This has been shown to be the case by Dolezalek.[6] The method followed is indicated in *Fig.* 3. If the potential difference is measured when a low charging current is flowing, a certain value will be obtained which will be in excess of the E.M.F. on account of the internal resistance of the cell, other disturbing causes

being practically absent when the value of the current is sufficiently low. If the current is gradually reduced the potential difference falls,

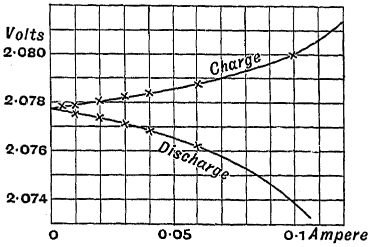

FIG. 3.

becoming more and more nearly equal to the E.M.F. Such observations are shown plotted in *Fig.* 3, giving a curve marked "charge." If this curve is produced until it cuts the axis, a point will be found corresponding to no current, and which may thus be regarded as the limiting value when the charging current is zero, or as the E.M.F. on charge. Similarly the E.M.F. on discharge can be found. If the two curves meet on the axis, as in fact they do, then it may be said that the E.M.F. on charge is the same as that on discharge and that the cell is truly reversible. In actual working, as will be seen later, there are certain variations of the E.M.F. on charge and discharge, but the above holds good for any given normal state of the plates.

§ (6) FÉRY'S THEORY.—Of the alternative theories, reference need be made only to the work of Professor C. Féry,[1] as this forms the most recent attack upon the double-sulphate theory. Féry holds the view that the oxide on the positive plate is Pb_2O_5 instead of PbO_2. This contention is based upon observations that (1) the colour of the active material is much darker than that of normal PbO_2; (2) the active material, when placed in a stream of dry hydrogen, heats up and gives off water until the colour changes to that of ordinary PbO_2; (3) the active material when used as one plate of a cell having zinc as the other plate in dilute sulphuric acid gives an E.M.F. of 2·4 volts, whereas PbO_2 gives 0·7 volt (contrary to the observations of Streintz), and a discharge is obtainable at 2·4 volts, followed by one at 0·7 volt; (4) quantitative analytical measurements indicate a composition approximating to the formula Pb_2O_5. The conclusion is reached that the discharge changes the positive plate from Pb_2O_5 to PbO_2. With regard to the negative, Féry suggests on the ground of colour (which does not appear white on discharge as would be expected from the formation of $PbSO_4$), and from quantitative experiments, that the active lead becomes Pb_2SO_4 on discharge instead of $PbSO_4$. Thermo-chemical support for these conclusions is lacking, as the necessary data are not available. There is other evidence beyond that here briefly given, but it may be said that much more confirmatory evidence will be necessary before this theory can be accepted in place of the double-sulphate theory.

III. METHODS OF FORMATION

There are three general methods of manufacturing the active surface of plates.

§ (7) THE ORIGINAL PLANTÉ METHOD.—Reference has already been made to the original method adopted by Planté. This gives an excellent type of plate, but the great disadvantage of the method is that it is very slow, particularly in the later stages as the thickness of the lead peroxide increases. Short-circuiting of the cell at intervals is necessary, as already explained, and the number of times that the operation of charging and short-circuiting must be carried through is large. Consequently the process is costly in electric energy and in the capital that is locked up during the period of manufacture.

The process of converting the lead (or oxides in other processes) into active material is termed "forming" the plate. The plates would generally be formed by using dummy plates as the cathodes. In the Planté process only positives are directly produced. Negatives are obtained by taking fully formed positives and reversing the current (*i.e.* using these positives as cathodes), so that the lead peroxide is not only reduced to sulphate, but the reducing process is continued until the active material is finally reduced wholly to spongy lead. The plate is then in the proper state to be used as a negative. Owing to its high cost the original Planté process is no longer employed.

§ (8) THE FAURE, OR PASTED, PROCESS.—In order to eliminate these difficulties Camille Faure introduced the use of lead oxides pasted on to a lead grid, so that some of the necessary work should thus be performed chemically, only the remaining oxidation or reduction being left for the current to perform. This method led to a great saving in time, and is therefore still in common use. There is the further advantage that both positive and negative plates can be formed at the same time. For the positives red lead or Pb_3O_4 is used, since this oxide has a high proportion of oxygen and it is to be subjected to further oxidation. For the negatives, on the other hand, a much lower oxide is desirable, because it is to be subjected to reduction, and therefore litharge or PbO is used. In either case the oxide is made up into a paste with dilute sulphuric acid, and this is applied to lead grids which act as the

mechanical support. The plates so made are allowed to dry and harden, and when they are sufficiently "seasoned" the positives are made anodes and the negatives cathodes in an electrolytic bath with dilute sulphuric acid as the electrolyte, and a suitable current is passed for a considerable time until the Pb_3O_4 is oxidised to PbO_2 and the PbO is reduced to spongy lead. Sometimes the plates are formed with dummies as the other electrodes.

§ (9) THE QUICK FORMATION PLANTÉ PROCESS.—Although the pasted type of plate can be made much more quickly than a Planté plate it is not so strong, the active material being more delicate. A further process has therefore been developed in which some of the corrosion of the lead plate is carried out by chemical or electro-chemical means much more rapidly. For example, if lead is boiled in very dilute nitric acid it becomes oxidised, and this coating of oxide may then be further peroxidised electrolytically. The more usual method, however, is to carry out the two operations together in an electrolytic bath by adding what are termed "quick formation re-agents." As examples of such bodies, nitrates, acetates and chlorates may be mentioned. These re-agents, under the influence of the current, attack the lead, probably forming somewhat unstable lead compounds, which are at once converted by the further action of the current into PbO_2. Thus a good Planté formation is obtained in a comparatively short time.

IV. GENERAL CHARACTERISTICS OF PLATES

§ (10) PLANTÉ PLATES.—Planté negatives are not generally used, as their advantages are not compensated by the additional weight of lead that is entailed. It is otherwise in the case of positives, and consequently Planté positives are employed extensively in stationary batteries where weight is unimportant. Cast lead is commonly used for plates, as this is more readily attacked in the process of formation than rolled lead. Since the capacity depends upon the active area many types of plate have been developed with a view to making the area as great as possible per unit of apparent or nominal surface (*i.e.* the area disregarding indentations), but the type now usually adopted is that which is cast with a large number of grooves, as shown in *Fig.* 4. There is a centre core at A (which is sometimes eaten away during the formation), and there are transverse ribs B at intervals, which give the necessary strength whether the centre core remains or is removed. By using carefully made gun-metal moulds the actual surface may thus become eight to ten times the nominal surface. As many as 40 ribs per inch have been cast in this way, but 30 ribs may be regarded as a more practical limit. A certain thickness of the rib must be left for formation, and if the ribs are very close together the grooves become so filled up with active material that the free circulation of the acid is impeded.

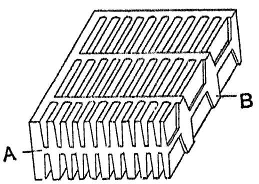

FIG. 4.

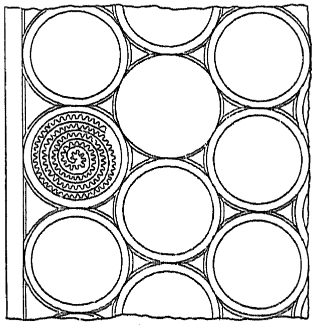

FIG. 5.

One exception to this type of plate has survived and should be mentioned here, namely, the Chloride positive. This is shown in *Fig.* 5. It consists of a grid of antimonial lead having a number of circular perforations. If lead contains a small percentage of antimony its strength is much increased and it is unaffected in the forming bath. The necessary soft lead is in the form of special strip, as seen in *Fig.* 6. This is rolled into spirals, which are fitted into the circular openings in the grid under pressure. The plates are then formed, the formation taking place only on the soft lead spirals.

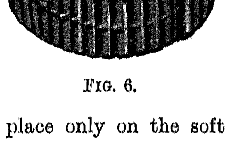

FIG. 6.

§ (11) PASTED PLATES.—The fundamental difficulty in the pasted type of plate is that the paste tends to fall away from the grid, and therefore all grids are made with a view to retaining the paste as completely as possible. Much ingenuity has been displayed in this direction. Broadly, such grids may be classed as (1) those in which the ribs are thicker outside than inside, and (2) those in which the ribs

are thicker inside than on the outside (see *Fig.* 7). Since the positive active material tends to expand, and the negative active material tends to contract, the first type is often used for positives and the second type for negatives, the idea being that the expansion or contraction, as the case may be, will serve to maintain

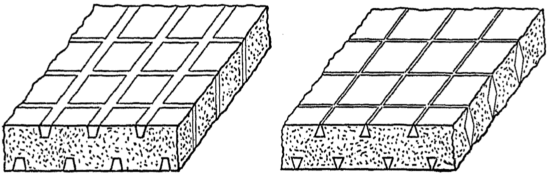

FIG. 7.

contact with the ribs. The grids are always cast from antimonial lead, as it is essential, apart from questions of strength, that they should not undergo formation. From the nature of the construction it follows that pasted plates are much lighter than Planté plates for a given capacity, and they can be made very light for special purposes.

§ (12) SEMI-PLANTÉ POSITIVE PLATES.—What may be described as "Semi-Planté" positive plates are made by taking a thick plate of soft lead, and making grooves or shelves in it such that these will readily hold a paste. Such a plate is shown in *Fig.* 8. They are only given a short formation, and initially they act as pasted plates. In the process of use, however, the supporting lead is acted upon; and, although the capacity of the paste may fall off, further peroxide is formed on the surface of the lead, so that the plate eventually becomes more of a Planté than a pasted plate.

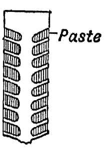

FIG. 8.

§ (13) CHARACTER OF THE ACTIVE MATERIAL.—Difficulties arise in the design, manufacture, and working of plates owing to the inherent properties of the active materials. It may be well, therefore, at this juncture to say something about the often conflicting conditions that have to be met.

From the very nature of the problem it is essential that the active materials should be porous, because the capacity of a plate in ampere-hours depends upon the conversion of a solid material into lead sulphate and the converse change upon charging. Since chemical changes in solids are generally restricted to the surface layers, at least when such changes have to be complete in a few hours, it follows that anything like complete conversion can only take place if the material is very porous. In practice it is improbable that more than about half the active material undergoes the chemical changes, and even so it is difficult to provide for free access for the required quantity of electrolyte.

There is a further consideration which renders high porosity a necessity. Gladstone and Hibbert [1] showed that the E.M.F. of a cell depended on the strength of the sulphuric acid. Their results are given in the form of a curve in *Fig.* 9, from which it will be seen that a change in percentage strength from 20 per cent to 40 per cent entails a rise of E.M.F. from 2·0 volts to 2·1 volts. Now, during the discharge of a cell the acid is being used up and thus becomes diluted within the pores of the active material. The higher the rate of discharge the more will the acid become weakened in this way, and it can only regain its normal strength by diffusion of the stronger acid from the body of the cell. This process leads to a temporary lowering of the E.M.F. on discharge. Similarly, in charging a cell sulphuric acid is set free within the pores of the active material

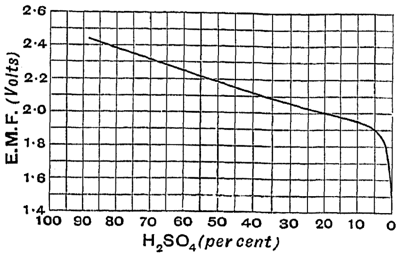

FIG. 9.

and results in the electrolyte being locally strengthened. This again causes the E.M.F. to be increased above the normal value until the strength of acid is reduced by diffusion. It is therefore desirable that the porosity should be sufficient to permit this diffusion to take place readily; otherwise the working of the cell can only be inefficient.

Thus both the spongy lead and the lead peroxide must be porous, but of the two the spongy lead is the more porous and the more yielding. This difference is of some importance, because lead sulphate is more voluminous than either the lead or lead peroxide from which it is formed; consequently the porosity on both plates diminishes on discharge and stresses are set up owing to the desire to expand. Owing to the more yielding character of the spongy lead, the stresses set up in negative plates are less serious than those set up in positive plates. In a positive plate, on the other hand, if there is much more chemical action on the one side than on the other, the stresses on the one side may be sufficient to

[1] *J. Inst. El. Eng.*, 1892, xxi. 412.

cause buckling of the plate, there being a lack of balancing stress on the other side. On this account a cell always contains one more negative plate than positive, so that both sides of every positive plate may be worked equally in charging and discharging. Buckling is practically limited to positive plates and may be caused by over-discharge, resulting in unequal action and more expansion than can be taken up.

Although porosity is of the utmost importance, it is essential that the plate as a whole should have sufficient mechanical strength to ensure a reasonable life. Many methods have been used to secure high porosity, but this has often been attained at the expense of the necessary strength, with the result that a high capacity has been obtained for a given weight but with a poor life, the active material becoming detached from the support or otherwise losing much of its value. For this reason the porous pot form of cell has been attempted more than once, but such cells have always failed to give ultimate satisfaction.

Another point to which considerable attention must be given, more particularly in large cells, is that the lead grids should have sufficient cross-section to carry the current without undue voltage drop. For efficient working and good life it is very necessary that the chemical action should take place evenly over the whole surface of the plate. Now the specific resistance of lead is about 13 times that of copper. It will be seen, therefore, that a serious drop in voltage for a given current is much more readily obtained with lead than with copper conductors, and that insufficient lead in the grids will lead to the chemical action taking place near the lug where the current is collected from the plate in preference to the more distant parts.

§ (14) Box Negatives.—Plates lose their capacity through the porosity of the active material becoming less and through loss of contact with the grid. Also an actual shedding of the active material occurs as the cell is used. As already mentioned, the spongy lead is more yielding than lead peroxide, and is liable to contract. For these reasons, what is known as the box type of negative has been introduced. As seen in *Fig.* 10, this consists of a series of small boxes having a top and bottom of perforated sheet lead. The boxes are made in two halves, and for this purpose a perforated sheet of lead is placed in a special mould into which molten antimonial lead is run. This becomes fused to the sheet, and the mould is so made that ribs are thus formed at intervals, running at right angles to one another, making a series of small trays as the final result. If two such trays are placed with the ribs against each other, a small box is formed having a perforated top and bottom. Actually the ribs of one set of trays are made with projecting pins at intervals, and these fit into corresponding holes in the other set of ribs, so that the two can be easily fixed together. Before doing so some unformed paste is placed in each box, and thus when the trays are fitted together we have a plate in which the paste is contained within perforated lead enclosures. This is now formed electrolytically in the usual way. The advantage of this form of construction is that the active material is well supported, and consequently a paste can be used giving very porous spongy lead.

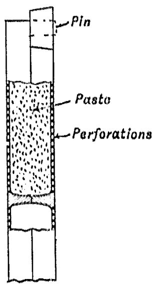

Fig. 10.—Part Section.

There still remains the difficulty of contraction and resulting loss of contact with the lead support, and to provide against this defect it is usual to add a certain proportion of an "expander." An expander is an inert material which slowly expands under the action of the cell and causes the active material to swell somewhat in the course of time, thus maintaining satisfactory contact between the spongy lead and the support. Secrecy is maintained as to the actual materials employed, but it may be mentioned that alumina has been used for this purpose. Expanders may be used in the ordinary pasted type of negative, but in that case care must be taken to avoid too large a proportion; otherwise the spongy lead becomes forced out, as the grid provides no means of yielding such as is inherent in the perforated lead plate of the box negative.

§ (15) Summary of Characteristics of Plates.—It may be said that the Planté positive is more robust than the pasted positive, but there is not the corresponding advantage in the Planté negative. Consequently it is usual in stationary batteries, where weight is of little consequence, to use Planté positives and pasted negatives. Planté positives must be thick to allow sufficient metal for further formation in the course of time through the effect of continued charge and discharge. Thus the positives tend to maintain their capacity. Negative plates, on the other hand, require much less metal, as this is not attacked, but they tend to lose their capacity through loss of porosity and through loss of contact. The negative active material is more porous and more yielding than the positive. The positive active material is more delicate, less yielding, and more subject to stresses which may cause buckling. Negative plates have greater capacity than positives, owing to the greater porosity of the active material. Typical plates by

Pritchett & Gold and Electrical Power Storage Co., Ltd., are shown in *Figs.* 11 and 12.

V. DETAILS OF CELLS

The details here given refer to the larger types of cells used in stationary work.

§ (16) BOXES AND SECTIONS.—First, there is the container or box. The material used for this purpose depends upon the size of the cell. Glass boxes are commonly used for the smaller sizes, and have the advantage that inspection of the plates is facilitated by being able to see through the spaces between the plates. For large cells glass becomes unsuitable, and then antimonial lead boxes may be used, or, more usually, wooden boxes lead lined. Ebonite and celluloid are only used for small portable cells.

A number of plates are used in parallel to obtain the necessary capacity. A set of positive plates or of negative plates for a cell is termed a positive or negative section. The plates are usually cast with lugs which, in the case of glass boxes, rest on the top edges of the box, the plates being thus suspended. Although in small cells plates sometimes rest on blocks of wood or porcelain at the bottom of the box, suspension from the top is much preferable, because this leaves a free space in which detached active material may collect without touching the plates. If this touches the plates it provides an internal leakage path, the material being more or less conducting, and the cell then fails to retain its charge satisfactorily. In the case of lead-lined boxes two vertical sheets of glass are placed in the box, one on each side, and the lugs rest on these above the lead lining. This is shown in *Fig.* 13, illustrating a battery by the Hart Accumulator Co., Ltd. The lugs of the positive plates are welded, or "burnt" on as it is termed, to a lead terminal bar, thus forming the positive section. Similarly, the negative plates are connected together, forming the negative section.

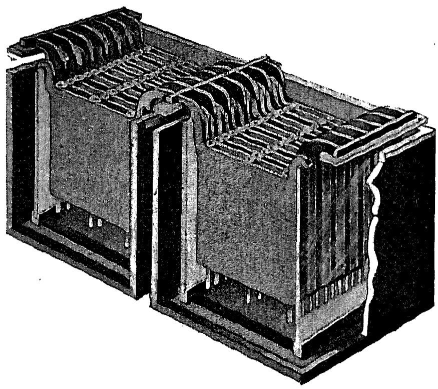

FIG. 13.

When cells are used in series as a battery the positive bar of one cell is connected to the negative bar of the next, the method of connection depending on the size of the cells. In the case of the smaller sizes the lugs of the terminal bars may be bolted together, brass bolts with lead-covered heads and nuts being

preferably used for this purpose. But if the cells are large the connections are made by lead burning. Up to a certain size the ends of the bars may be connected together, but in the largest cells the individual plates are placed in position in the cells, and the lugs of positive and negative plates in adjacent cells are burnt on to a common connecting bar between them, so as to reduce the resistance of the connection as far as possible. The general arrangement will be followed from *Fig.* 13.

§ (17) SEPARATORS.—It is desirable to place separators between the plates to prevent accidental contact and short-circuits. Ebonite is sometimes used for this purpose in small portable cells. In large cells the distance between the plates is usually about ½ inch, and glass tubes standing vertically on the floor of the boxes have been extensively used as separators. The objection to this method is that detached active material may sometimes form a bridge between the plates, more particularly when the plates are not quite true, and where consequently the distance between plates may be reduced considerably here and there. This difficulty has been overcome by the use of the wood board separator, which consists of a thin sheet of wood about the same size as the plates. *Fig.* 14 shows a separator

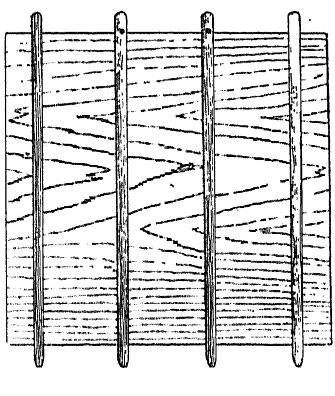

FIG. 14.

of this kind as used by Pritchett & Gold and E.P.S. Co., Ltd. It is carried by wooden dowels and is suspended from the tops of the plates, or is supported by the dowels resting on the bottom of the box. Thus internal short-circuits are almost impossible. A soft wood is used in making these separators, and it is subjected to special treatment, so that such bodies as acetates, which would be harmful to the plates, are removed. Such separators do not materially increase the internal resistance.

The tops of the plates in open cells are generally covered by loose sheets of glass. These are termed "spray arresters," and serve to arrest the acid spray which is given off at the end of a charge when a good deal of gas is being evolved through the decomposition of the electrolyte.

§ (18) ELECTROLYTE.—The electrolyte is dilute sulphuric acid, of specific gravity 1·200-1·215 when the cell is fully charged. On discharge the specific gravity falls to 1·170. These results refer to stationary cells. Pure "Brimstone Acid" should be used (*i.e.* acid made from sulphur), as acid made from pyrites may contain harmful impurities. Water is required at intervals for supplying the loss due to evaporation and gassing, and for this purpose distilled water should be used. Ordinary water leads to the gradual introduction of salts which may be harmful. Rain water may be used, but in towns this contains ammonia, and the accumulation of this impurity, beyond a certain figure, may lead to loss of capacity in the negatives and to abnormal growth in the positives. For the same reason condensed steam from steam pipes is not desirable.

§ (19) EFFECT OF IMPURITIES ON THE PLATES.—The effect of metallic impurities on the plates depends upon whether the impurities are electro-positive or electro-negative to the plate in question. There are four cases to be considered, but only two of them are important, namely, where the impurity is electro-positive to lead peroxide, or electro-negative to lead. These two cases will be followed from *Fig.* 15.

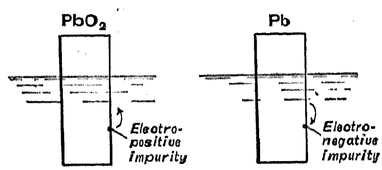

FIG. 15.

The effect is simply one of local action (as described in the article on "Primary Batteries"). On the positive plate, if the impurity is electro-positive to lead peroxide, a local current will flow as shown, the impurity will dissolve, the surrounding lead peroxide will be reduced by the resulting hydrogen, and lead sulphate will be formed. In the case of the negative plate, if the impurity is electro-negative to lead, the local current will be in the opposite direction, hydrogen being deposited on the impurity, and the surrounding lead will be converted into lead sulphate. In both cases it may be said that the plates become more or less discharged. Arsenic, copper, lead, iron, and zinc are electro-positive to lead peroxide; arsenic, copper, and platinum are electro-negative to lead. Platinum is particularly harmful. Many impurities

may find their way into the cell by the electrolyte, as already stated, and some may be introduced in the lead. As a commercial metal, lead is generally fairly pure, but it may contain copper, iron, arsenic, zinc, etc. Of these, iron and copper are the most harmful.

Impurities may also be introduced by the positive plates if manufactured by a quick formation process, and if the quick formation reagent is not thoroughly washed out. If such a reagent is introduced it gives rise to further formation and abnormal growth of the positives.

VI. Capacity, Efficiency, and Working

§ (20) Capacity.—The capacity of a cell is expressed in ampere-hours, and is the number of ampere-hours which it gives on discharge. If a cell is discharged at a constant current such that the commercial discharge is complete in, say, 10 hours, it is said to be discharged at the 10-hour rate; if in 5 hours, at the 5-hour rate, and so on. Before capacity can be defined it becomes necessary to decide when the discharge must be considered to be at an end. Experience has shown that there is a point beyond which it is undesirable to go, and this point is given by the potential difference at the terminals of the cell. This, of course, varies with the current; and therefore the value of the current, as given by the discharge rate, must be taken into account in fixing any limit. The limits fixed by the Tudor Company are as follows:

10-hour rate	1·83 volts per cell		
5 ,,	1·82	,,	,,
3 ,,	1·80	,,	,,
2 ,,	1·78	,,	,,
1 ,,	1·75	,,	,,

Notwithstanding the fact that the voltage limit is lower as the current is increased, the capacity falls off as the rate of discharge is raised. The figures obtained in practice are somewhat as follows, taking the capacity at the 9-hour rate as 100:

Rate of Discharge . .	9 hr.	6 hr.	3 hr.	1 hr.
Capacity	100	90	73	50

At the 1-hour rate the capacity is only about half that at the 9 or 10-hour rate.

Curves of discharge at four rates are given in *Fig.* 16. The E.M.F. cannot be taken as an

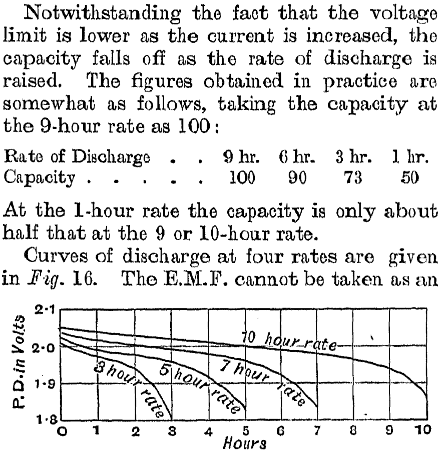

Fig. 16.

indication of the state of a cell, because this varies but little when a cell is not giving current. Immediately after charge the E.M.F. may be as high as 2·4 or even 2·6 volts, but this rapidly falls to a value between 2·05 and 2·1 volts.

§ (21) Efficiency.—The efficiency of a cell can be defined in two ways: (1) Quantity, or ampere-hour, efficiency, which is the ratio of the ampere-hours obtained on discharge to the ampere-hours required on charge; (2) Energy, or watt-hour, efficiency, which is the ratio of the watt-hours obtained on discharge to the watt-hours required on charge. Losses are due to (1) internal resistance, which, however, is small; (2) polarisation, which is comparatively unimportant; (3) low E.M.F. on discharge and high E.M.F. on charge due to changes in acid concentration in the pores of the active material; (4) gassing at the end of a charge. Curves of charge and discharge are given in *Fig.* 17 for one particular rate. It

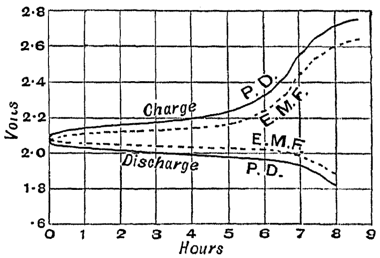

Fig. 17.

will be noticed that the variation of the P.D. is greater than that of the E.M.F. The effect of the first three losses mentioned above is to make the P.D. on charge considerably higher than the P.D. on discharge, and this is where the main energy loss is found. As the rate is raised this difference becomes greater and the efficiency becomes lower.

In testing for efficiency, the maker's limits are taken for the end of the discharge. The corresponding point of cut-off on the charge curve is taken where the curve begins to rise rapidly, *i.e.* where gassing begins to be serious, or where the current is beginning to decompose the electrolyte instead of doing useful work. Constant current is used in both charge and discharge. It is necessary to repeat the tests under identical conditions until the same results repeat themselves, because the results depend upon the previous history of the cell, and if this precaution is not adopted it is possible to obtain a figure for quantity efficiency above 100 per cent.

A distinction must be drawn between efficiency determined in the laboratory and efficiency under working conditions. In the laboratory the quantity efficiency should be about 98 per cent, but in practice this becomes 90-95 per cent. This lower figure is due to the

fact that considerable gassing is necessary if cells are to be kept in condition. Similarly, in the laboratory the energy efficiency is about 85 per cent, which in practice drops to about 75 per cent.

§ (22) WORKING.—In ordinary use it is essential that cells should not be left in the discharged condition, nor discharged below the prescribed voltage limits, because under these conditions the normal lead sulphate changes to a form which is not easily reduced, and the plates are then said to be "sulphated." The precise nature of this change has not been discovered.

The usual indications by which the state of a cell is judged are the specific gravity of the acid and the potential difference. The specific gravity shows a certain lag due to diffusion from the pores of the active material. In practice it is essential that both plates should gas at the end of a charge and that this gassing should continue for half an hour or more, say once a fortnight.

A very useful means of determining whether the positive or negative is at fault is to use a stick of cadmium as a third electrode. This method renders it possible to study the behaviour of both plates separately and compare the results with those of cells which are known to be normal.

VII. SPECIAL CELLS

§ (23) CELLS FOR AUTOMOBILE WORK.—If cells are to be used for driving automobiles or for aeroplane work the reduction of weight becomes of great importance. This is secured in two ways: (1) by reducing the weight of the plates, and (2) by reducing the volume of the electrolyte. The weight of plates is reduced by using pasted plates for both positives and negatives and by making them as thin as possible consistent with the desired life. Plates have been made as thin as $\frac{1}{16}$ inch, but for use on automobiles they must be somewhat thicker.

It is, of course, essential that the normal quantity of H_2SO_4 should be retained, but the water may be considerably reduced with a corresponding saving in weight. This means that the range of specific gravity over which a cell works must be increased. The normal reactions do not take place if the specific gravity is below 1·100 or thereabouts; and if it is above 1·300 the acid acts directly upon the negative plates to a serious extent, giving so-called self-discharge. A range of, say, 1·140-1·280 is practicable.

By adopting these measures much lighter cells may be made. Their effectiveness from this point of view is best expressed in terms of "specific output," or as watt-hours output per lb. of complete cell for a stated rate. The best that can be expected is about 14 watt-hours per lb. at the 5-hour rate, but this figure falls off during the life of the cell somewhat seriously.

§ (24) THE "IRONCLAD EXIDE" CELL.—A special type of cell has been developed by the Chloride Co., and is termed the "Ironclad Exide" cell to emphasise its strength, not as an indication that iron is an element in its construction. The essential feature is the positive, which is made up of an ebonite cylinder with a lead core, the space between being packed with the positive active material, as shown in *Fig.* 18. The ebonite cylinder has a large number of fine saw cuts on each side, so that it acts like a porous pot, permitting the chemical actions to take place, but keeping the delicate active material in position. A positive plate is made by fitting a number of these elements into a lead frame, each end of the lead core being burnt to the frame. The negative is an Exide pasted plate of the usual type. Satisfactory results have been obtained with this cell, which is largely used in automobiles, being more robust than the usual type.

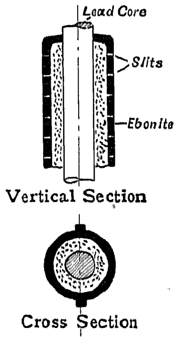

FIG. 18.

§ (25) THE "BIPOL" CELL.—This cell, which is due to H. Leitner and W. H. Exley, is of interest, as it introduces a novel principle. The plates are built up on a wooden frame, the wood being recessed, as seen in *Fig.* 19. In each recess is a lead spiral, and the recesses are filled with paste under pressure. Thus the paste is retained by the wooden structure, but the spirals form, as it were, the conducting grid. Also the paste on each side of the centre web is keyed by having holes through the web. Further, the paste in the grooves is alternately positive and negative, and the spirals of alternate grooves are connected together. The result is that every plate is half-positive and half-negative. The positive portions act with the adjacent negative portions, and as the distance between the two is quite small a low internal resistance is secured. Also very even action is ensured throughout the plate, because

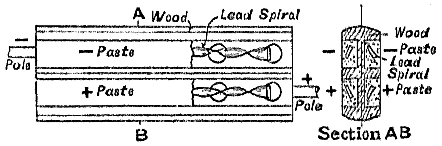

FIG. 19.

every positive portion has a negative portion near to it.

B. The Iron-nickel or Edison Cell

§ (26) *The Iron-nickel or Edison Cell.*—The iron-nickel cell has not been examined theoretically to anything like the same extent as the lead cell. The name of Edison has been chiefly associated therewith, but E. W. Jungner has also worked for years successfully at this subject. The cell has been developed with a view to a high specific output.

Taking the main constituents, it may be said that the charged cell consists of a positive having an oxide of nickel as the active material, a negative with iron as the active material, and an electrolyte of potassium hydrate dissolved in water. The exact formula of the nickel oxide does not appear to have been completely established, but as an approximation we may suppose that it is NiO_2, or the hydrated form $Ni(OH)_4$. The action is more readily seen if the hydroxides are taken, and it may then be represented by *Fig.* 20. On discharge the OH ions of the KOH go to the negative, so that the iron becomes oxidised, and the K ions go to the $Ni(OH)_4$, reducing it to $Ni(OH)_2$. On charge the converse change takes place. As a chemical equation this may be written

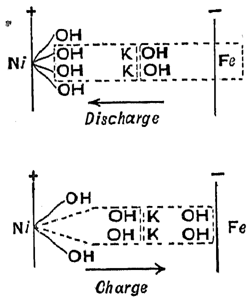

FIG. 20.

$$Ni(OH)_4 + KOH + Fe \rightleftarrows Ni(OH)_2 + KOH + Fe(OH)_2.$$

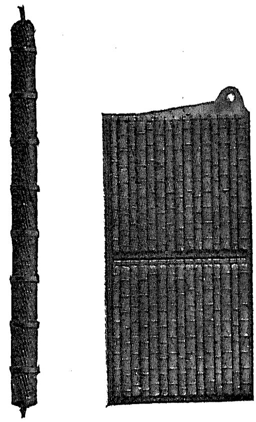
From these considerations an important fact at once becomes evident, namely, that the electrolyte as a whole remains unchanged; it acts merely as a vehicle for the transfer of OH from one plate to the other, and consequently the charge and discharge are not accompanied by any change in specific gravity of the electrolyte.

§ (27) Construction of the Edison Cell.—In practice the electrolyte consists of a 21 per cent solution of potassium hydrate, to which is added a certain percentage of lithium hydrate. The action of the latter is not understood, but it has the effect of materially increasing the capacity. This point has been investigated by L. C. Turnock.[1] It is stated that the amount normally used is 50 grammes per litre.

[1] *Am. Electrochem. Soc. Trans.*, 1917, xxxii. 405.

All the metal parts of the Edison cell are made of sheet steel, nickel plated, and as nickel has a tendency to peel off, the sheets are heated up to a high temperature so as to ensure combination between the steel and the nickel.

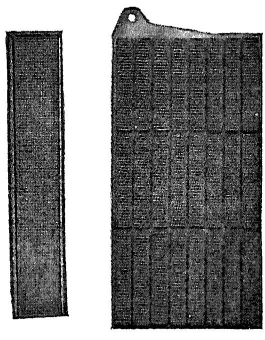
The positive plates consist of 30 tubes held in a nickelled steel frame. The tubes themselves are made from very finely perforated strip of nickelled steel, which is spirally wound and reinforced with steel rings at intervals. The tubes are about four inches long and a quarter of an inch in diameter. They are filled with nickel hydroxide. This material, however, is a rather poor conductor, and consequently thin layers of flake nickel are inserted at intervals. There are over 300 of these double layers, highly compressed, in each tube. The arrangement will be understood from *Fig.* 21.



Tube. Positive Plate.

FIG. 21.

The negative plate is somewhat similar, but in place of tubes 24 flat pockets are used, as seen in *Fig.* 22. The latter are made from finely perforated nickelled steel strip and are filled with specially prepared iron oxide. Here again the conductivity of the oxide is not sufficiently good, and it is therefore improved by incorporating a little mercury. When the pockets are filled they are corrugated, which has the effect of increasing the rigidity and of forcing the metal into close contact with the contents.



Pocket. Negative Plate.

FIG. 22.

Two steel terminal posts are used, having transverse bolts, and upon these are bolted together as many positive and negative plates respectively as are required. The plates of like sign are separated by washers on these

bolts, and the plates in the two sections are kept apart from those of opposite sign by ebonite strip separators. Two end-insulators are provided, so that the whole forms a unit, as seen in *Fig.* 23. This is now inserted in a nickelled steel container. The terminal posts are brought through insulating glands in the cover, and the latter is welded into position. A spring valve is fitted between the terminals, as seen in *Fig.* 24, so that any gas generated can escape, and water or electrolyte can be added. An extremely mechanical arrangement is thus obtained. If cells are connected up to form a battery they are usually mounted in trays so as to keep the containers (being metal) from touching one another.

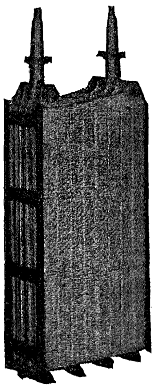


FIG. 23.

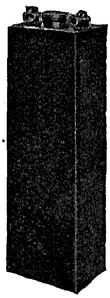

FIG. 24.

The plates are formed by giving the cell a prolonged charge.

§ (28) CHARACTERISTICS.—The E.M.F. of the Edison cell is about 1·4 volt. Upon discharge the P.D. drops continuously and the discharge is considered complete at the 5-hour rate when the P.D. reaches 1 volt. The average P.D. at this rate is about 1·2 volt. From *Fig.* 25 it will be seen that the drop is more continuous and a larger percentage of the initial P.D. than in the case of the lead cell. Charging at constant current is carried out with the same value of the current as in discharging at the 5-hour rate, but the charge is continued for 7 hours. The fall, after the initial rise, which is noticeable in the charge curve is due to the cell warming up, with consequent fall in the resistance of the electrolyte. At the end of the charge the P.D. becomes steady at about 1·84 volt per cell. Since there is no variation in the specific gravity of the electrolyte the state of the cell is judged by the value of the P.D.

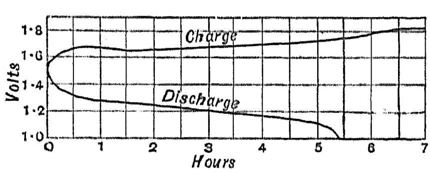

FIG. 25.

The quantity efficiency at the normal 5-hour rate as here described varies from 75 to 80 per cent, and the energy efficiency varies from 55 to 60 per cent. The low efficiency is largely due to decomposition of the electrolyte, which is noticeable even at the beginning of a charge and is very marked at the end. The specific output may be 15 watt-hours per lb., or higher for large-size cells, and the figure is maintained, as the capacity tends to increase when the cell is in use, and this continues for a much longer period than in the case of the lead cell. On the other hand, the watt-hours per cubic foot of space occupied are lower. The internal resistance is higher, potassium hydrate not being such a good conductor as sulphuric acid.

The variation of capacity with rate of discharge is comparatively small, and therefore the number of ampere-hours taken from a cell may be taken as an approximate measure of the extent of discharge under varying conditions.

The electrolyte is kept from carbonating by the container being practically air-tight. Owing to the decomposition during charging it is necessary to add distilled water frequently, but a special device has been developed to facilitate this operation.

The cell is particularly robust, both mechanically and electrically. It may be left in the undischarged state, short-circuited, and charged at high rates. These features, coupled with the high specific output, have caused the Edison cell to be adopted largely for driving electric vehicles.

W. R. C.

BATTERY SWITCH: a switch used to control a number of accumulators. See "Switchgear," § (15).

BECK ARC: a high-intensity arc with the positive carbon rotated and surrounded with methylated spirit vapour. See "Arc Lamps," § (6).

BECQUEREL EFFECT: a change in the electrode potential caused by illuminating the electrode surface. See "Photo-electricity," § (4).

BELLINI-TOSI SYSTEM: an arrangement of receiving apparatus which permits of the determination of the direction from which signals come. See "Wireless Telegraphy Transmitting and Receiving Apparatus," § (11).

"BIPOL" CELL: a special type of lead cell, due to Messrs. H. Leitner and W. H. Exley, having a low internal resistance and very even action throughout the plate. See "Batteries, Secondary," § (25).

CABLES, INSULATED ELECTRIC

Although it is generally recognised that the physical problems connected with the design and manufacture of electric cables are fundamentally bound up with chemical considerations, the interdependence of electrical properties on these relations is not so clearly appreciated.

For example, with regard to conductor materials, the pure metals are better conductors than alloys; and when, by alloying, better physical properties are sought than a given pure metal affords, it is invariably found that such improvements can only be attained at the sacrifice of conductivity.

Again, in dielectric materials, chemical composition (assuming great purity and stability), in conjunction with physical structure, largely determines the degree of excellence of their electrical qualities. Being complex bodies, however, these relations are less direct and simple than in the case of metals; and, as in the familiar case of vulcanised rubber, the chemical composition—as determined by the mechanism of the vulcanising reaction—may be beneficial from both physical and electrical standpoints or advantageous to the one and deleterious as regards the other.

The simple case of conductor materials has been fairly exhausted in the course of production of commercial conductors fulfilling the maximum mechanical requirements compatible with high conductivity, but an enormous amount of work remains to be done in the highly (chemically and physically) complex substances capable of being used as cable dielectrics.

§ (1) Conductors.—With regard to conductor materials commercially admissible for insulated wires and cables, copper occupies the premier position. Its high conductivity not only allows it to be rated at a high current density for a given voltage drop—in other words, the loss incurred in transmitting a given amount of power through it is small compared with that entailed by the use of other commercial metals—but also tends to economise the costly dielectric and protective coverings by reason of their being applied at a radius which is smaller than in the case of a metal of lower conductivity. For purely conductive purposes its only serious rival is aluminium, which, however, requires to have a diameter 28 per cent (or 64 per cent sectional area) in excess of that of copper for equal resistance or a given voltage drop.

This, from the competitive point of view, is largely counterbalanced by its lower specific gravity—2·71 against 8·89 for copper—and, assuming conductivity alone is concerned, the choice largely resolves itself into a matter of relative market prices, although the costs of other components of the complete cable have a bearing on the matter.

There are, however, a number of pros and cons in the case from other standpoints to

which space only permits brief reference. Some of these are of a technical character, while others relate to cable design, and others again to cost considerations entailed by the larger diameter of aluminium cable for a given duty. Technical considerations relate chiefly to the jointing of conductors, which is difficult in the case of aluminium on account of its great affinity for oxygen, which renders soldering—an easy and efficient process in the case of copper—almost impossible, recourse having usually to be made to mechanical joints. The highly electro-positive relation of aluminium to most of the common metals also necessitates careful protection of junctions with them from air and moisture. With regard to design the larger diameter of aluminium is in some cases not a disadvantage, *e.g.* where limitations of dielectric stress [1] demand a conductor radius which is greater than current-carrying capacity requires.

The cost considerations referred to concern cases where the diameters of ducts, or the size of joint boxes, feeder pillars, and fittings are appreciably increased by the use of aluminium.

It is comparatively seldom that tensile strength considerations are predominant in insulated cables, this being, in large cables, sufficiently provided by steel wire armouring. In small cables, where this necessity arises, steel wire is used, either stranded up with the copper conductors or in the form of a suspension strand embodied in the cable, otherwise than as a conductor.

The conductivity of steel wire is, however, of some considerable importance apart from such special cases, because even when its primary function is the mechanical protection of a cable, it should, for reasons of safety and efficient maintenance, form part of a complete earthed circuit. (According to the Home Office Regulations regarding the installation and use of electricity in mines, under the Coal Mines Act of 1913, the effective area of the metallic sheath of any cable has to be equal to 50 per cent of that of the largest conductor contained therein.) For the same reason the conductivity of lead as used for cable sheathings is of interest. Moreover, it is sometimes, in the case of certain concentric systems in which the outer conductor is earthed, used to supplement the latter by carrying a proportion of the working current.

The average specific resistance of steel wire of the kind generally used for armouring purposes is about 7·75 times, and that of lead about 12 times, that of annealed copper.

Phosphor bronze is sometimes used as an insulated conductor, when considerable strength, combined with high conductivity, is required, but on the whole shows little, if any, general economy as compared with hard-drawn electrolytically refined copper.

† Fleming and Dewar, *Phil. Mag.*, Sept. 1893.

Zinc has been used in Germany during the recent European War as an emergency substitute for copper, and while there is no likelihood of its continued use under conditions even approximately normal (its specific resistance being about three and a half times and its strength only about a third of that of copper, and its low melting-point—420° C.—practically precluding soldering of joints), it is interesting to note that it was for the first time commercially produced in wire form by extrusion of the metal in the form of rods which were afterwards drawn down in the usual way.

Magnesium and the magnesium-aluminium alloys are somewhat attractive from the point of view of conductivity for weight, but there are considerable difficulties in the way of their use in insulated cables.

The table above shows some of the properties of the metals referred to.

[1] See "Dielectrics," §§ (2-4).

§ (2) Dielectrics.[1]—The general suitability of a dielectric material for a given purpose clearly depends on its electrical, chemical, and physical properties.

The interdependence of these properties—as mentioned at the commencement of this article—is not clearly understood or appreciated.

Moreover, it is exceedingly difficult to indicate in a brief and comprehensive manner their relations.

Naturally, electrical properties are of primary importance, and these are affected by chemical composition and physical structure, these in turn being interrelated.

As an example of the former, hydrocarbons have vastly better electrical properties than carbohydrates or proteins, *e.g.* the phosphoprotein, casein.

As an instance of the latter, rubber, vulcanised in the ordinary way by the agency of sulphur and heat, may have the mechanism of its vulcanising reaction varied by the introduction of small quantities of different metallic oxides, with the effect that its physical structure will also vary; corresponding differences will be found in its electrical properties.

Chemical properties affect the durability of the dielectric material and its general stability under working conditions, normal and abnormal.

Physical properties are closely allied to chemical properties, in that they are largely dependent on chemical composition, which (in conjunction with manipulative treatment) determines physical structure.

The mechanical requirements of the conditions of manufacture and usage of an electric cable determine the minimum radial thickness of dielectric, and this is clearly dependent on the physical limitations of the dielectric material.

In practice it is almost invariably the case that when the requirements regarding dielectric strength are low, *i.e.* in all low-pressure cables, the necessary electrical properties are amply provided when the mechanical requirements are fulfilled.

The fundamental importance of the physical properties of dielectric materials is therefore obvious.

It must be premised that commercial considerations have a considerable over-all bearing on the subject of dielectric materials, and that, in what follows, only permanent dielectrics are under discussion, as distinct from "coverings" permeable to moisture, such as cotton coverings used for dry indoor work, *e.g.* bell, telephone, telegraph, and analogous work at very low voltages, and usually under intermittent conditions of use.

The resultant effect of all the ordinary considerations which enter into the matter is that present-day dielectric materials are practically confined to gutta-percha, vulcanised rubber, vulcanised bitumen, paper, and varnished cambric.

[1] See also "Dielectrics."

Neither of these approximates to an ideal material, and hence their applications are more or less confined to different spheres of usefulness, or their disposition in the cable has to be varied in accordance with their physical or other limitations.

Commercially it is much more feasible to aim at the lower ideal of a reasonably perfect material (combined with suitable methods of utilisation and disposal) for one general set of conditions of use than to strive after an ideal material which would fulfil all conditions.

General consideration of the properties of the above-mentioned materials reveals the first broad distinction, viz. hygroscopic as distinct from water-resisting or non-hygroscopic material.

Gutta-percha is the best representative of the latter class, whereas paper and varnished cambric (or, in fact, any fibrous materials) are hygroscopic to an extent which, under practical conditions, requires the protection of a homogeneous waterproof covering, such as lead sheathing.

Thus the detailed construction of the various types of cable depends on the dielectric material employed.

A further broad distinction is that, as conditions of manufacture, transport, and installation (apart from special requirements of use) demand that cables should be more or less flexible, so that they may at least be coiled and uncoiled without injury, the dielectric materials have either to possess natural flexibility, as in the case of gutta-percha, indiarubber or vulcanised bitumen, or be so subdivided and applied (*i.e.* cut into strips and spirally wound around the conductor, as in the case of paper or varnished cambric) as to compensate by such disposition for lack of that physical property.

Moreover, it is practically essential from the manufacturing point of view that the materials which possess inherent flexibility should be capable of being reduced to a suitable state of plasticity in order that they may be rolled into strips or shaped and extruded in cylindrical form around and enclosing the conductor. For manufacturing reasons also they must possess considerable cohesion and—at least when warm or when freshly cut—natural adhesion under mechanical pressure. Fortunately they do, at some stage or in some condition which can be taken advantage of in manufacture, possess such physical properties. Unvulcanised rubber strips, for example, can be butt welded in the cold by pressing freshly cut edges together and hammering in a manner comparable with welding white-hot iron strips.

With regard to physical properties demanded by conditions of use, these flexible non-hygroscopic materials require to possess resilience or toughness, or a modicum of each, in order to resist deformation.

Vulcanised rubber possesses a maximum of the former property, gutta-percha a maximum of the latter but a minimum of the former, especially at slightly elevated temperatures, such as 80° to 100° C.

Vulcanised bitumen is in an intermediate position, being tough and showing little resilience at 15°-20° C. (even approaching a hard brittle state at a few degrees below the freezing-point of water), but at 50°-70° C. becomes very resilient and loses its toughness, its behaviour under mechanical stress being then roughly comparable with that of a gelatinous body.

Paper and woven fabrics, such as form the foundation of varnished cambric (and of the treated tapes used for the protection or reinforcement of the non-hygroscopic dielectric materials), possess certain flexibility. In paper this is comparatively small, the flexibility of the dielectric as a whole being attained by the relative movement of the convolutions, *i.e.* by their sliding on each other; in varnished cambric, largely by the relative movement of warp and weft of the woven fabric; and in tape coverings partly by this and partly by distortion of the underlying compressible dielectric material.

In connection with the case of varnished cambric, it is worthy of note that the varnish films are invariably less extensible than the fabric and are therefore very liable to be broken up by undue extension of the latter, with considerable detriment to the electrical properties of the whole dielectric.

It is necessary, in order to be able to form a clear view of the relation of properties to uses of dielectric materials, to take into account some of their chemical characteristics. For instance, gutta-percha is liable to oxidation when exposed to air and light, and as above-ground conditions entail such exposure as well as risk of moderately elevated temperatures—which as already noted are physically detrimental to it—it is fortunate that its particularly good non-hygroscopic qualities permit its excellent electrical properties to be taken advantage of under conditions which do not entail its exposure to the above-mentioned deleterious factors, *i.e.* for under water-purposes, such as submarine telegraph work.

Pure unvulcanised rubber, such as produced from the latex of *Hevea Brasiliensis*, having a low resin content, and preserved from enzyme action, etc., by smoke coagulation, is a very stable material under ordinary atmospheric conditions. Its physical structure is such, however, that it will absorb appreciable quantities of water (as received from Para in laminated ball or "biscuit" form, it contains 16-20 per cent by weight of moisture). Its use as a dielectric material is therefore limited. When compounded and vulcanised it is rendered non-absorbent. Like gutta-percha it is susceptible to the action of sunlight, a remarkable feature being that, while the ultra-violet rays have a detrimental action, certain rays corresponding to the blue-green portion of the spectrum have a strengthening action on newly formed sheets of pure rubber.[1]

The chemical stability of vulcanised rubber is variable, primarily because the production of "soft rubber" goods—under which category rubber dielectrics fall—is dependent on the arresting at a suitable stage of a chemical reaction which is incomplete. Ebonite might for the sake of illustration be regarded as the "saturated" product of such a reaction, although such a description is not complete without reference to the proportion of vulcanising ingredients.

In addition to this the quality and proportion of the raw rubber, the skilful design of the rubber "mixing," and its suitable vulcanisation are important factors in determining its rate of natural deterioration and its susceptibility to atmospheric and other deteriorating influences.

Among the latter an important source of deterioration is the catalytic "oxygen carrying" effect of copper conductors on rubber in contact with them, which happens when the tin coating on them is weak or damaged.

This is, of course, primarily a superficial action, just as is the oxidation of the external surface of rubber by exposure to air at high temperatures, or the chemical action of acid fumes, etc., and although the gradual penetration of such action is slow, it must be remembered that the attack on both sides of such a comparatively thin sheet of rubber as an ordinary thickness of dielectric represents is a severe condition.

Distinct from this, however, is the kind of autoxidation or deterioration of the mass which may arise either from the so-called "after vulcanisation" effects or from bad design of the rubber compound.

The latter may be taken to include the use of organic adulterants, or unskilful proportioning of the ordinary legitimate inorganic compounding ingredients and vulcanising agents.

The chemistry of this matter is rather complicated and somewhat obscure, and cannot be adequately referred to here. The mass deterioration above mentioned, however, may be regarded as resulting in weakening of the physical structure due to chemical

[1] Patent No. 23727/10 Beaver and Claremont.

decomposition or rearrangement of the original molecular state.

The "after vulcanisation" effects above mentioned are not usually very clearly distinguishable from those more palpably due to the use of unsuitable materials, but in so far as they are more liable to occur when an excess of uncombined sulphur is present in the rubber (some free sulphur always exists) their cause may be regarded as closely related to bad composition design.

In general, all vulcanised rubber compounds are more or less susceptible to this mass deterioration, which is commonly accepted as a natural occurrence.

Given moderately good design and suitable vulcanisation treatment, however, it is generally greater in low-grade rubber compounds, *i.e.* containing comparatively small percentages—say 25-35 per cent—of rubber, than in those containing 50-70 per cent, the former obviously consisting, from the physical aspect, of a more extended network of rubber substance—holding a large amount of more or less amorphous matter—than the latter; in which, moreover, the proportion of non-rubber substance is small enough to be largely composed of materials which to some extent enter into the vulcanising reaction, resulting in a more than proportionately homogeneous mass.

Apart from chemical analysis—interpretation of the results of which is difficult, even in expert hands—the susceptibility to these forms of deterioration is judged in ordinary commercial practice by large buyers, by means of standard physical tests consisting of heat treatment in air and in steam.

Vulcanised bitumen is remarkably inert to ordinary atmospheric influences and to acids. It is, however, somewhat susceptible to the action of alkalies, although in the ordinary cases of exposure—of which the water of coal mines in this country may be taken as typical—such action is slight and superficial. If, however, as the result of leakage from an incipient fault, alkaline matter is produced by electrolytic decomposition of water at the virtual negative electrode of the leakage circuit, the action is such as to convert the material into a structureless mass of the consistency of clay or mud.

Another type of action, in which leakage current is a factor, first investigated and described by the author,[1] results in the conversion of the normal resilient non-meltable rubber-like state to a condition resembling that of soft pitch, possessing no resilience and readily liquefiable by heat.

Apart from these actions which arise from unsound electrical conditions, however, the material is, as stated above, remarkably inert, and is practically free from the mass deterioration to which vulcanised rubber is more or less naturally susceptible, the above mentioned actions being quite local.

Paper is normally an exceedingly durable material, but may vary in this respect according to the character of the fibres of which it is composed and the methods of preparing them for the paper-making process.

The fibrous composition may vary from pure cellulose, represented by bleached cotton, to mechanical wood, the cellulose content of which is of the order of 45 per cent to 62 per cent, depending on the botanical origin of the wood.

Chemical wood, prepared by the sulphite process, is sufficiently freed from non-cellulose substances (lignone) by the treatment, to have a cellulose content of 80-90 per cent, although this partakes to some extent of the character of oxycellulose, which has less resistance to oxidation and other chemical changes than pure cellulose.

Given careful manufacture, however, and freedom from residual chemicals, very strong and durable paper may be made from chemical wood, especially if only a moderately drastic chemical treatment is employed and a comparatively low yield of cellulose is acceptable for the sake of a more permanent product.

The difference between the chemical stability of pure cellulose (cotton) or pectocellulose (flax, hemp, etc.) and ligno-cellulose (mechanical wood) is demonstrated by the fact that cotton and flax papers exist which have been exposed to atmospheric influences for hundreds of years without as much deterioration as may occur to a mechanical wood paper (newspapers, for example) in a few months.

The strong durable papers used in cable manufacture have usually been made from the pectocellulose group of fibres, manilla, flax, hemp, etc., but at the present time the shortage caused by the recent European war—large areas now devastated having formerly produced the major portion of the world's supply of hemp and flax—is causing advantage to be taken of the improved products of the chemical wood pulp industry, and mixtures of this class of fibre with manilla and hemp are being largely employed by European cable makers.

The following diagram (*Fig.* 1) illustrates the relative durabilities of similarly made papers of different composition, as indicated by their breaking strengths after various intervals of time when heated at 120° C. *in vacuo*. This temperature was chosen in order to obtain the comparative results within a reasonable time, and not as representing practical conditions. The vacuum—averaging twenty-eight inches of mercury—was maintained in order to prevent undue oxidation

[1] *I.E.E. Journal*, liii., Paper on "Cables."

and to ensure uniform conditions as regards humidity.

In the varnished cambric type of dielectric material, given a pure varnish, fully oxidised

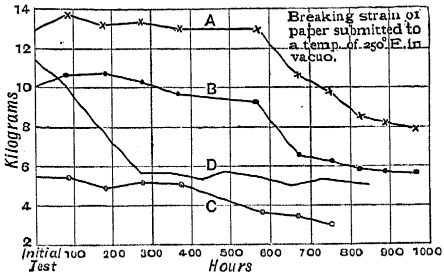

FIG. 1.

Curve *A* represents a pure manilla paper:
,, *B* a mixture of manilla with 50-60 per cent of chemical wood:
,, *C* a pure flax paper: and
,, *D* a paper consisting solely of chemical wood.

to the stage represented by "linoxyn," the product is very durable and resistant to ordinary atmospheric influences, even at the highest temperatures which are permissible for the fabric constituting its foundation. It is, however, susceptible to "superoxidation"[1] when exposed to nascent ozone which may be produced in close proximity to it under conditions of electric stress sufficient to cause static discharges on its surfaces or even in air gaps in the dielectric mass.

The consequent decomposition of the varnish film not only destroys its physical structure, but produces strongly acid bodies which attack and weaken the fabric.

§ (3) CONDITIONS OF USE OF INSULATED CABLES.—These may be divided into (*a*) external and (*b*) internal conditions.

The former chiefly relate to considerations of ambient air temperature, moisture conditions, chemical influences, and so forth. Such conditions or influences are generally countered in various ways, *e.g.* moisture, by impervious sheathings; corrosion, by resistant coverings, etc., and do not necessarily affect the question of the type of dielectric which can be used for a given duty.

The latter (internal conditions) bear more directly on this question, and a brief consideration shows that these conditions differ widely according to the purpose for which a cable is used.

With regard, for example, to heat produced internally, it will be recognised that this is negligible in certain cases for two or three reasons.

Firstly, in telegraph, telephone, and signalling cables not only is the use intermittent, but the current is usually of such low order of average magnitude that the minimum size of conductor which practical conditions render permissible is large compared with the duty.

Secondly, for a continuous small load—as in the case of electric light wires—considerations of minimum size, together with required conditions of voltage drop, keep the current density and the temperature rise low in circumstances where the former could, from the heat dissipation point of view (viz. in small cables), be higher than in larger cables.

Thirdly, in large cables where the current density is fairly high, but still limited by considerations of voltage drop.

In the case of power (feeder) cables, however, not only may voltage drop considerations be comparatively negligible, but in addition to the heat produced by I^2R losses in the conductor, there may be, in very high-pressure cables, additional heating in the cable due to losses in the dielectric.

There is a direct connection in any given dielectric material between the latter and another important internal condition, viz. the electric stress in the dielectric. This only comes into consideration in the case of cables for use at working pressures exceeding a few thousand volts, mechanical considerations (as already indicated) preponderating in the determination of dielectric thicknesses at low pressures, thus keeping dielectric stresses at low values. Heating from this source is therefore a matter of the electrical design of the cable.

§ (4) DESIGN.—In low-pressure cables the dielectric thickness increases with the size of the conductor, but where electric stress considerations predominate, the thickness may decrease as the size of the conductor increases above a critical point which depends on the relation between the working pressure and the maximum permissible stress in the dielectric.[2]

As is well known, in the case of a homogeneous dielectric surrounding a cylindrical conductor the maximum stress is at the surface of the conductor.

If S is the maximum permissible stress in kilovolts per centimetre, E is the working pressure in kilovolts, r is the radius over conductor in centimetres, R is the radius over dielectric in centimetres, and ϵ is the base of Napierian logarithms $=2\cdot7183$, then we find that $S=E/r\log_\epsilon(R/r)$.

It follows that $$\frac{R}{r}=\epsilon^{\frac{E}{Sr}},$$

and that for given values of E and S, R will be a minimum when $E/Sr=1$, *i.e.* when $r=E/S$; in which case $R=r\epsilon=2\cdot7183r$.

[1] Beaver, *Jour. I.E.E.*, 1911, xlvii. 530. Discussion on Fleming and Johnson's Paper on "Chemical Action in the Windings of High-voltage Machines."

[2] See "Dielectrics," § (7).

This ratio for the smallest cross-section of cable for given values of E and S is exemplified in the following diagram (*Fig.* 2), in which various values of r/R are plotted against SR/E, and from which it will be seen that the smallest ordinate has a value of $r/R = \cdot 37$ or $R/r = 2\cdot 7183$.

The permissible value of working stress in a dielectric depends on the margin of safety desired, and on the degree of dielectric heating which is allowable. The dielectric strength of impregnated paper varies in practice between 200 and 300 kilovolts per cm., and the margin of safety is not usually less than 6 or 7. In high-pressure cables considerations of dimensions and weight per length (and consequently of cost) demand that dielectric stresses should be pressed to the highest practicable limit,[1] but it has to be borne in mind that while dielectric losses vary generally as the square of the voltage, they also increase rapidly (above a critical point) with temperature, so

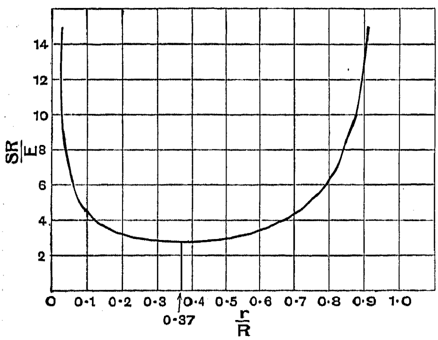

FIG. 2.

that the dielectric heating, superimposed on that due to the I^2R losses in the conductor, is liable to become cumulative, with destructive effects.

The magnitude of the dielectric loss depends, of course, on the power factor of the insulating material.

The following diagram, *Fig.* 3, illustrating the general order of variation of power factor with temperature, is based on average figures given by Still,[2] which agree closely with values determined by Clark and Shanklin[3] at 60 cycles.

Taking the broadest view of design, the cable designer has to primarily consider, in a given case :

(*a*) The requirements entailed by the conditions of use, both internal and external.

(*b*) The intrinsic properties of the available dielectric materials.

(*c*) The compatibility of (*b*) with (*a*).

[1] For data regarding these relations, see the author's Paper on "Cables," *l.c. ante.*

[2] *Electric Transmission of Energy*, p. 224.

[3] *A.I.E.E. Journal*, xxxviii. No. 6, p. 663.

From the foregoing notes regarding properties of dielectric materials, and conditions of use of insulated cables, it scarcely needs

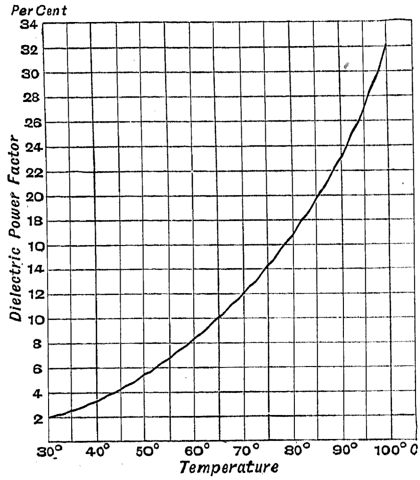

FIG. 3.

pointing out—to take one or two examples—that gutta-percha is never usable for work which entails either internal or external heating, and that on account of its susceptibility to heat and light, and on the other hand its high specific insulation resistance, low specific inductive capacity, and imperviousness to water, its ideal sphere of usefulness is for submarine telegraph work; that vulcanised rubber is best employed where non-hygroscopic properties and moderate resistance to heat is required, and for purposes where its great flexibility, combined with the resistance to mechanical damage, which its strength and resilience affords, is demanded by the conditions of installation and use.

In transmission and distribution cables generally, considerations of cost alone preclude the use of rubber insulation ; and as it happens that the cheaper fibrous (hygroscopic) dielectrics — of which impregnated paper is practically the only type now used for such purposes—have not only superior durability, but also high dielectric strength, low specific inductive capacity and low power factor, the provision of a waterproof sheath, usually lead, is all that is necessary to complete a very efficient type of cable which can be employed almost anywhere in fixed positions, *i.e.* except where portability is a condition of use.

Vulcanised bitumen shares, to a limited extent, as has been already noted, the physical properties of rubber and the commercial advantages of paper insulation ; and although, through lack of appreciation of its limitations and the susceptibilities (previously mentioned)

to certain local deteriorating influences caused by unsound electrical conditions, its employment for ordinary feeder and distributor networks has not been an unalloyed success, its non-hygroscopic character and general chemical stability, together with the advantage in weight which the absence of a metal sheath gives it, renders it a valuable dielectric material for special purposes such as mining work.

Varnished cambric, like vulcanised bitumen, has suffered somewhat in reputation and esteem through non-recognition of its limitations.

Its use, in the early days of electric lighting (in America), without lead sheathing, revealed the fact that its supposed non-hygroscopic qualities were of an insufficient order for ordinary use in underground conduits, and it is not now used for such purposes without being provided with a waterproof sheath.

When so constructed, however, it has no electrical nor commercial advantages over a corresponding paper-insulated, lead-sheathed cable. Its freedom from hygroscopic properties, although falling far short of that of the non-fibrous materials, is of a sufficiently high order to render it suitable for many indoor and protected situations, with the advantage in its favour of not requiring cumbersome and expensive end boxes. Such use will probably be found in the near future in generating and sub-station cabling work, which alone would provide a very wide field for it.

Apart from the pros and cons which determine the type of dielectric, the designer has to consider the construction, proportioning, and assembly of the component parts of cables. These are chiefly dictated by electrical considerations, though with due regard to mechanical requirements.

The former entail not only provision for adequate conduction and insulation, but also for the minimising of losses due to inductive effects between the insulated conductors comprising an alternating current circuit, and between them and metal sheathings or other earthed conductors.

This is accomplished by symmetrical assembly and arrangement of the working conductors in relation to one another and to sheathings, etc.

Thus, in a cable to carry single-phase current, the two conductors are arranged either in twin form with the cores laid up spirally together, or in concentric form with one conductor completely surrounding the other. In a 3-phase cable, the three conductors are laid up so that they occupy positions 120° apart.

In either of these cases it will be observed that the condition of complete symmetry is fulfilled.

The most delicate case in which inductive effects due to lack of symmetry come into consideration is that of long distance telephone cables, where the "balance" may be appreciably affected by such a small factor as unequal tension during the twinning operation of the wires comprising a pair, whereby they are unequally disposed around their virtual axis. This results in a liability to interference with adjacent circuits in the same cable, permitting "cross talk" effects to become evident.

Similar conditions regarding geometric symmetry of assembly are demanded by mechanical considerations, although they may be complied with—for D.C. cables—without necessarily attaining electrostatic or electromagnetic symmetry, for example in the case of the triple concentric form of cable often used for D.C. 3-wire distribution.

Purely mechanical considerations — other than that of simple tensile strength—are so often taken for granted in connection with cables that one or two other aspects of mechanical design may be briefly referred to at this juncture.

Taking first the conductor, it is a *sine qua non* that a certain degree of flexibility is required in it, and the purpose for which a cable is intended determines whether such flexibility is simply in the nature of some degree of pliability enabling it to survive bending a few times without becoming kinked or distorted, or whether—as in the case of a portable or trailing cable—provision has to be made for almost indefinitely repeated bending.

Solid wires and ordinary stranded circular and shaped stranded conductors will usually comply with the first-mentioned requirements to a sufficient extent for ordinary non-portable purposes, while on the other hand extreme pliability can be obtained by using very fine wires.

For portable purposes, however, it is practically essential to employ the multiple strand principle, in which a number of stranded "multiples" are taken (in place of the single wires of the ordinary strand) and these stranded together. In addition to the general flexibility of the whole conductor, each member is then flexible in itself, and in addition has a certain lateral stiffness, so that when such members (and their component wires) are relatively displaced by bending the complete cable, each will return to its original position when the cable is straightened out, and this can be repeated indefinitely.

The assembly of the wires forming any stranded conductor must, of course, be in spiral formation, and — within limits — the shorter the pitch or "lay" of the spiral the greater the flexibility, because the degree

of lateral movement of an individual wire for a given radius of bending of the whole is thereby lessened. At the same time, the shorter the lay the greater the ohmic resistance of the conductor, the rate of increase of the latter—at lengths of lay usually employed in stranding conductors—corresponding to the steep part of the hyperbolic curve representing the relation between increase in length and pitch of a spiral.

Another feature of importance in connection with the relation between lateral displacement and lay of a stranded conductor is that the latter should bear a fairly constant relation to the pitch diameter in all layers. Otherwise, for a given radius of bend applied to the whole, some wires bear more tensile stress than others, and consequently do not retract so completely when the bend is removed. Under these conditions, on repeated bending, local kinking and breaking of a proportion of the wires occurs, and the whole stranded conductor becomes distorted.

A general mechanical requirement in the assembly and building up of a cable is that, when finished, the resultant of all the torsional effects due to the spiral application of the component parts should be practically zero. This is of particular importance where, in installing a cable (*e.g.* in a pit shaft), considerable lengths are free to twist, *i.e.* to relieve any unbalanced torsional stress in them while the cable is suspended prior to fixing. Such cables are almost invariably armoured with steel wires, and it will be obvious that such a tendency will be much more acute in a cable armoured with one layer of wires than in a double armoured cable in which the two layers are applied in opposite directions.

§(5) Rating.—The current-carrying capacity of cables is limited by heating effects, and is consequently dependent on heat dissipation facilities.

Rating has only been more or less tentatively standardised up to the present by such authorities as the Institution of Electrical Engineers, the American Institute of Electrical Engineers, and the Verband Deutscher Electrotechniker, and as the basis of evolution of the Rules of each of these bodies varies (*e.g.* maximum permissible temperatures), little complete fundamental data are available. Moreover, as will be shown later, the work of various investigators has only touched the fringe of the subject and is difficult to co-ordinate.

The reason for this appears to be partly because of the almost infinite variety of sizes and assembly of conductors, types, and qualities of dielectric and covering materials, and methods of laying and installing the finished cables, and partly because the total amount of experimental work has been comparatively small and the results obtained therefrom are not readily convertible into independent physical constants from which reliable formulae can be constructed and applied to specific cases.

In general, regarding a cable as a hollow cylinder having an inner diameter (d) represented by the diameter of the conductor, and an outer diameter (D) represented by the diameter over the dielectric, its thermal conductivity (Z) in watts per cm. length per degree C., according to text-books, will be [1]

$$Z_1 = \frac{2\pi k}{\log_\epsilon \frac{D}{d}},$$

where k is the specific thermal conductivity of the dielectric material in watts per cu. cm. per degree C., and $\log_\epsilon$ represents Napierian logarithms.

Its surface thermal conductivity (emissivity) per cm. length of cable per degree C. will be

$$Z_2 = \pi D h,$$

where h is the emissivity in watts per sq. cm. per degree C. The total thermal conductivity of these two thermal conductors, if regarded as analogous to electrical conductors in series, will be

$$Z_3 = \frac{Z_1 Z_2}{Z_1 + Z_2}.$$

If values of k and h are known, the current-carrying capacity will be derivable from

$$I^2R = Z_3(T - T_a),$$

where T is the maximum permissible temperature, and T_a is the temperature of the surrounding air or other medium.

The earliest investigation on the heating effects of electric current appears to have been carried out by Joh. Müller on bare wires in 1849.[2] Müller deduced from his results that the temperature rise varied as the 1·5 power of the current. (More recent investigators have found the exponent to be of the order of 1·25 to 1·3.)

The subject appears to have received no further attention until Professor George Forbes, in 1882, published his results "On the thickness of wires required to carry different electric currents without overheating." [3]

The earliest data of value relating to insulated cables were due to the work of Kennelly, in America, in 1893.[4] The scope was, at that stage of development of the electrical industry, naturally much more limited than at the present time, and the principal results directly applicable to cable work were consequently those relating to rubber insulated wires and cables run in wooden casing.

Fisher, also in America, published the

[4] "Carrying Capacity of Electric Cables submerged, buried, or suspended in Air," *The Electrical World*, 1893, xxii.

results of a large number of tests in 1905, and a year later prepared a table of current ratings.

Then followed—between 1905 and 1912—a number of investigations, both in this country and America, bearing indirectly on the subject, such as those mentioned below.[1]

Professor Porter's Paper (see footnote) is worthy of note, referring as it does to a little appreciated possibility in connection with the dissipation of heat, viz. that of obtaining a set of conditions (thermal conductivity and radius of coating) in which a covering on a wire carrying current may have the apparently paradoxical effect of cooling it as compared with a similar uncoated wire carrying the same current.

The general fact that coating a body with insulating material may in some circumstances have the effect of keeping it cool was fairly well known to physicists, references to it being made by Lord Kelvin [2] and also by Professor Forbes [3] in 1884.

Experimental proof appears to have been first made on coated wires by Professor Porter.

In Melsom and Booth's Paper [4] on "The Heating of Cables with Current," which was the most important and, so far as modern cables were concerned, the first work bearing directly on the rating of cables, it was shown that the critical point in this respect would be reached when D—the diameter—equalled $2k/h$, after which any increase in the thickness of the insulation would tend to keep the conductor warm instead of cooling it. Dr. Russell made a valuable contribution on this point in the discussion on this Paper.

Melsom and Booth's earlier work, carried out in the National Physical Laboratory with the object of forming a basis of revision for the I.E.E. Wiring Rules, dealt chiefly with the types of wire and cable (rubber and paper insulated) used in interior wiring work. In a later Paper [5] the question of buried cables is dealt with.

They developed the following formula for the relation between current density and copper temperature—

$$i=\frac{4}{d}\sqrt{\frac{T-T_a}{1+qT}}\sqrt{\frac{Dk}{0\cdot48\rho\left(D\log_e\frac{D}{d}+2\frac{k}{h}\right)}},$$

where i is the current density in amperes per sq. cm., ρ the specific resistance of copper at 0° C., and q is the temperature coefficient for copper—they found that the factor $(D\log_e(D/d)+2(k/h))$ was practically constant for a wide range of sizes of cable. k is the thermal conductivity and h the emissivity of the cable. For a definite temperature rise under uniform conditions the formula could therefore be written

$$i=K\left(\frac{D}{S}\right)^n,$$

where S is the sectional area of the conductor, K a constant depending on the system of units adopted and the amount of the temperature rise under consideration, and n a constant.

The authors give the following table showing the values of these constants where i represents current density in amperes per sq. cm., S is the total cross-section of the conductors ("either single concentric or twin") in sq. cms., and D is in centimetres.

For temperature rise of

Type of Cable.	11·1° C.	16·7° C.	27·7° C.
Rubber covered in air . .	$i=101\left(\frac{D}{S}\right)^{0\cdot616}$	$i=126\left(\frac{D}{S}\right)^{0\cdot616}$	..
Rubber covered in casing .	$i=91\left(\frac{D}{S}\right)^{0\cdot66}$	$i=106\left(\frac{D}{S}\right)^{0\cdot66}$	..
Lead covered in air . . .	$i=110\left(\frac{D}{S}\right)^{0\cdot50}$	$i=137\left(\frac{D}{S}\right)^{0\cdot50}$	$i=175\left(\frac{D}{S}\right)^{0\cdot50}$

Following Melsom and Booth's valuable work, two or three important contributions to the subject of rating of cables were made, between 1913 and 1916, in America.[5]

In Japan, Matsumoto[6] obtained valuable results from tests on paper-insulated lead-covered cables laid in sand inside a large iron cylinder.

All these investigators dealt with underground ("buried") cables, those in America directing their attention principally to duct lines—the drawn-in system being the chief method of laying according to American practice—while Matsumoto's work bore on

conditions more closely related to the "direct laid" system.

Each appears to have done some experimental work, and then endeavoured to convert the results into physical constants and to construct formulae for general application. Experience shows, however, that such expansion is, for the reasons previously referred to, of little practical use.

The materials and their relative disposition in cables are so complex and varied, and their surroundings in actual use are so diverse, that the possibility of treating the subject on similar lines to any ordinary engineering problem is very remote.

For example, taking the simplest case of single-conductor paper-insulated lead-sheathed cable through which a given current is being passed, and in which consequently a given amount of energy is being converted into heat per unit length, the thermal conductivities of the dielectric and sheathing materials and the emissivity of the latter may be accurately known, but the actual means of heat dissipation may be either by conduction or radiation or partly by each, according to whether the cable is embedded in solid material, slung in the air, or drawn into a tube or duct.

Under the first-named condition the heat gradient in the cable itself will be affected by the thermal conductivity of the embedding material, and if this be, for example, the bitumen filling of a cable trough, it will be further affected by the thermal conductivity of the material of which the trough is made, which may vary from wood or earthenware (materials of low conductivity) to asphalt or iron; and still further by the character of the soil, which may vary from the dry brick-like "laterite" soil largely met with in India, to wet sand.

Under the second-mentioned condition, *i.e.* slung in the air, the dissipation of heat is by radiation (into which convection may enter appreciably) which depends largely on the emissivity of the sheathing material, the temperature gradient in the cable being fixed by the relation between this and the thermal conductivity of the dielectric and its sheathings or coverings. It should also be noted that emissivity varies with temperature, and further that the emissivity of a given material varies according to its condition, *e.g.* that of a blackened lead sheath is greater than when the sheath is new and bright.

Under the third general set of conditions represented by drawn-in systems, the material of which the duct is composed (which may vary from fibre to metal) and that in which it is set (which may vary from concrete to clay or sand) will affect the conduction of heat, while the relation between cable and duct diameters will largely determine the radiation component in the total dissipation.

The juxtaposition of other cables, and warm areas in the cable route will also have an appreciable effect on the permissible rating of a given cable.

The form of cable, *i.e.* whether single, twin or multicore, and the presence or absence of dielectric heating will also affect the total temperature of the cable.

Fig. 4[1] illustrates in a simple manner a few of these variations as determined by the writer some years ago.

It will be noted that the curves all relate to one size of single-conductor cable, insulated with various dielectric materials, and laid or fixed in various ways, and to one current density.

Even under these elementary conditions the variations due to the use of different dielectric materials and methods of laying or fixing are very marked, and without labouring the point it is fairly evident that in the present state of knowledge the calculation of carrying capacity without experimental checking on an ample scale is likely to give unreliable results.

A striking illustration of the necessity for reliable data is furnished by the fact that according to the Rules of the A.I.E.E. (stipulating a reduction of 1° C. from the maximum of 85° C. for paper-insulated cable for each 1000 volts of working pressure) the current density decreases as the operating voltage increases, whereas in fact the reverse is permissible, at least for pressures up to 30,000 volts. A formula of the Melsom and Booth type would tend to indicate this, and practical results show that although the necessary correction factors would modify, they would not reverse this tendency.

The Rules of the V.D.E. also indicate slightly lower ratings for cables for working pressures above 3000 volts than for lower operating voltages.

The I.E.E. give no data in this connection.

A fair amount of work, as yet unpublished, has been and is being done on the heating produced in extra high tension cables by the combined effect of I^2R and dielectric losses, which, as pointed out earlier in this article ("Conditions of use") may become cumulative under certain conditions.

The decided upward turn of the loss/temperature curve (previously mentioned) which occurs in most makes of paper dielectric at a more or less elevated temperature, appears however to be generally above the maximum temperature ordinarily permissible in high pressure cables under working conditions.

[1] Beaver. Discussion on Melsom and Booth's Paper, "The Heating of Cables with Current," *l.c. ante.*

Bang and Louis[1] have investigated the effect of dielectric losses on the permissible current capacity of sets of cables in duct lines, but apart from their Paper the literature of the subject is very scanty.[2]

Clearly, the increase of temperature due to dielectric losses above that due to 1^2R losses referred to, but also because of the limiting effect on the current rating.

The extra heating due to dielectric losses in present day 3-core paper-insulated cables for 30-40 kilovolts working is of the general order of 10-12 per cent of that due to 1^2R losses.

It is clearly, however, dependent on the

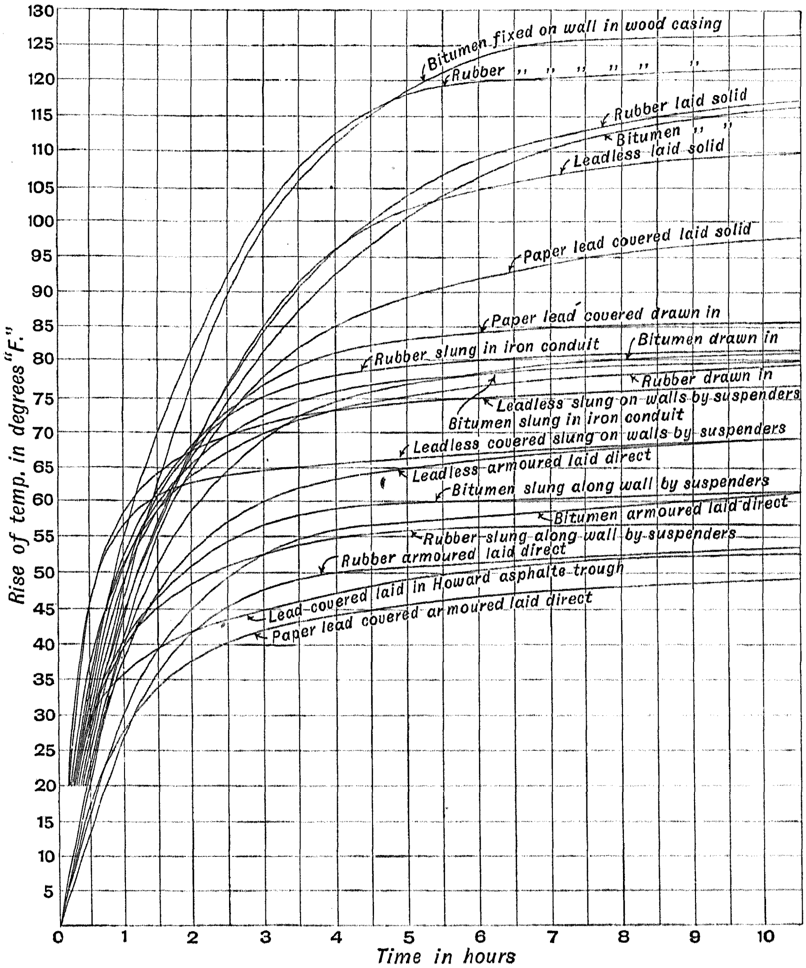

FIG. 4.—Temperature Rise in Four Types of 0·5 sq. in. Single Cables laid in various ways. C.D. 1500 amps. per sq. in.

in extra high pressure cables is of great importance, not only on account of the risk of approaching the cumulative effect above actual values of maximum stress in the dielectric, and on the current density in the conductors, the relation between these factors

[1] "The Influence of Dielectric Losses on the Rating of H. T. Underground Cables," *Jour. A.I.E.E.*, 1917, xxxvi.

[2] Since this article was prepared for the Press, a succinctly written article by Mr. Ralph W. Atkinson has appeared in the *Journal of the A.I.E.E.*, Sept. 1920, p. 831, on "The Current Carrying Capacity of Lead Covered Cables," in which the author gives certain tables of fundamental data and methods of arriving at carrying capacities therefrom by calculation.

The article refers solely to the duct (drawn-in) system of laying, and chiefly to 3-core cables of the paper or varnished cambric-insulated lead-covered type, but is nevertheless a valuable contribution to the literature of the subject, in that it crystallises an important part thereof into a practically usable form.

bringing into view the economic question as to the advantage of reducing dimensions (and therefore the capital cost of the cable) by forcing up the dielectric stress, or conversely reducing the latter so that the current density may be raised as high as possible, the latter tending to reduce the "annual charges" of distribution.

With regard to the effect on rating of the assembly of conductors in a cable, in a recent revision of the Wiring Rules of the I.E.E. (dated October 1919) the following constants are added for use as multipliers for the currents given in the Table for single cables:

Conc.	0·93
3-core	0·88
4-core	0·82

Theoretically these figures should be approximately 0·85, 0·76, and 0·62, and as the values tend to decrease with increasing size of conductors, average practical conditions would probably be met by rounding off these figures to 0·8, 0·7, and 0·6 respectively.

Powell (*l.c. ante*), after working out—on the above-mentioned A.I.E.E. basis—current values for single paper-insulated lead-covered cables for 750, 5000, and 15,000 volts, drawn into ducts, gives the following table of factors connecting the current carrying capacity of multiple conductor cables with that of single conductor cables "having the same total thickness of insulation."

No. of Conductors.	Type of Cable.	Multiply One Conductor Capacity by
		per cent.
2	Flat	87
2	Round	80
2	Concentric	75
3	Round	70
3	Oval Sector	77
3	Clover-leaf Sector	80
4	Round	67

The V.D.E. Rules give ratings for several types of cable (laid direct in the ground) under two headings, viz. for working pressures up to 3 kilovolts and from 3 kilovolts to 10 kilovolts, from which the following ratios may be roughly deduced:

Type of Cable.	Ratio to Carrying Capacity of Single Cable.	
	Working Pressures up to 3 K.V.	Working Pressures 3 to 10 K.V.
	per cent.	per cent.
Twin . . .	70	65
3-core . . .	61·5	59
4-core . . .	57	54
Concentric . .	70	. .
Triple Conc. .	57	. .

It will be quite apparent, however, that any such calculated values may be appreciably fouled by manufacturing variations. For example, a large heavily insulated 3- or 4-core cable is—in the nature of things—liable to be less compactly made than a smaller lightly insulated one of the same type, so that the same effective value of thermal conductivity is not attained, thus varying the temperature gradient in the cable, and consequently the relative sheath temperature; and further, as the emissivity varies with temperature, the total dissipation may be appreciably different.

Multiplying factors for different methods of laying might similarly be experimentally determined under approximately standardised conditions. For example, it can easily be deduced from the foregoing diagram that for a given temperature rise a paper-insulated cable laid solid will only carry about 70 per cent, or when slung in air, about 84 per cent, of the current it will carry when armoured and laid direct in the ground.

Clearly an enormous amount of work remains to be done in order to afford the necessary experimental support to mathematical treatment before the rating of cables can be put on a scientific basis.

Given this support, probably the soundest method of evolving fairly complete formulae would follow Matsumoto's theory, which considers the isothermal lines surrounding a cable as a group of eccentric cylinders, and to add, where necessary, emissivity and other factors—for example, pertaining to the type of cable, the assembly of conductors, and the various methods of laying or fixing them—and in such manner produce empirical formulae, similar to those of Melsom and Booth. It should then be only necessary to insert dimensions and thermal values of the various materials involved in a given case to determine the temperature rise for any value of current.

§ (6) Deterioration of Cables and Palliative Measures.—If this be broadly defined as such deterioration as will permit the electrical failure of a cable by mechanical rupture or weakening of its dielectric or (in the case of hygroscopic insulating materials) of its protective sheathing, permitting the penetration of moisture, it will be readily appreciated that it may be brought about by a large variety of agencies.

These may be classified under two headings, viz.:

(*a*) Natural causes.

(*b*) Abnormal conditions encountered in use.

Some of these causes have necessarily been touched upon in considering the chemical characteristics of dielectric materials in the early part of this article.

With regard to (*a*) it has already been

noted that under normal conditions the dielectric and sheathing materials used in cable manufacture are very inert, although it is well known that vulcanised rubber has an appreciable "natural" rate of deterioration depending on its quality and the skill with which it is designed and manufactured.

This deterioration (in the case of vulcanised rubber) is in the nature of a physical weakening which may be conveniently visualised as the physical breakdown of a network of cohesive material consequent on change in molecular constitution.

Whether the resultant condition is in the nature of hardening or softening depends on the nature of this change, which is in turn dependent on the initial molecular composition of the vulcanised rubber, which again, as mentioned in the early part of this article, is largely dependent on whether its non-rubber ingredients have participated in the vulcanising reaction or not.

Some degree of protection is afforded against this "natural" deterioration (or deterioration under *normal* conditions of exposure) by the application of tapes, braids, and preservative compounds, which tend to exclude air and light. Such exclusion, however, is only partial, as evidenced by the difference between the life of gutta-percha (which, as already noted, is particularly liable to oxidation by exposure to air) when immersed in water and when simply protected from atmospheric influences by these more or less pervious coverings.

The forms of deterioration which fall under category (*b*) pertaining to conditions which may arise in practical use, might perhaps more accurately be defined as more or less local happenings conducive to the production of faults. They are very numerous and complex; and the design of preventive measures depends largely on accurate diagnosis of the causes and processes of development of troubles, and knowledge of practical working conditions.

It will readily be perceived that diagnosis of the primary causes of deterioration is liable to be rendered very difficult in some cases by reason of effects of faults being superposed on the evidence bearing on the conditions leading thereto. For example, a physical or mechanical cause may lead to a fault which may produce electro-chemical (or even purely chemical) effects, due to the action of substances formed electrolytically in the vicinity, as referred to later, which may almost completely mask the original cause.

A few forms of deterioration due to abnormal conditions may with advantage be briefly noted, because with the rapidly increasing use of electric power the variety of conditions of use also becomes multiplied.

Regarding, for instance, the physical effects of temperature on the chief components of an insulated cable, we have as the result of exposure to extreme cold a stiffening effect or loss of resilience in the case of rubber, a tendency to brittleness in the case of vulcanised bitumen, and in impregnated paper a tendency for the laminations to adhere instead of sliding freely over each other.

Rubber which has been frozen exhibits a reluctance to resume its normal resilience on being simply warmed, although it readily regains its normal state on being stretched at normal temperature. In other words, it differs from other materials (in conjunction with some of which it may be used) in regard to the relation between temperature and physical condition, *i.e.* having a lag in this respect which other materials have not.

Generally there is some risk in sharply bending any form of cable when its temperature is very low, although the composition design usually allows for a fair margin of safety in this respect. This risk applies chiefly to installation conditions.

On the other hand, heat—which applies more generally to working conditions—accelerates the natural deterioration of rubber, weakens the resistance of vulcanised bitumen to mechanical stresses, and reduces the viscosity of the impregnating media of paper dielectrics, causing in some cases a tendency for it to become displaced.

Alternations of heating and cooling naturally cause expansion and contraction in cables, and although, as might be expected in view of the spiral construction of most of the component parts of a cable, a considerable proportion of this is accommodated transversely, the more rigid paper-insulated lead-covered type of cable frequently suffers on account of the linear movement. Particularly is this the case where such cables are laid in ducts, because of the comparative freedom which this method of laying affords for movement in a longitudinal direction.

Although the resistance to movement in such cases is small, however, it is not in practice uniformly distributed, *i.e.* so that the movement takes place equally on either side of the centre between two free ends, for example, in a duct length. It therefore sometimes happens that a cable may be expanded largely in one direction (*e.g.* into a manhole at one end of a duct), and subsequent contraction may fail to bring about a corresponding return movement, so that a gradually increasing tensile stress may be set up by successive cycles of expansion and contraction, ultimately resulting in a fracture of the lead sheath. This "creeping" effect is often particularly marked in sloping ducts where cables are fairly heavily loaded. Pallia-

tive measures in the way of anchoring appear to be useless in such cases, and "stepping" the ducts, so that each section between manholes is horizontal, is probably the only satisfactory solution of this trouble.

A feature of the fractures in lead sheaths in such cases is the local crystallisation of the metal, evidently as a result of the mechanical stress. Crystallisation of lead is also producible by pounding or vibration effects and in some obscure cases by chemical attack. It is, however, very difficult to experimentally reproduce such effects, probably because some particular structure of the original lead constitutes a predisposing cause. Further study of this important matter is required. Meantime preventive measures as regards mechanical production of crystallisation relate chiefly to means of obviating the direct transmission of shocks and vibrations to the cable.

So far as underground cables are concerned, methods of laying may be varied to protect them from various deteriorating influences. Effects of movement, *e.g.* pounding by heavy traffic, will be better withstood by an armoured cable laid direct than by a cable laid solid in troughing, because the troughing is comparatively weak at joints between sections, and the movement due to pounding or intermittent stress becomes concentrated thereat.

Armouring is, of course, the best mechanical protection against blows, abrasion, or crushing forces, and in the form of a close sheath of wires affords tensile strength. On the other hand, solid laying in bitumen-filled troughs gives the best chemical protection.

In the case of wires and cables above ground, protection against chemical fumes, etc., has generally to be provided by special coverings and by their treatment with special compounds according to the properties of the chemicals against which protection is desired. In some cases which are neither very severe nor complex, such as in battery rooms where sulphuric acid spray alone has to be considered, a tough acid-resisting rubber sheath, the smooth surface of which can be periodically wiped clean, affords the best protection. Such sheaths can also be made of special rubber compound which resists the action of petrol and oils to a remarkable extent.

The action of ozone (produced by high-tension static discharges) on rubber dielectrics exposed thereto at cable ends trimmed of their coverings to prevent surface leakage, furnishes a remarkable instance of an abstruse kind of deterioration, which often appears in the form of splits or cracks. The writer has demonstrated that this only occurs when the rubber is under tension, as on the outer periphery of a bend, and not when the cable end is straight and therefore free from tensile stress at any part of its surface. In the former case the defect may occur within a few minutes of the exposure of the rubber to the gas, whereas practically no deterioration occurs—as judged by the effect of heat tests on the rubber—in the latter after long exposure.

A point of interest in this connection is that vulcanised bitumen is quite immune from this peculiar effect, but admixture of a very small percentage of rubber with it destroys this immunity. The cause of this phenomenon has not been determined.

Apart from direct chemical action, the likelihood of which is usually known from the character of the surroundings of a cable, electro-chemical action on metal sheathings of cables, caused by vagrant currents in presence of electrolysable media in contact with or in close proximity to a cable, is not only generally more severe, but also more insidious in character; because practically any kind of moisture which is likely to be in contact with a cable sheath will be a good electrolyte, and the paths of stray currents cannot—in detail—easily be foretold.

These vagrant currents may originate from the cable itself (or from a neighbouring cable) by way of leakage over trims at joints or ends, or from incipient faults, or more commonly as return currents from tramway or railway circuits. The magnitude and direction of the latter can, by systematic measurement of potential differences between cable sheaths and earth at various parts of a cable route, be more or less accurately determined; but the former, being of accidental origin, are more difficult to control.

Experience shows that solid laying in bitumen-filled troughs is not a preventive against electrolytic action on the cable, in fact under some circumstances it may aggravate it, because the virtual electrode area is very restricted, and therefore the current density is likely to be high and the corrosion effects correspondingly severe. Again, for similar reasons, metal-sheathed wiring in damp situations in buildings, particularly if run in wood casing, is liable to be badly attacked unless special precautions are taken. These precautions consist in metallically bonding all sheathings together, and earthing them at the source of supply. Intermediate earth plates may be necessary in some cases where the electrolytic survey indicates that current would enter or leave the sheath, so that it can do so by a metallic path. Care has to be taken, however, to avoid inviting vagrant currents on to the cable sheaths.

In principle, the whole matter amounts to short circuiting all the potential electrolytic paths so that any current flowing from or to sheathings passes along metallic conductors instead of by electrolytic paths.

This general principle, first enunciated by the writer many years ago, in opposition to the principle then being largely supported of segregating the sheaths of adjacent lengths of cable, together with the Board of Trade restrictions bearing on maximum earth return voltages, has rendered electrolytic troubles on large networks in this country almost negligible, so far as vagrant currents from external sources (such as electric tramways) are concerned. It has also permitted the free use of metal-sheathed wiring in buildings, which for many years was under an inexplicable cloud owing to troubles which were—though usually attributed to other causes—due to electrolytic action arising from leakage currents from the wires and cables themselves. At the present time the strictest attention is paid to continuity bonding and earthing in metal-sheathed wiring systems; in fact the chief features of most of the special systems now in vogue bear on the matter of efficient and permanent bonding.

The character of the effects of corrosion of lead coverings varies considerably according to the rate at which the action proceeds, and the nature of the electrolyte. A slow or intermittent action may ultimately produce a white powdery deposit of carbonate of lead, due to the formation of a lower oxide and its exposure to moist air, while a rapid action may cause the complete conversion of the entire thickness of lead into a higher oxide, not readily convertible into carbonate, and only rendered noticeable by its reddish colour. The symptoms are not always clear, because in practice effects which are characteristic of actions occurring at anode and cathode in a simple electrolytic cell are frequently mixed up, in close proximity to cable sheaths, owing to the presence of a heterogeneous mass of conducting substances and electrolytes. For this reason it is sometimes difficult to determine from examination whether a direct current has passed to or from an affected sheath. On the other hand, in the case of electrolytic action due to leakage in an alternating current cable, the effects are often less complicated because of the rectifying effect of the electrolyte.

The phenomenon of electric endosmose often plays a conspicuous part in the development of electrolytic cable faults.

When the lead sheath of a paper-insulated cable has been pierced, or penetrated by corrosion, or an incipient fault in a non-metallic sheathed cable has reached a sufficiently low resistance value and a fault circuit is established, this effect causes moisture to be driven from the positive to the negative conductor, with the result that not only is the resistance to earth of the latter reduced by the local accumulation of moisture, but the products of electrolytic action also tend to be concentrated thereat. Many cases have been known of the electrolytic formation of metallic sodium and potassium in close proximity to the virtual negative electrode—the negative cable conductor—surrounded of course by salts of metals. The strongly alkaline character of the moisture in such cases is frequently responsible for direct chemical attack.

It is common knowledge among engineers in charge of direct current networks that failures on negative conductors are much more frequent than on positive conductors; in fact in cases where faults have been known to be in the course of development, a final breakdown has often been postponed by changing the polarity of the affected cables.

When passages exist in a negative cable—even of a capillary order—water is forced along them for considerable distances and up to appreciable pressures by the endosmotic effect. In rubber cables, for instance, blisters full of water are sometimes found to be produced, and on cutting a badly affected cable, water will sometimes spurt for a considerable distance.

It need hardly be pointed out that conditions such as these, as well as others which have been touched upon, should never arise, and would not exist under adequate conditions of maintenance.

The question of a standard of maintenance is a very difficult one, and in spite of its importance its due consideration has lagged behind the advances which have been made in manufacture during the last decade or two. The difficulty appertains chiefly to distributing networks, and may be broadly regarded as due to two chief causes: firstly, the practical impossibility of adequately testing all parts independently of trims and connected apparatus because of the enormous amount of preparatory work entailed in eliminating surface leakage; and secondly, even if the first was rendered possible, of obtaining tests accurately representing the intrinsic values of the insulation resistance of the cable dielectrics, because in a large proportion of cases they are surrounded by other partially insulating materials. For example, in the cases of non-metallic sheathed cables laid in bitumen-filled wooden troughs—a common condition—a test between conductor and earth reveals little regarding the state of the cable dielectric, because any flaw therein is in series with a path of high resistance through the filling and troughing material to earth.

A brief reference may here be made to an incidental though sometimes serious effect arising from or developing out of the conditions last mentioned. When the resistance of such a fault path becomes low enough for an

appreciable current to flow, local heating ensues, and considerable volumes of combustible gas are formed by the volatilisation of the bituminous, trough-filling, and cable-covering materials. Many cases have occurred in which gases generated in this manner have found a way into adjacent feeder pillars, cellars, etc., and have caused violent explosions.

Such high-resistance fault circuits cannot exist for long in metal-sheathed cables, and consequently the explosion risk is less in their case. It is not uncommon, however, for faults in lead-covered cables to repeatedly "clear" themselves by fusing the lead away round a burn out, thus reconverting the fault

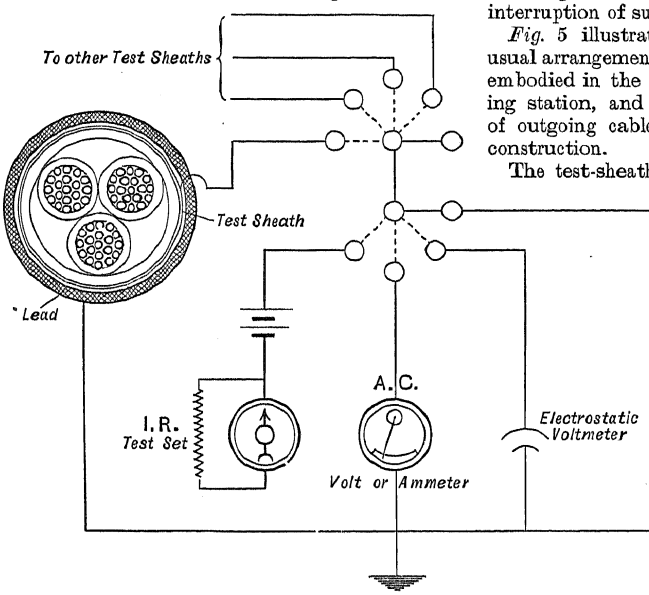

FIG. 5.

into a high-resistance one by increasing the length of its path.

It will therefore be apparent that even in the case of a lead-covered cable a considerable amount of damage may occur before the fault ultimately declares itself.

These considerations, as well as the great general discrepancy between maintenance of cables and that of other component parts of an electric power-supply equipment, led the writer some years ago to devise a simple arrangement [1] whereby a constant watch could be kept on the state of metal-sheathed cables without interruption of supply.

It consists in inserting between the outer boundary of the insulation proper and the metal sheath, an auxiliary conductor in the form of a thin spiral copper tape enveloping all the conductors and their insulation, and insulated from the metal sheath by a thin layer of hygroscopic material, of sufficient thickness to withstand the maximum ill usage to which the cable may be subjected during installation, etc.

The cardinal principle of this construction is that this auxiliary conductor is bound to intercept injurious effects—such as penetration of moisture—proceeding from outside the cable earth, and also leakage from the main conductors to earth. If, therefore, it is connected to suitable observation and testing instruments, indications may be obtained at any desired moment of any abnormal condition arising in the cable, and this without interruption of supply.

Fig. 5 illustrates diagrammatically the usual arrangement of a "detective" panel, embodied in the switchboard of a generating station, and serving for any number of outgoing cables of this "test sheath" construction.

The test-sheath conductor of each cable is connected to separate insulated terminals on the panel, and the selector switch is manipulated to connect any one of them to the test switch, through which they are then connected to observation and testing instruments, such as those shown in the diagram. The electrostatic voltmeter first gives an indication of the existence of any appreciable leakage from the main conductors to the test sheath, and the second instrument affords facility for determining the degree of such leakage. If these first two steps in the test indicate normal conditions in the interior of the cable, the third step is taken of testing the insulation resistance of the hygroscopic dielectric between the test-sheath conductor and the lead covering of the cable, this affording a definite indication of the integrity or otherwise of the waterproof metal sheath of the cable. (It may here be noted that the primary source of failure of a cable is almost invariably extraneous, very few cases ever arising in practice of breakdown due to internal causes.)

The value of this insulation resistance at 15° C. is from 30 to 60 megohms per mile, depending on the diameter of the cable. Lower values are actually obtained under working conditions owing to the warming up of the cable under load, but such variations are easily

[1] Patent No. 22355/12, Beaver and Claremont.

diagnosed, and are not such as to give false indications. In fact, if logged day by day, they give additional interesting information regarding variations in temperature between different cables, and at different periods, *e.g.* during a day or week.

Generally, it will be seen that the system ensures immediate detection of the first phases of development of a fault, and the importance of this in preventing secondary deteriorating effects, such as the electrolysis and other forms above mentioned, can hardly be overrated, especially as little is definitely known as to the time element in the process of fault development in the case of ordinary cables.

In detail, in the event of a fault being indicated on a given cable, not only can an approximate idea be obtained of its degree and probable character (this being largely a matter of intelligent interpretation of test results), but its rate of development can be watched, and a basis formed for decision as to whether prompt action (*i.e.* switching out the cable) is necessary, or whether the location and repair may be deferred to a convenient time. In the latter case the test-sheath conductor is of great value in fault-localising operations (being of known resistance and in intimate contact with the fault), and exact location is rendered possible while the cable is still alive.

Repeated instances have occurred on E.H.T. power systems where this procedure has enabled repair gear to be sent to the located spot at the week end, or some other selected period of light load, thus saving much valuable time and inconvenience.

An important system of automatic protection is also based on this test-sheath design, so that it may be utilised for protective as well as detective functions. This, however, is outside the present scope. (A general description appeared in the *Electrician* of July 5, 1918.)

The difference between the maintenance facilities afforded by this—or any equivalent—system, and the comparative absence thereof represented by previous practice, is obvious; it will also be clear that the method described tends to raise the level of cable maintenance to a plane which is comparable with that of the station plant, or at any rate to one which is more worthy of the important part played by cables in the general scheme of electricity supply.

CAPACITY, ELECTRICAL, AND ITS MEASUREMENT

I. Introductory and Theoretical

§ (1) Definitions.—There is a tendency to replace the term "electrical capacity" by the word "capacitance," which takes its

proper place among the analogous terms resistance, inductance, reactance, admittance, etc., according to Heaviside's system, which has already been so helpful in improving the clearness of electric terminology.

It seems best here to begin with a definition referring to a simple particular case and then to pass to more general conditions.[1]

Let A and B be two conductors infinitely distant from all other conductors, and let B be kept at zero potential while A receives a charge. If q be the charge necessary to bring A to potential v, then

$$q=Kv, \quad . \quad . \quad . \quad . \quad (1)$$

and K is called the capacity (or capacitance) of A.

A quantity of electricity $-q$ will at the same time be induced on B. If B had been kept at potential v_1 instead of zero, while A is brought up to potential v_2, then

$$q=K(v_2-v_1). \quad . \quad . \quad . \quad (2)$$

In equation (1) the values may all be in absolute C.G.S. units (abcoulombs, abfarads, and abvolts). When practical units[2] are used, if q is in coulombs and v in volts, K will be in farads. But K is more usually expressed in *microfarads* (μF), in which case the equation becomes

$$q=10^{-6}Kv. \quad . \quad . \quad . \quad (3)$$

Small capacities are often expressed in millimicrofarads ($m\mu$F) or in micromicrofarads ($\mu\mu$F). For micromicrofarads the shorter term picofarads may be used.

In calculating capacities from dimensions the results are obtained in the electrostatic system of units (abstatfarads). To reduce to microfarads these results have to be divided[3] by 900,000, and we have the following relations:

$$1 \text{ micromicrofarad} = 0{\cdot}90 \text{ abstatfarad}, \quad (4)$$
$$1 \text{ abstatfarad} = 1{\cdot}11\ \mu\mu\text{F}.$$

The electrostatic unit is often written cm. as its dimensions are those of a length.

Caution.—Certain writers mix electromagnetic and electrostatic units in the same formulas; for example, $\lambda_{cm}=4\sqrt{L_{cm}C_{cm}}$. This practice seems quite indefensible and can only lead to confusion.

§ (2) Potential Energy of Charge.—The work done (in *ergs*) in charging a body with quantity Q (to potential V)

$$=\tfrac{1}{2}KV^2=\tfrac{1}{2}QV=\tfrac{1}{2}\frac{Q^2}{K}, \quad . \quad . \quad (5)$$

where Q, V, and K are in absolute units.

If K is in microfarads, Q in coulombs, and V in volts, the work done, in *joules*,

$$=\tfrac{1}{2}KV^2\times 10^{-6}=\tfrac{1}{2}QV=\tfrac{1}{2}\frac{Q^2}{10^{-6}K}. \quad . \quad (6)$$

[1] A. Russell, *Alternating Currents*, vol. i. chap. i.
[2] See "Units of Electrical Measurement," §§ (3), (25).
[3] See "'v,' the Ratio of the Electrical Units," § (6).

This is, of course, also the amount of work given out when the body is discharged.

§ (3) Capacities in Parallel and Series.—If K_1, K_2, K_3 . . . are a number of capacities all connected in parallel, the total resulting capacity is

$$K=K_1+K_2+K_3+\ .\ .\ . \quad . \quad (7)$$

If they are all in series, the capacity of the circuit is

$$K=\frac{1}{1/K_1+1/K_2+1/K_3+\ .\ .\ .}. \quad . \quad (8)$$

When there are only two of them, this reduces to

$$K=\frac{K_1K_2}{K_1+K_2}. \quad . \quad . \quad . \quad (9)$$

For when the capacities are in parallel the potentials are the same for each and the total charge is the sum of the charges. Thus

$$Q=K(V-V'),$$
$$Q_1=K_1(V-V'), \quad Q_2=K_2(V-V'), \ .\ .\ .\ \text{etc.}$$

But $\quad Q=Q_1+Q_2+\ .\ .\ .\ Q_n.$

Hence

$$K(V-V')=\{K_1+K_2+\ .\ .\ .\ \}(V-V'),$$

or $\quad K=K_1+K_2+\ .\ .\ .\ K_n.$

When the capacities are in series the charge on each is the same while the resulting potential difference is the sum of those for each. Thus

$$V_1-V_2=\frac{Q}{K_1}, \quad V_2-V_3=\frac{Q}{K_2}, \ .\ .\ .\ \text{etc.}$$

Hence

$$\frac{Q}{K}=V_1-V_n=Q\left\{\frac{1}{K_1}+\frac{1}{K_2}\ .\ .\ .\ \frac{1}{K_n}\right\},$$

or

$$\frac{1}{K}=\frac{1}{K_1}+\frac{1}{K_2}+\ .\ .\ .\ \frac{1}{K_n}.$$

§ (4) Maxwell's Equations for a System of Conductors.—In many practical problems in which the effects of capacitance occur, the simple definition given by equations (1) and (2) is not sufficiently general. The general case of a system of conductors of any form has been treated by Maxwell[4] as follows. Let $A_1, A_2, A_3, \ldots A_n$ be n conductors in a dielectric medium whose properties remain constant; let $q_1, q_2, q_3, \ldots q_n$ be their charges, and $v_1, v_2, v_3, \ldots v_n$ their potentials. Then Maxwell shows that for a state of equilibrium the charges are determined by a set of n linear equations,

$$\left.\begin{aligned} q_1&=K_{11}v_1+K_{12}v_2+K_{13}v_3+\ .\ .\ .\ +K_{1n}v_n \\ q_2&=K_{21}v_1+K_{22}v_2+K_{23}v_3+\ .\ .\ .\ +K_{2n}v_n \\ &\ .\ \ .\ \ .\ \ .\ \ .\ \ .\ \ .\ \ .\ \ . \end{aligned}\right\}, \quad (10)$$

where $K_{11}, K_{12}\ .\ .\ .$ depend only on the dimensions and positions of the conductors and on the inductive capacity (or dielectric constant) of the medium.

[4] J. Clerk Maxwell, *Electricity and Magnetism*, 2nd ed., vol. i. § 87.

The coefficients K_{11}, K_{22}, K_{33} . . . are called the *capacities* of the respective conductors, while K_{12}, K_{13} . . . are called the *coefficients of statical induction* and are always negative.

As Orlich [1] points out, it is more convenient for practical purposes to put the equations into the form

$$\left.\begin{aligned} q_1 &= c_1v_1 + c_{12}(v_1 - v_2) + c_{13}(v_1 - v_3) + \ . \ . \ . \\ q_2 &= c_2v_2 + c_{21}(v_2 - v_1) + c_{23}(v_3 - v_2) + \ . \ . \ . \\ &\cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \end{aligned}\right\}, \quad (11)$$

where
$$\left.\begin{aligned} K_{11} &= c_1 + c_{12} + c_{13} + \ . \ . \ . \\ K_{22} &= c_2 + c_{21} + c_{23} + \ . \ . \ . \\ &\cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \end{aligned}\right\}, \quad . \quad (12)$$

and
$$K_{12} = -c_{12}, \quad K_{21} = -c_{21} \ . \ . \ . \quad (13)$$

As Maxwell has shown that $K_{12} = K_{21}$, $K_{13} = K_{31}$ . . . , there are in all n capacities and $\frac{1}{2}n(n-1)$ coefficients c_{12}, c_{13} . . . The c coefficients are called by Orlich *component capacities* (Teilkapazitäten).

We have also $c_{12} = c_{21}$, and so on. . . . (14)

The general expression for the energy (in ergs) to charge the system is now

$$\tfrac{1}{2}(K_{11}v_1^2 + K_{22}v_2^2 + \ . \ . \ . \ + K_{12}v_1v_2 + K_{13}v_1v_3 + \ . \ . \ .). \quad (15)$$

The use of the component capacities is illustrated in *Figs.* 1 and 2. In *Fig.* 1 are

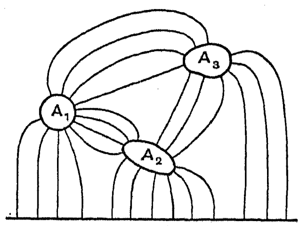

Fig. 1.—System of Three Conductors.

shown three conductors, A_1, A_2, and A_3, and each of them has a field of lines of (electrostatic) force reaching to the earth and to each of its neighbours. The three sets of lines of force from any one of the conductors correspond to the three components of the total charge on that conductor, and the whole system may be represented, as in *Fig.* 2, by the six simple condensers c_1, c_2, c_3, c_{12}, c_{13}, and c_{23}. The potential differences and charges then follow equation (11).

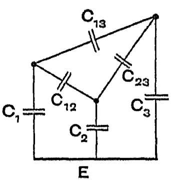

Fig. 2.—Equivalent Simple Condensers.

[1] E. Orlich, *Kapazität und Induktivität*, 1909, p. 20, § 10 (Vieweg u. Sohn).

§ (5) Condensers.—A *condenser* usually means an arrangement of two conductors such that the greater part of the capacity effect is between the conductors and very little of it to earth or other conductors. In a *simple condenser* the whole effect is between the plates. In diagrams a simple condenser is commonly indicated by —||— or —⊂⊃—.

With condensers of capacitances of 0·1 μF and higher the earth capacities seldom cause much error, but for any condenser whose bulk is large in relation to the capacitance the earth capacities may have to be taken into account. For small condensers the safest plan is to construct the condenser with an outer metallic screen connected to one of the sets of conductors. In use the terminal connected to the screen should be practically at earth potential.

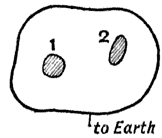

Fig. 3.

There are, however, important practical cases in which it is impossible to ignore the earth capacities. The simplest case of this kind is an open condenser, which may be represented as in *Fig.* 3 by two conductors, 1 and 2, enclosed in a conducting sheath which is earthed. It is equivalent to three simple condensers as shown in *Fig.* 4. Orlich defines the *working capacity* as for the condition $q_1 = -q_2$. When this condition holds, we have from equation (11)

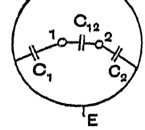

Fig. 4.

$$c_1v_1 + c_2v_2 = 0, \quad . \quad . \quad . \quad (16)$$

and

$$\text{Working Capacity} = \frac{q_1}{v_1 - v_2} = c_{12} + \frac{c_1c_2}{c_1 + c_2}. \quad (17)$$

This case applies to an ordinary double plate condenser in which the distance between the plates is not extremely small compared to the length or breadth of the plates. It also applies to a two-core cable in which the two conductors are open or enclosed in a conducting sheath. As Orlich shows, then, if the conductors are symmetrically arranged, $c_1 = c_2$; and if in use

$$v_1 = \frac{v}{2} = -v_2,$$

then the working capacitance

$$\frac{q_1}{v} = c_{12} + \frac{c_1}{2}, \quad . \quad . \quad . \quad (18)$$

where v is the voltage between the conductors 1 and 2.[2]

[2] For discussion of three-core and other more complicated cables see A. Russell, *Alternating Currents*, vol. i. chaps. iv. and v.

§ (6) INDUCTIVE CAPACITY.—The insulating medium between the two conducting systems in a condenser is called the *dielectric.* If K_0 is the capacitance when this medium is a vacuum and K the value when the dielectric is some substance, then

$$K = \kappa K_0,$$

where κ is constant for the given substance (temperature and other conditions being kept constant). It is called the *inductive capacity* of the substance or the *permittivity* (Heaviside); it is also called the *dielectric constant* or the *dielectric coefficient* of the substance. It is taken as unity for a vacuum. As will be seen later, the inductive capacity of air at atmospheric pressure is also very nearly unity, and may be taken as unity for nearly all practical purposes.

The capacitance of a condenser depends only on the geometrical dimensions and positions of the conductors and the inductive capacity of the dielectric. Its value for air as dielectric can be calculated from the geometrical configuration of the conductors; when the dielectric is some other substance, it is only necessary to multiply the result by the inductive capacity of that substance.

In the following section are given a number of formulas for the calculation of the capacities of condensers of various simple geometrical forms. Unless where otherwise stated the values are for *air dielectric* and are expressed in electrostatic units (*abstatfarads*), the dimensions being in *centimeters.* To reduce to microfarads the values must be divided by 900,000.

§ (7) FORMULAS FOR CALCULATION OF CAPACITANCE. (i.) *Concentric Spheres,* radii r_1 and r_2.—

$$K = \frac{r_2 r_1}{r_2 - r_1} \text{ (abstatfarads)}. \quad . \quad . \quad (19)$$

This may also be written

$$K = \frac{\sqrt{S_1 S_2}}{4\pi b}, \quad . \quad . \quad . \quad (20)$$

where S_1 and S_2 are the surfaces of the spheres and b is the axial distance between their surfaces.

Single Sphere.—By making r_2 infinite in equation (19) we obtain for a single sphere of radius r (far from surrounding bodies)

$$K = r. \quad . \quad . \quad . \quad . \quad (21)$$

For example, a sphere of 1 cm. radius would have capacitance of 1 abstatfarad or about 1·111 $\mu\mu$F. If it were hung near the centre of an empty room 4M × 4M × 4M, this value would be correct to within about 5 in 1000. (A small sphere sometimes forms a convenient rough standard of small capacitance.)

Note. The concentric spheres and the single sphere are almost the only cases in which an exact formula is available. In most other cases the mathematical difficulties due to edges and ends render the formulas only approximate.

(ii.) *Two Spheres,*[1] radii r_1 and r_2 at relatively great distance a apart.—

$$K = \frac{a r_1 r_2}{a(r_1 + r_2) - 2r_1 r_2}. \quad . \quad . \quad (22)$$

(iii.) *Two Equal Spheres*[2] close to one another.—Let the radius of each be r and let the distance between the nearest points be x. Then

$$K \doteq \frac{r}{2}\left(1 + \frac{x}{6r}\right)\left(1{\cdot}2704 + \tfrac{1}{2}\log_\epsilon \frac{r}{x} + \frac{x}{18r}\right). \quad (23)$$

For more elaborate formulas for spheres see Russell (*loc. cit.*).

(iv.) *Two Concentric Circular Cylinders,* radii: r_1 inner, r_2 outer; length l.—When the length is so great (relatively to r_2) that the end effects may be neglected,

$$K = \frac{l}{2 \log_\epsilon (r_2/r_1)}. \quad . \quad . \quad (24)$$

When the distance between the surfaces is very small compared with the radii, *i.e.* $(r_2 - r_1) \ll r_2$,

$$K \doteq \frac{l r_1}{2(r_2 - r_1)}, \quad . \quad . \quad . \quad (25)$$

$$\doteq \frac{S}{4\pi b}, \quad . \quad . \quad . \quad . \quad (26)$$

where S is the surface of one cylinder and b is the axial distance between the two surfaces.

(v.) *Single Circular Wire,*[3] radius r, length l (great compared with r).—If the wire is parallel to the earth at height h,

$$K = \frac{l}{2 \log_\epsilon \dfrac{h - \sqrt{h^2 - r^2}}{r}}. \quad . \quad . \quad (27)$$

(vi.) *Two Long Parallel Horizontal Wires,*[3] each of radius r, length l, at height h and distance apart b.—The capacity between them is

$$K = \frac{l}{4 \log_\epsilon (2h/r) - 2 \log_\epsilon (1 + 4h^2/b^2)}, \quad (28)$$

where h and b are large compared with r.

For a great height, making h infinite, the formula becomes

$$K = \frac{l}{4 \log_\epsilon (b/r)}. \quad . \quad . \quad (29)$$

(vii.) *Two Parallel (Equal) Plates,* area (of one) S, distance apart b.—If the edge action and earth capacitances are neglected the approximate formula is

$$K \doteq \frac{S}{4\pi b} \text{ abstatfarads}. \quad . \quad . \quad (30)$$

[1] W. H. Eccles, *Handbook of Wireless Telegraphy and Telephony*, p. 53.
[2] A. Russell, *Roy. Soc. Proc.* A, 1909, lxxxii. 524.
[3] A. Russell, *Alternating Currents*, vol. i. chap. v., where other cases are also investigated.

If the dielectric between the plates has a dielectric constant κ,

$$K = \frac{\kappa S}{4\pi b \times 900{,}000} \text{ microfarads}, \quad (31)$$

$$\doteq \frac{\kappa S}{113 \cdot 1 b} \mu\mu F. \quad (32)$$

Condensers are commonly constructed of a number of conducting plates, with the alternate ones connected in parallel forming the two conducting systems of the condenser. If there are in all N metal plates, there will be only N − 1 spaces between, and hence

$$K \doteq \frac{(N-1)S}{4\pi b} \text{ abstatfarads}. \quad (33)$$

In most practical condensers these equations are sufficiently accurate to give values near enough for the purposes of design.

Pair of Parallel Plates with a Number of Different Dielectrics in Parallel Layers between.—If the layers have thicknesses b_1, b_2, b_3 . . . and dielectric constants κ_1, κ_2, κ_3 . . ., then

$$K \doteq \frac{S}{4\pi(b_1/\kappa_1 + b_2/\kappa_2 + b_3/\kappa_3 + \ldots)}. \quad (34)$$

(viii.) *Plates at Small Angle.*[1]—If two equal plates of width a are at a small angle θ (radians) to one another with the edges (a) parallel to the line of intersection of their planes, then

$$K \doteq \frac{a}{2\pi\theta} \log_\epsilon \left(\frac{r_2}{r_1}\right), \quad (35)$$

where r_1 and r_2 are the respective distances of the parallel edges from this line.

(ix.) *Single circular plate*, radius r, thickness negligible.

$$K = \frac{2r}{\pi}. \quad (36)$$

(x.) *Two circular plates*, radii r, thickness t small compared with r, distance apart b (also small compared with r).

This is a case where, for accuracy, the capacities to earth should be taken into account.[2] By Orlich's method, as in § (5), when both plates are insulated we have

$$K = c_{12} + \frac{c_1 c_2}{c_1 + c_2}. \quad (37)$$

Neglecting t for the parts c_1 and c_2, we have by equation (36)

$$c_1 = c_2 \doteq \frac{r}{\pi}.$$

When one plate is earthed,

$$K_1 = c_{12} + c_1 = c_{12} + \frac{r}{\pi}. \quad (38)$$

[1] L. E. Dodd, *Phys. Rev.*, 1917, ix. 96.

[2] R. Jaeger, *Dissertation*, Berlin, 1917, and *Ann. d. Physik*, 1917, liii. 409.

Kirchhoff[3] gives the complete formula *for this latter case* as follows:

$$K_1 = \frac{r^2}{4b} + \frac{r}{4\pi}\left[\log_\epsilon \frac{16\pi(b+t)r}{b^2} + \frac{t}{b}\log_\epsilon \frac{b+t}{t} + 1\right]. \quad (39)$$

Hence

$$c_{12} = \frac{r^2}{4b} + \frac{r}{4\pi}\left[\log_\epsilon \frac{16\pi(b+t)r}{b^2} + \frac{t}{b}\log_\epsilon \frac{b+t}{t} - 3\right], \quad (40)$$

and, therefore, by equation (37), when both plates are insulated,

$$K = \frac{r^2}{4b} + \frac{r}{4\pi}\left[\log_\epsilon \frac{16\pi(b+t)r}{b^2} + \frac{t}{b}\log_\epsilon \frac{b+t}{t} - 1\right]. \quad (41)$$

Guard Ring.—In general in a plate condenser the electric field is almost perfectly uniform except near the edges of the plates. In order to maintain the uniformity of the field at the edges (thus rendering the use of the simple formula of equation (30) much more accurate), Lord Kelvin introduced the device of a guard ring. This is shown in section in *Fig.* 5. The disc P is surrounded by a flat ring GG of the same thickness, concentric with P and separated from it by a narrow channel. The outer diameter of the guard ring GG is equal to that of the opposing plate Q. In use P and the guard ring are brought to the same potential, but the charge on P can be determined independently of that on the ring. As the channel has appreciable width, a small correction has to be applied for it. Let r be the diameter of P, and let w, the width of the channel, be small compared with r and b, the distance between the plates. Then,[4] for the capacitance between P and Q,

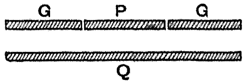

FIG. 5.—Plate Condenser with Guard Ring.

$$K \doteq \frac{r^2}{4b} + \frac{1}{4} \cdot \frac{rw}{b + 0 \cdot 22w}\left(1 + \frac{w}{2r}\right). \quad (42)$$

Another formula is given by Kirchhoff (*Abhandlungen*, p. 117).[5] The ratio of r to b may have any desired value, so long as the radial width of the guard ring is at least 4 or 5 times b.

In a similar way cylindrical guard rings can be applied to the ends of a cylindrical condenser.

§ (8) Residual Charge and Absorption.—In discussing the behaviour of condensers in circuits where they are charged and discharged, it is convenient to confine our attention to the charge that goes in or out at one terminal. Thus when we say that a condenser receives

[3] G. Kirchhoff, *Gesamm. Abhandl.* p. 112, and *Berlin Akad. Monatsberichte*, 1877, p. 144.

[4] J. Clerk Maxwell, *Electricity and Magnetism*, 2nd ed. vol. i. § 201.

[5] See F. Kohlrausch, *Lehrbuch d. prakt. Physik*, 2nd ed., 1905, p. 565.

a charge Q, we mean that a charge $-Q$ has at the same time entered by the other terminal. This is equivalent to a quantity $+Q$ passing in at one terminal and out at the other.

If a condenser receives a charge Q and is then discharged by short-circuiting the terminals, in general the total quantity that passes out is less than Q, and hence a certain part of the energy of the charge Q is spent in the condenser. Usually the greater part of the discharge takes place very quickly, but a certain portion is temporarily bound in the condenser and is slowly discharged if the short-circuit is maintained. This portion is called *residual charge*, and the general effect is described as *absorption*. If the short-circuit (which keeps the terminal potential difference zero) is broken after the main discharge, the terminal potential difference will slowly rise to a small amount owing to the residual charge being gradually set free. In extreme cases continued discharge may be observed even for days.

A *perfect condenser* is one without absorption or leakage, and for many purposes a good air condenser with high insulation gives an extremely near approximation to this ideal. Condensers with solid or liquid dielectrics all show absorption in varying degree depending on the nature and condition of the dielectric substance.[1]

§ (9) Condenser in Alternating Current Circuit.—Let v and i respectively be the instantaneous values of sine-wave alternating voltage and current of pulsatance ω, where $\omega = 2\pi \times$ frequency n, and let V and I be the corresponding effective values. Then

$$v = V_{\max.} \sin \omega t. \quad . \quad . \quad (43)$$

If the voltage v is applied to the terminals of a perfect condenser of capacitance K, and if q is the quantity in the condenser at any moment, then

$$q = Kv \quad . \quad . \quad . \quad . \quad (44)$$

and
$$i = \frac{dq}{dt} = K\frac{dv}{dt} = K\omega V_{\max.} \cos \omega t$$
$$= K\omega V_{\max.} \sin\left(\omega t + \frac{\pi}{2}\right). \quad (45)$$

Hence

$$I = \omega KV, \text{ (amperes, volts, farads).} \quad (46)$$

[In symbolic notation we write

$$v = \frac{1}{j\omega K} i = -\frac{j}{\omega K} i, \quad . \quad . \quad . \quad (47)$$

where $j = \sqrt{-1}$.]

Table I. gives approximate values of the current taken by various condensers at 100 volts for frequencies of 100, 1000, and 1,000,000 ∿ per second respectively.

[1] For discussion of theories of absorption see F. W. Grover, *Bureau of Standards Bulletin*, 1912, vii. 518.

Table I

Condenser Currents at 100 Volts

K.	n=100.	1000.	1,000,000.
μF.	Milliamps.	Milliamps.	Amps.
0·001	0·063	0·63	0·63
0·1	6·28	62·8	62·8
1·0	62·8	628	628

§ (10) Condenser in Series with Inductive Coil.—Let the circuit AB have capacitance K in series with resistance R and self-inductance L, as in *Fig.* 6. Let Z be the impedance and z the symbolic impedance;

Fig. 6.

then
$$z = R + j\left(\omega L - \frac{1}{\omega K}\right). \quad . \quad . \quad (48)$$

After a steady state is reached,

$$v = zi = \left[R + j\left(\omega L - \frac{1}{\omega K}\right)\right]i \quad . \quad (49)$$

or
$$v = I_{\max.} \sin(\omega t + \phi), \quad . \quad . \quad (50)$$

where
$$\tan\phi = \frac{(L\omega - 1/\omega K)}{R}. \quad . \quad . \quad (51)$$

Also

$$V = ZI = I\sqrt{R^2 + \left(L - \frac{1}{\omega^2 K}\right)^2 \omega^2}, \quad (52)$$

when $\omega^2 LK = 1$, $\phi = 0$, and $Z = R$.

The circuit is then said to be electrically tuned or in *resonance* for pulsatance ω (or frequency n); and the current I is then a maximum for given R, L, V, and ω.

§ (11) Condenser in Parallel with Inductive Coil.—If a condenser K is in parallel with an inductive circuit (R, L) as in *Fig.* 7, then $1/j\omega K$ and $(R + j\omega L)$ are in parallel, and hence

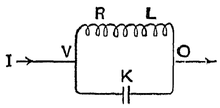

Fig. 7.

$$z = \frac{(R + j\omega L)/j\omega K}{R + j\omega L + 1/j\omega K}$$
$$= \frac{R + j\omega L}{1 - \omega^2 LK + j\omega RK} \quad . \quad . \quad (53)$$

and
$$Z = \frac{R^2 + \omega^2 L^2}{(1 - \omega^2 LK)^2 + \omega^2 R^2 K^2}. \quad . \quad (54)$$

When K is adjusted to make Z a minimum,

$$K = \frac{1}{R^2/L - \omega^2 L}$$

or
$$\omega^2 LK = 1 - \frac{R^2 K}{L} \quad . \quad . \quad (55)$$

Then we have *current resonance* (Orlich); and the current I is a maximum for given R, L, V, and ω.

Also
$$Z = \frac{L}{KR} = R + \frac{\omega^2 L^2}{R}. \quad . \quad . \quad (56)$$

§ (12) Power Loss in Condensers.—As pointed out in § (8), a condenser which shows absorption does not when discharged return the whole quantity which was put into it in charging. Let a condenser be taken through a complete cycle of charge and discharge, and let q, the instantaneous value of the quantity in the condenser, be plotted against v, the instantaneous value of the terminal voltage. The area of the resulting closed curve will be zero in the case of a perfect condenser, but if the condenser has absorption the area ($\int v dq$) of the curve will represent the energy lost in the condenser in one cycle. The result will be in joules if the quantity and voltage are expressed in coulombs and volts. If the cycle is periodically repeated n times per second, the power lost in the condenser will then be $n \times$ (area of curve) in watts. This loss of power is partly due to *dielectric hysteresis*, and has some analogy to the loss due to magnetic hysteresis when iron is magnetised and demagnetised. Since the bound charge takes time to free itself, the loss per cycle usually varies with the frequency n.

An additional amount of power is in general lost due to actual leakage current through the dielectric or across bad insulation at the terminals. Sometimes there is appreciable loss due to the resistance of internal wires and connections or of the plates themselves.

§ (13) Power Loss with Alternating Current.—If alternating voltage V is applied to the terminals of a perfect condenser, by equation (45) the resulting current I will be equal to KωV and its phase will be exactly 90° in front of V (leading). But if the condenser has internal power loss, ϕ the angle of lead will be less than 90° and the *power factor* $\cos\phi$ will not be zero. Then, if W is the power spent in the condenser,

$$W = VI\cos\phi = VI\sin\theta, \quad (57)$$

where $(\pi/2 - \phi) = \theta$, which is called the *phase displacement.*

§ (14) Equivalent Circuit.—For most purposes a condenser with power losses of any kind (dielectric hysteresis, leakance, etc.) may, for a given frequency, be taken as equivalent to a perfect condenser either (A) in series or (B) in parallel with a non-inductive resistance, as the resistance in either case can be so chosen as to waste the same amount of power as the absorptive condenser and thus also give the same phase angle.

Fig. 8.

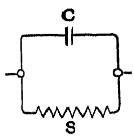

Fig. 9.

In the two systems (A) and (B) let the circuits shown in *Figs.* 8 and 9 be equivalent to the same condenser for pulsatance $\omega = 2\pi n$.

System A.—*Series Resistance.*

If z is the vector impedance,

$$z = R - \frac{j}{\omega K} \quad (58)$$

and

$$\frac{V}{I} = Z = \left(R^2 + \frac{1}{\omega^2 K^2}\right)^{\frac{1}{2}} \quad (59)$$

Here the effective resistance $=R$ and the reactance $= -1/\omega K$.

Thus power spent $= W = RI^2$. (60)

Also $W = VI\cos\phi$,

where

$$\tan\phi = \frac{1}{\omega RK} \quad (61)$$

and

$$\tan\theta = \omega RK. \quad (62)$$

When θ is small, $\theta \doteq \omega RK$ radians, and the *power factor* $\cos\phi \doteq \tan\theta \doteq \omega RK$.

System B.—*Parallel Resistance.*

We have

$$z = \frac{S/j\omega C}{S + 1/j\omega C} = \frac{S}{1 + j\omega SC}$$

or

$$z = \frac{S - j\omega S^2 C}{1 + \omega^2 S^2 C^2}. \quad (63)$$

Thus

$$\frac{V}{I} = Z = \frac{S}{\sqrt{1 + \omega^2 S^2 C^2}}. \quad (64)$$

Here the effective resistance

$$R' = \frac{S}{1 + \omega^2 S^2 C^2}, \quad (65)$$

and the reactance

$$X = -\frac{\omega S^2 C}{1 + \omega^2 S^2 C^2}. \quad (66)$$

Very often $\omega^2 S^2 C^2$ is very large compared with 1, and then we have $R' \doteq 1/\omega^2 SC^2$ and $X \doteq -1/\omega C$.

Also

$$W = \frac{V^2}{S} \quad (67)$$

or $= VI\cos\phi$,

where

$$\tan\phi = \omega SC. \quad (68)$$

When θ is small, $\theta \doteq 1/\omega SK$ radians, and the *power factor* $\cos\phi \doteq \tan\theta \doteq 1/\omega SK$.

Comparison of Systems A *and* B.—We can pass from one equivalent system to the other by means of the following relations:

$$\omega KR = \frac{1}{\omega SC}, \quad (69)$$

$$R = \frac{S}{1 + \omega^2 S^2 C^2}, \quad (70)$$

and

$$K = C\left(1 + \frac{1}{\omega^2 S^2 C^2}\right). \quad (71)$$

$$S = R\left(1 + \frac{1}{\omega^2 K^2 R^2}\right) \quad (72)$$

and

$$C = \frac{K}{1 + \omega^2 K^2 R^2}. \quad (73)$$

In good condensers the power factor ωKR is a small fraction, and in this case

$$\mathrm{K} \doteqdot \mathrm{C} \quad . \quad . \quad . \quad . \quad (74)$$

and
$$\mathrm{R} \doteqdot \frac{1}{\omega^2 \mathrm{SC}^2}. \quad . \quad . \quad . \quad (75)$$

§ (15) Discharge with Inductive Circuit.—The discharge of a condenser through an inductive circuit has very important practical applications. The complete mathematical theory was given by Lord Kelvin [1] many years ago.

Let a (perfect) condenser of capacitance K, charged to a potential difference V_0, have its terminals, at time $t=0$, connected to a circuit of resistance R and self-inductance L. A current will begin to flow out of the positively charged terminal. Let i be the value of this current at time t, and let q and v be the corresponding values of the quantity in the condenser and the terminal potential difference respectively. Let Q be the initial charge, where $\mathrm{Q}=\mathrm{KV}_0$.

Then
$$v=\mathrm{R}i+\mathrm{L}\frac{di}{dt}, \quad . \quad . \quad . \quad (76)$$

$$q=\mathrm{K}v, \quad . \quad . \quad . \quad (77)$$

and
$$i=-\frac{dq}{dt}. \quad . \quad . \quad . \quad (78)$$

These three equations are sufficient to determine q, i, or v in terms of the time t.

Eliminating v and i we have

$$\frac{d^2q}{dt^2}+\frac{r}{\mathrm{L}}\cdot\frac{dq}{dt}+\frac{1}{\mathrm{KL}}q=0, \quad . \quad . \quad (79)$$

the differential equation by which q can be determined in terms of t.

The complete solution of (79) is

$$q=\mathrm{Q}\epsilon^{-bt}\left[\frac{\epsilon^{at}+\epsilon^{-at}}{2}+\frac{b}{a}\cdot\frac{\epsilon^{at}-\epsilon^{-at}}{2}\right], \quad (80)$$

where
$$b=\frac{\mathrm{R}}{2\mathrm{L}} \quad . \quad . \quad . \quad (81)$$

and
$$a=\sqrt{\frac{\mathrm{R}^2}{4\mathrm{L}^2}-\frac{1}{\mathrm{LK}}}. \quad . \quad . \quad (82)$$

The nature of the discharge depends upon the value of a, which may be real, zero, or imaginary. Thus three cases arise.

Case 1.—If $\mathrm{R}^2 > 4\mathrm{L/K}$, then a is real.

In this case equation (80) holds as it stands. It may be written

$$q=\mathrm{Q}\epsilon^{-bt}\left(\cosh at+\frac{b}{a}\sinh at\right). \quad . \quad (83)$$

Since $a^2-b^2=-1/\mathrm{LK}$, and $i=-dq/dt$,

$$i=\mathrm{Q}\left(\frac{a^2-b^2}{a}\right)\epsilon^{-bt}\cdot\frac{\epsilon^{at}-\epsilon^{-at}}{2} \quad . \quad (84)$$

$$=\frac{\mathrm{V}_0}{\mathrm{L}a}\epsilon^{-bt}\sinh at\,; \quad . \quad . \quad . \quad . \quad (85)$$

also
$$v=\frac{q}{\mathrm{K}}=\mathrm{V}_0\epsilon^{-bt}\left[\frac{\epsilon^{at}+\epsilon^{-at}}{2}+\frac{b}{a}\cdot\frac{\epsilon^{at}-\epsilon^{-at}}{2}\right]. \quad (86)$$

Fig. 10 shows examples of the curves connecting q, v, and i with the time t.

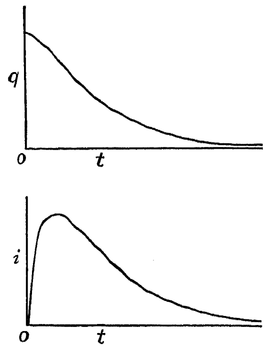

Fig. 10.—Non-oscillatory Discharge.

The current begins at zero, rises to a maximum value

$$a\sqrt{\mathrm{LK}}\left(\frac{b+a}{b-a}\right)^{-b/2a}$$

when
$$t=\frac{1}{2a}\log_\epsilon\left(\frac{b+a}{b-a}\right),$$

and then falls asymptotically to zero at infinite time.

Case 2.—If $\mathrm{R}^2=4\mathrm{L/K}$, then $a=0$.

Thus equation (80) becomes

$$q=\mathrm{Q}\epsilon^{-bt}(1+bt)\,; \quad . \quad . \quad (87)$$

also
$$i=\frac{\mathrm{V}}{\mathrm{L}}t\epsilon^{-bt}, \quad . \quad . \quad . \quad (88)$$

and
$$v=\mathrm{V}_0\epsilon^{-bt}(1+bt). \quad . \quad . \quad (89)$$

The curves for q, v, and i are very similar to those of *Fig.* 10. The discharge is aperiodic (just not oscillatory). The current begins at zero, rises to a maximum value $2\mathrm{V/R}\epsilon$, when $t=1/b$, and then falls asymptotically to zero at $t=\infty$.

Case 3.—If $\mathrm{R}^2 < 4\mathrm{L/K}$, then a is imaginary. Let $a=j\omega$, where $j=\sqrt{-1}$.

The equations then are

$$q=\mathrm{Q}\epsilon^{-bt}\left(\cos\omega t+\frac{b}{\omega}\sin\omega t\right), \quad . \quad (90)$$

$$i=\frac{\mathrm{V}_0}{\mathrm{L}\omega}\epsilon^{-bt}\sin\omega t, \quad . \quad . \quad (91)$$

and
$$v=\mathrm{V}_0\epsilon^{-bt}\left(\cos\omega t+\frac{b}{\omega}\sin\omega t\right)$$

$$=\frac{\mathrm{V}_0}{\omega\sqrt{\mathrm{LC}}}\epsilon^{-bt}\sin(\omega t+\phi), \quad . \quad . \quad (92)$$

where
$$\tan\phi=\frac{\omega}{b}.$$

[1] William Thomson, *Phil. Mag.*, 1853, v. 393, and *Mathematical and Physical Papers*, i. 540.

The curves are of the type shown in *Fig.* 11. At successive equal intervals of time they touch curves of the form $y = \pm A\epsilon^{-bt}$ above and below the axis of t.

The discharge is now oscillatory, the condenser becoming recharged at regular intervals with alternately negative and positive charges of gradually decreasing amount. The action is analogous to dynamic vibration with damping, potential energy being transformed into kinetic energy twice in each cycle, with continuous loss of energy until it is all dissipated. The loss of electrical power is here due to the resistance R, in which the energy is ultimately transformed into heat. The damping of the oscillations is determined by b (*i.e.* R/2L), which is called the *damping coefficient* or the *coefficient of decay*.

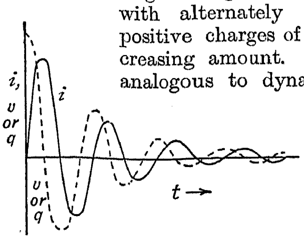

FIG. 11.—Oscillatory Discharge (large damping).

The oscillation *frequency* n is equal to $\omega/2\pi$, and T the *complete period* $=1/n$.

If δ is the *logarithmic decrement* for a complete period

$$\delta = \log_\epsilon\left(\frac{i_0}{i_T}\right) \text{ by definition;}$$

hence
$$\delta = \frac{b}{n}. \quad . \quad . \quad . \quad (93)$$

Equations (91) and (92) show that if the direction of the discharge is taken positive (as here) the current lags behind the voltage by the angle ϕ, which is nearly 90° when b is very small.

If K and R are given, the frequency is 0 when $L = KR^2/4$; then for increase of L it increases to a maximum for $L = KR^2/2$, after which it slowly decreases to 0 as L becomes infinite.

By suitable variation of K and L an enormous range of frequencies can be actually obtained, reaching from a few alternations per minute up to at least 5×10^{10} ∾ per second. The system is of fundamental importance in Radio Telegraphy. For further information see the articles [1] on that subject.

§ (16) CHARGE AND DISCHARGE WITH NON-INDUCTIVE CIRCUIT.—(i.) If a voltage V_0 is applied, at time $t=0$, to a circuit consisting of a condenser K in series with a resistance R, then

$$i = \frac{V_0}{R}\epsilon^{-\frac{t}{KR}}, \quad . \quad . \quad . \quad . \quad (94)$$

where $+i$ is the current going in;

also
$$q = KV_0\left(1 - \epsilon^{-\frac{t}{KR}}\right) \quad . \quad . \quad (95)$$

[1] "Radio Frequency, Measurements at," and "Wireless Telegraphy."

(ii.) If a condenser K charged to voltage V_0 is connected across a resistance R at time t_0, the *discharge current* i is given by equation (94); also

$$q = KV_0\epsilon^{-\frac{t}{KR}}. \quad . \quad . \quad . \quad (96)$$

In both cases the current follows a curve of the kind shown in *Fig.* 12, beginning with a maximum value V_0/R and falling asymptotically to 0 at $t = \infty$. The fraction of its initial value to which the current falls in time t depends on KR, which is called the *time constant* of the circuit. Thus the time constant is the time the current takes to fall to $1/\epsilon$th part of its initial value. The capacitance K is here in farads if R is in ohms.

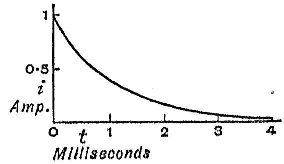

FIG. 12.—Charge or Discharge with Resistance only.

In most cases occurring in practice, except where the resistance R is very large or the condenser has absorption, the charge or discharge is practically complete in a small fraction of a second, as the following example will show. Let a 1 μF condenser charged to 1000 volts be discharged through a resistance of 1000 ohms. Here the time constant $KR = 10^{-3}$ and the initial current is 1 ampere. In 0·001 sec. the current has fallen to 0·37 ampere, in 0·01 sec. to 0·000045 ampere, and in 0·1 sec. it is less than 10^{-56} ampere. The curve in *Fig.* 12 has been drawn for this case.

II. DIELECTRIC CONSTANT

§ (17) MEASUREMENT OF DIELECTRIC CONSTANT.—The inductive capacity or dielectric constant has been defined in § (6). For most insulating materials its value lies between 1 and 10, but in some cases values as high as 80 to 90 occur. Various methods have been used for its measurement, and for pure materials the results obtained by different observers are in tolerably good agreement. Unfortunately, however, the dielectrics, such as mica, glass, or ebonite, which are most useful in practice are usually of variable or uncertain composition, and hence definite values cannot easily be assigned to them. The variations of the dielectric constant with frequency, temperature, or pressure are also of importance.

Many of the methods of measurement involve the determination of capacitance, the actual methods for which will be described in Part IV. For solid and liquid materials tested by comparison with air, it is quite sufficient to take the dielectric constant of

air as 1, but in the case of gases whose inductive capacities are all near unity it is necessary to take for air the more exact value $1{\cdot}0005_8$. The comparative results must be multiplied by this figure.

A. Solids. (i.) *Plate Condenser Method.*—The most usual method is to test the solid in the form of a thin sheet with parallel faces forming the dielectric in a plate condenser, the area of the sheet being much greater than that of the condenser plates. Sometimes these plates are of tinfoil stuck to or pressed against the dielectric sheet, and sometimes of solid metal. In the latter case allowance must be made for the small air spaces due to imperfect contact. For porous materials like paper or silk a correction has also to be made for the internal air spaces, if the result is to apply to the actual solid material. If a guard ring is not used, Kirchhoff's formula for the capacity of two circular plates is applicable, equation (40) giving the air capacity. The intercapacity c_{12} with the given material is got from the observed capacity by subtracting R/π or $R/2\pi$ according as one plate is earthed or both insulated during the measurement.[1]

(ii.) *Equivalent Displacement.*—A more accurate method[2] uses a special air condenser in which the plates are kept accurately parallel while the distance between them can be varied. The plates are set at a certain distance apart and the capacitance measured or merely balanced; the sheet of material is then introduced and the distance between the plates is increased until the balance is restored or the capacitance has the same value as before. If δ = the change of distance, and b = thickness of sheet, then the dielectric constant κ is given by

$$\kappa = \frac{b}{b-\delta}. \qquad . \quad . \quad . \quad (97)$$

This method appears to be more accurate than (i.).

(iii.) *Fusible Materials.*—When the material can be melted it is sometimes possible to pour it into a condenser such as is used in testing liquids (iv.) and allow it to solidify in position. When it contracts much on cooling trouble may arise from air spaces left between the material and the metal surfaces of the condenser.

B. Fluids. (iv.) *Condenser Methods.*—For fluids the condenser can be of such a form that one of the conductors is almost entirely screened from earth by the other; for example, two concentric cylinders. The capacitance of such a condenser is first tested in air (with the outer cylinder earthed), and a further test made with the whole immersed in the fluid to be examined. Nernst's[3] system of condenser consists of a deep metal trough with flat bottom and cylindrical sides forming one conductor, while the other conductor consists of a metal disc which can be supported horizontally inside the trough at various distances from the bottom. After a test with the trough empty, it is filled with the liquid and another test made without altering the position of the disc. Turner[4] used a condenser of this form for very accurate determinations of the dielectric constant of a number of very pure liquids. The disc was supported by a metal stem passing through an insulating cover of the trough. He found that the most accurate method was to test the capacitance with the vessel full and empty, first with the disc and stem in position and then with the stem alone.

In the more modern tests high-frequency currents generated by triode valves are used.[5]

(v.) *By Electric Attraction (Dynamical Effects).*—If two very small spheres at a distance d from one another in air (or rather in a vacuum) have charges of $+q$ and $-q$ abcoulombs respectively, the force of attraction F between them will be q^2/d^2. But if they are in a medium of dielectric constant κ the force will be $q^2/\kappa d^2$. If their intercapacity in air is C and their potential difference V, then

$$q = \mathrm{CV},$$

and $$\mathrm{F} = \frac{\mathrm{C^2V^2}}{d^2}.$$

For the other medium, if the potential difference is still V,

$$q_1 = \kappa \mathrm{CV},$$

and hence $$\mathrm{F}_1 = \frac{\kappa^2\mathrm{C^2V^2}}{\kappa d^2} = \kappa \mathrm{F}.$$

Similarly,[6] if any two conductors are maintained at a given difference of potential the force between them is proportional to the dielectric constant of the medium. Thus the dielectric constant can be determined by measuring the attraction between two conductors, for a given difference of potential, in air and in the other medium respectively.

Lefèvre[7] used two plates and measured the forces by the help of an ordinary balance.

Silow[8] employed a special quadrant electrometer (used idiostatically) which could be filled with the dielectric to be tested. The needle was suspended by a fine wire, which a later observer[9] replaced by a silvered quartz fibre. Alternating potential difference is used to avoid trouble due to polarisation.

(vi.) *By Measurement of Electrical Wave-lengths.*—If electrical waves (Hertzian) are set

up in a dielectric medium by oscillations of a given frequency, the wave-length is proportional to $1/\sqrt{\kappa}$.[1] Thus the dielectric constant κ can be determined by comparing the wave-length λ_0 in the dielectric with λ the wave-length in air. Then $\kappa = (\lambda_0/\lambda_1)^2$.

Stationary waves are set up along a pair of parallel wires (Lecher System) by means of some source giving oscillations of suitable frequency (n of the order of 2×10^8). For example, the source may be a Blondlot oscillator excited by an induction coil with zinc or cadmium spark gap and Tesla transformer.[2] The wires should be about 1 cm. apart and have their far ends connected. The positions of two wire bridges across the wires are adjusted until an indicator half-way between the bridges shows maximum potential difference. Then the distance between the bridges is half the wave-length. The voltage indicator may be a vacuum tube, a bolometer, a hot-wire voltmeter, or other instrument suitable for such high frequencies. An experiment is first made with the wire system in air, giving λ. Then the wires are immersed in the dielectric liquid contained in a long trough and λ_0 similarly determined. Drude gives a table of corrections to be applied for the limited size of the trough.

§ (18) Values of Dielectric Constant.—In Tables II. and III. are given values of the dielectric constant for a number of solids, liquids, and gases. Where the temperature is not stated it may be assumed to be from 15° to 20° C. For the solids the test frequency may be taken as of the order 1000 ∿ per sec., and for the liquids and gases as 10^6 ∿ per sec. or higher.

§ (19) VARIATION WITH TEMPERATURE.—The temperature coefficients for the more commonly used solids are small (except for very low frequencies). According to Mattenklodt,[1] mica shows no change (to within 1 in 10,000) for a rise of temperature of 30° C., and the capacity shows constancy with variation of voltage up to 600,000 volts per cm.

For ebonite and paraffin wax Pellat and Sacerdote [2] found the following temperature coefficients :

	a, per cent per °C.	Range.
Paraffin wax . . .	−0·036	11 to 32° C.
,, ,,	−0·056	11 to 83
Ebonite	+0·088	10 to 20

According to Schmidt,[3] for sulphur $a = +0·1$ per cent per ° C.

[1] E. Mattenklodt, *Ann. d. Physik*, 1908, xxvii. 359.
[2] H. Pellat and P. Sacerdote, *Comptes Rendus*, 1898, cxxvii. 544.
[3] F. Schmidt, *Ann. d. Physik*, 1914, xliv. 329.

As will be seen from Table II., many of the liquids show higher temperature coefficients than these solids. Dewar and Fleming [4] investigated the dielectric constants of a number of (frozen) liquids down to a temperature of −185° C. They found that many substances which, like water or ethyl alcohol, show abnormally high dielectric constants, give quite small values at the very low temperatures. For example, ice at −185° C. gives $\kappa = 2·4$ to 2·9, and nitrobenzol descends from 32 at 15° C. to 2·6 at −185° C. (These values are for frequencies of the order of about 100 ∿ per sec.)

At very slow frequencies [5] (*e.g.* below 1 ∿ per sec.) the effect of change of temperature is usually very marked.

§ (20) VARIATION OF DIELECTRIC CONSTANT WITH FREQUENCY.—Many substances (solids or liquids) show little change in dielectric constant for change of frequency over a range from 100 ∿ per sec. up to very high values. For example, R. Jaeger [6] tested ebonite, india-rubber, quartz, and a number of kinds of glass, etc., at various frequencies from 250 up to 3×10^7 ∿ per sec. (corresponding to wave-lengths $1·2 \times 10^6$ down to 10 metres) and in general there was at most a variation of 1 or 2 per cent throughout the whole range.

At very low frequencies most substances, however, show considerable increase in dielectric constant (see Curie and Compan, *loc. cit.*).

§ (21) EFFECT OF MOISTURE.—Substances which absorb moisture show large variation in dielectric constant according to the amount of moisture present.

In general also the variations with temperature and frequency increase with increase of moisture.

An example of the large variation with frequency for celluloid and paraffin paper at 19° C. (from the experiments of Thomas [7]) is given by the curves of *Fig.* 13 for low frequencies.

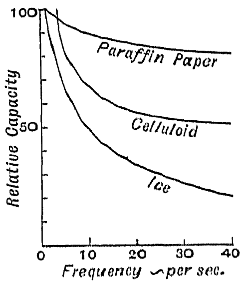

FIG. 13.—Variation of Apparent Dielectric Constant with Frequency (Thomas).

The effect extends to the higher frequencies; from 250 to 2000 ∿ per sec. the apparent dielectric constant of the celluloid fell 7 per cent and that of the paraffin paper 20 per cent. A similar change with frequency is shown by ice (*Fig.* 13).

Many of the fibrous and other insulating materials used in electrical engineering absorb moisture appreciably. Paper is one of the most important of these, and it is also one of the most absorbent. In the manufacture of air-space telephone cables the paper is dried very thoroughly and sealed up hermetically in a lead tube. As it is desirable to keep the capacity as small as possible the paper strips are wrapped round the numerous wires in such a way as to keep them apart with the smallest possible amount of solid supporting material. The advantage of thorough drying in reducing the dielectric constant and increasing the insulation resistivity is illustrated by the following values [1] obtained for solid (colloidal) cellulose (Table IV.). The resistivities were measured at 200 volts (direct current) after one minute's electrification.

TABLE IV

Material.	Condition.	Dielectric Constant at 15° C.	Resistivity at 25° C. Megohm-cm.
Solid cellulose	Air dry	14	4
	Dried at 105° C.	7·3	1500 million
Cellulose triacetate	Air dry	4·7	200 million
	Dried at 105° C.	3·9	9000 million

In Table IV. are also given, by way of contrast, corresponding values for cellulose acetate, which is largely used as a tough insulating varnish for thin wires. It will be noticed that in its ordinary condition (air dry) it is a good insulator, and that the drying has a comparatively small effect on it. In the case of cellulose (of which paper is a fibrous and porous form) it would appear that a certain portion of the associated moisture can never be got rid of by any process of drying without absolute decomposition of the material. Thus in well paraffined paper or paraffined cotton-covered wire the moisture effects still show themselves.

Gutta-percha, when kept in water, goes on absorbing water for years, but all the while its insulation resistivity is *rising*. It shows, however, considerable change of dielectric constant with frequency [2] (*e.g.* a fall of 8 per cent for 200 up to 2000 ∿ per sec.).

§ (22) VARIATION OF DIELECTRIC CONSTANT WITH PRESSURE.—Ortvay [3] determined the dielectric constants of a number of liquids at varying pressures from 0 up to 500 kgm. per sq. cm. He found that they all obeyed the law $\kappa_p = \kappa_1(1 + \alpha p - \beta p^2)$, where p is the pressure and α and β are positive. The dielectric constant increases as the pressure is raised, but the rate of increase becomes less at the higher pressures.

The behaviour of gases at different pressures has been investigated by Occhialini and Bodareu [4] and others. The following are typical values for air:

p	1	149	334 atmos.
κ	1·000585	1·0839	1·1691.

The values for air practically follow the Mossotti Clausius formula,[5]

$$\frac{\kappa-1}{\kappa+2}\cdot\frac{1}{d}=\text{const.}, \quad . \quad . \quad (98)$$

where d is the density. Nitrogen and hydrogen also obey this law up to pressures of 100 atmos.

§ (23) DIELECTRIC CONSTANT AND OPTICAL PROPERTIES.—According to Maxwell's [6] electromagnetic theory of light the dielectric constant should be equal to the square of the refractive index μ (for the same wave-length λ). As the two quantities cannot be measured at the same wave-length, it is usual to employ Cauchy's formula,

$$\mu = A + \frac{B}{\lambda^2}, \quad . \quad . \quad . \quad (99)$$

or one of the more modern formulae connecting refractive index and wave-length, in order to find by extrapolation the value of μ for wave-lengths much longer than those reached in the infra-red spectrum. Maxwell's law is found to hold for certain gases and for hydrocarbon oils, but not for animal or vegetable oils.

Rubens [7] determined optically the reflecting power (R) of a number of solid and liquid dielectric substances for wave-lengths up to about 0·3 mm. (313 microns). He found that, as the wave-length was gradually raised to this value, R for most of the solids first fell and then rose to a maximum, after which it fell asymptotically towards a steady value. For all the liquids except castor oil (which showed R nearly constant) R followed almost a straight-line law of increase from 30 up to 300 microns wave-length. Rubens also determined the

[5] See F. Hasenohrl, *Wien. Ber.*, 1896, cv. pt. ii. 460, and D. Negreano, *Comptes Rendus*, 1899, cxxviii. 814, who attributes formula (98) to Lorentz (1880).

[6] Maxwell, *Electricity and Magnetism*, 2nd ed., 1881, § 788.

[7] H. Rubens, *Deutsch. Phys. Gesell. Verh.*, 1915, xvi. 315.

dielectric constants (κ) for the same set of substances by the Lecher method using waves of 10 to 30 metres wave-length. By Fresnel's formula the relation between R and κ should be

$$R = 100\left(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\right) \quad . \quad . \quad . \quad (100)$$

He found that for the solids the values of R_∞ obtained from this formula were in good agreement with the limits approached in the optical experiments, thus indicating that in the unexplored range from $\lambda = 0{\cdot}3$ mm. to $\lambda = 10{,}000$ mm. there is probably no anomalous dispersion. R. Jaeger (*loc. cit.*) tested the same samples of the solid materials and found that in general their dielectric constants were practically constant down to moderate frequencies.

On the other hand, the results found by Rubens for the liquid dielectrics do not show agreement with formula (99) and indicate the presence of anomalous dispersion.

§ (24) Dielectric Constant of Glass.—The various kinds of glass which are manufactured for optical purposes possess such diversity in composition that it is not surprising that their dielectric constants should include a long range of values. Some typical examples (from Jaeger) are given in Table V., the approximate chemical composition in each case being indicated in columns 2 and 3. All the glasses except the Uviol Crown also contained 1 per cent or less of As_2O_3.

Table V

Various Glasses

Designation.	Chief Constituents (each over 10 per cent).	Constituents under 10 per cent.	Dielectric Constant (for $\lambda=10$ m.).
Uviol Crown. U.V. 3199	SiO_2 B_2O_3, K_2O	ZnO	5·61

Heaviest Silicate Flint	PbO, SiO_2	..	17·70

Gray and Dobbie[1] investigated the dielectric constants of a number of glasses (of known analysis) for quick time of charge both at room temperature and at temperatures of the order of 130° C., also determining the resistivities at temperatures from about 70° up to 140° C. Although the fall in resistivity were enormous over this range of temperature, the increase of dielectric constant was in most cases not large, being of the order of 4 to 15 per cent.

[1] A. Gray and J. J. Dobbie, *Roy. Soc. Proc.*, 1900, lxvii. 197.

III. Construction of Condensers

§ (25) Condensers may be classified according to the purposes for which they are designed, as primary standards, secondary standards, and common condensers. It is more convenient, however, in describing the various types, to arrange them according to the dielectric used in their construction. For good condensers the desirable qualities are permanence, constancy of capacitance, small change with temperature or frequency, small power loss with alternating current, and capability of standing considerable applied voltage. For several reasons compactness (relatively small bulk) is also desirable, and hence in most cases the dielectric substance must be capable of easy subdivision into thin sheets. Few readily obtained materials fulfil the desired conditions, and for present-day practice the list need only include *mica, paraffin-waxed paper, shellacked paper, ebonite, glass, air,* and *oil.* Electrolytic condensers form a class by themselves and will be discussed separately.

§ (26) Dielectric Strength.—The insulating material should be able to bear as high an applied voltage as possible; this property is measured by the *dielectric strength*, which is expressed in volts per cm. of thickness necessary to cause breakdown of the material by sparking through it. The dielectric strength is not constant for various thicknesses of sheet, but decreases with increase of thickness. In Table VI. are given approximate dielectric strengths of the most important materials used in making condensers. They are mostly taken from T. Gray's[2] results, which were obtained with slightly convex discs as electrodes. As most of the materials may vary very considerably in composition, the values in the table must only be taken as indicating the order of magnitude to be expected for a given material.

[2] T. Gray, *Phys. Rev.*, 1898, vii. 199.

TABLE VI

DIELECTRIC STRENGTHS

Material.	Thickness. mm.	Dielectric Strength. Volts per cm.
Air (at normal pressure and temperature)	0·2	57 500
	0·6	49 200
	1	43 600
	6	32 700
	10	29 800
Ebonite . . .	1	500 000
Glass (density 2·5)	1	285 000
	5	183 000
Mica	0·01	2 000 000
	0·1	1 150 000
	0·2	950 000
	1·0	610 000
Paraffin oil . .	..	60 000-100 000
Paraffin wax . .	..	130 000-270 000
Paraffin - waxed paper	0·1	400 000-600 000
Vaseline . . .	..	91 000

§ (27) MICA CONDENSERS. (i.) *Methods of Construction.*—For condensers of the order of 1 μF mica is pre-eminently the best dielectric material. By reason of its natural cleavage it can be readily split into very thin sheets, and its mechanical properties are good, for its resistance to crushing is very great. Also, as is seen from Table VI., its dielectric strength is very high. Even though very thin sheets can be made, a large number are required for a condenser of the order of 1 microfarad. One sheet of 25 sq. cm. area and 0·05 mm. thick gives a capacity of about 0·002 μF, and hence for 1 μF about 500 mica sheets of this size would be required. The actual sheets should have considerably greater area to allow sufficient edges for insulation. For the best standard condensers the sheets must be of well-selected clear ruby mica. These are assembled with alternate sheets of tinfoil in hot melted paraffin wax, the most scrupulous care being taken to avoid any traces of moisture. The operator must have an exceptionally dry skin, for if the high temperature of the process causes any perspiration in the hands, traces of moisture, salt, etc., get into the wax and lower the quality of the condenser. Paraffin wax of melting-point about 63° C. is suitable. In chemical constitution it should consist of only a small number of different paraffins. The pile of sheets is compressed while hot and a certain amount of the paraffin is squeezed out. The behaviour of the condenser afterwards depends on the amount of paraffin wax allowed to remain. The temperature coefficient of the capacitance is usually about −0·02 per cent per degree C.; but, as Curtis[1] showed, by applying sufficient pressure it can often be reduced nearly to zero and sometimes even made positive. Some good authorities, however, state that condensers so treated are very liable to break down, and that it is very desirable to leave a greater proportion of paraffin if good constancy is to be ensured.

[1] H. L. Curtis, *Bureau of Standards Bull.*, 1910, vi. 147.

The two alternate sets of tinfoil sheets are soldered to a pair of flexible leads of low resistance, and as soon as possible the condenser is sealed up permanently in an air-tight case. If this precaution is neglected, the gradual absorption of moisture by the paraffin wax in time spoils the condenser.

Instead of using sheets of tinfoil, sometimes the conducting surfaces are formed by chemically silvering opposite sides of the mica sheets. Condensers made in this way, however, have been found to show slight inconstancy in capacity, which has been traced to uncertainty of contact between patches of the silver with the mica.

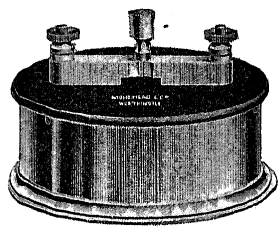

FIG. 14.
Muirhead 1 μF Condenser.

Mica condensers are mounted in a variety of ways. *Fig.* 14 shows one of the most usual forms for a single-valued condenser. When a number of condenser sections are mounted together, a very common plan is to connect them in series to plug blocks as shown in *Fig.* 15. By this system the sections can each be used alone, or they can be connected as desired in series or in parallel to the long blocks which carry the terminals. For example, with the plugs A B in the positions

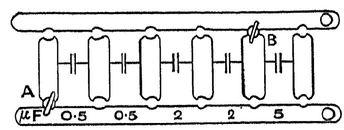

FIG. 15.—Parallel Series Connections for Condenser.

shown the capacitance would be 0·5, 0·5, 2, and 2, all in series, *i.e.* 0·2 μF.

A much more elaborate and convenient arrangement shown in *Fig.* 16 has the sections in decades with 10-fingered switches to put any desired number of the sections in parallel.

Note.—A word of warning is here necessary with regard to the marking of standard condensers. Many condensers in use at the present time marked in microfarads are really in the old B.A. microfarads, which are larger than international microfarads, the relation between these units being

$$1 \text{ B.A. } \mu\text{F} = 1{\cdot}0134 \text{ International } \mu\text{F}.$$

(ii.) *Importance of Steady Temperature.*—Condensers of the type described above, having

their plates embedded in a considerable mass of paraffin wax, do not quickly follow the room temperature when it varies rapidly. For the most accurate work it is best to keep the condenser in an enclosure at constant temperature for several hours before using it. When a condenser is tested at the National Physical Laboratory it is kept in a constant temperature room for 24 hours before the test is made.

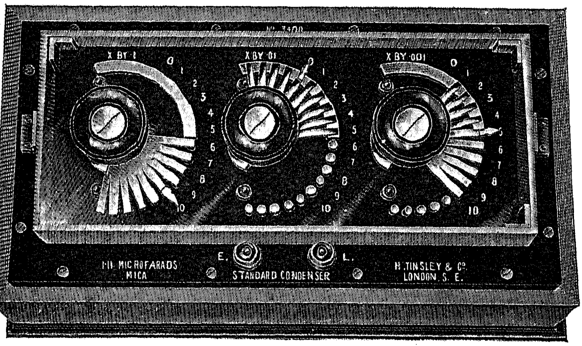

FIG. 16.—Tinsley Subdivided Condenser.

(iii.) *Condensers for High Voltage.*—If a condenser is to stand high voltage, it should not be built with very thick mica sheets, but should consist of a number of equal sections (with mica of normal thickness) connected permanently in series. If there are m equal sections, then each of them will only have to stand $1/m$th of the total voltage. The capacity of each is of course m times the capacity required.

§ (28) PARAFFIN PAPER CONDENSERS.—Mica condensers of large capacitance are very expensive, for the mica is a costly material and large sheets of it are not available. For many purposes paraffin paper condensers can be used instead. In their manufacture the paper must be extremely well dried before paraffining, and the same precautions must be taken to exclude moisture as already described for mica condensers. Only very good paper should be used, free from all surface loading or added mineral matter. A good working thickness is about 0·025 mm. To avoid the danger of breakdown due to pin-holes or other weak spots it is best to use at least two or three sheets together between each pair of tinfoils.

A high-class subdivided paraffin paper condenser having a total capacitance of 20 μF is illustrated in *Fig.* 17.

Mansbridge Type (with tinfoiled paper).—In modern telephone work (since 1900) an immense number of condensers are used. For instance, in 1907 the total world output of condensers, chiefly for this purpose, represented a capacitance of about 5,000,000 microfarads (*i.e.* 5 farads). The method used for standard condensers of assembling the sheets singly by hand was too slow and costly to meet the large demand and much quicker systems of manufacture have been developed. In 1899 Sir John Gavey introduced to the British Post Office the system of forming the condensers by winding together a number of strips of paper and tinfoil. About the same time Mansbridge [1] made two great improvements in the process: (1) the condenser is assembled without paraffin wax, then desiccated in a vacuum oven, and while hot impregnated with melted paraffin, being allowed to cool under pressure in a screw press; (2) instead of tinfoil, paper metallised or coated with a very thin layer of tin is used for the conducting strips. To coat the paper the tin in the form of an impalpable powder, precipitated chemically or electrolytically, is made into a mud with water and a little size to form the adhesive, and then applied evenly to the paper. After drying the paper is passed through heated heavy steel rollers, which compress the tin coating into a lustrous coherent film. The conductivity of this film is only about 25 per cent of that of pure tin, but is sufficient for its purpose. The usual thickness employed is about 0·0025 mm., with about 2 mgm. of tin per sq. cm. A width of 10 cm. will carry a current up to about 4 amperes. Condensers made with it are usually "self-sealing"; if a breakdown occurs at a weak spot the fault burns itself out almost instantly and the insulation is restored. To get rid of pin-holes and other weak spots, before use the paper insulation is subjected to a potential difference of 100 to 200 volts by being passed over a metal roller connected through a resistance to one terminal of a supply circuit, while the film side is connected to the other terminal. In this way a great many of the defective spots are rendered

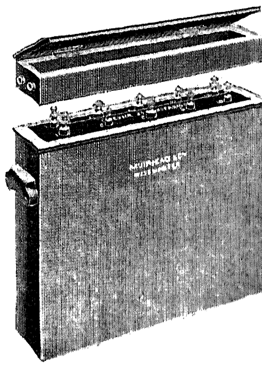

FIG. 17.—Paraffin Paper Condenser (Muirhead).

[1] G. F. Mansbridge, British Patent 19451, 1920, and *J. Inst. El. Eng.*, 1908, xli. 535.

safe. In making a condenser two foiled strips are wound up with two strips of plain paper, and the connections are made by two strips of very thin copper foil laid across the opposite foiled surfaces about the middle of the winding in order to reduce the total internal resistance. The condenser is finally placed in a metal case with semi-plastic paraffin wax, and the opening through which the leads pass out is sealed with a composition which does not contract on setting, consisting of gutta-percha 20 parts, rosin 14, stearine pitch 6, and Stockholm tar 14 parts.

In telephone work the normal capacitance is 2 μF. A foiled paper condenser of this capacitance can be got into a space of 12 cm. × 4·2 cm. × 4·2 cm., and will weigh about 280 grams including the tinplate case.

Mansbridge remarks that for checking the spark in the primary circuit of an induction coil a condenser with low insulation is best. Ordinary paper without paraffin wax has sometimes been used in condensers for this purpose.

§ (29) Shellacked Paper Condensers.—Condensers are sometimes constructed with paper impregnated with shellac or other similar substance. In Meirowsky's type the lacquered paper is passed through hot rollers and wound on a mandrel under great pressure, sheets of tinfoil with projecting tag ends being placed in at suitable intervals as the winding proceeds. The resulting tube, when drawn off the mandrel, is very hard and strong, and the tinfoil sheets are very thoroughly embedded in it. A protecting case is not found necessary. By suitably choosing the thickness allowed between the tinfoil sheets, single sections can be constructed to work at any desired voltage from 500 up to 30,000 volts. A 2 μF condenser of this type to work at 1000 volts (and 50 ∿ per sec.) weighs 6 kgm.

§ (30) Ebonite Condensers.—Ebonite is used as dielectric in certain types of condenser. When in good condition it has high insulating properties, and it can be united very firmly to metal conductors by being "cured on" in manufacture. In the Fleming cymometer [1] (for the determination of high-frequency wave-lengths) the adjustable condenser consists of a long brass tube sheathed with thin ebonite over which another tube slides, thus giving a long range of capacitance.

As another example may be mentioned the adjustable condensers supplied by the Marconi Wireless Telegraph Company, in which very thin sheets of ebonite are arranged between metal plates, giving a comparatively large capacity in small bulk.

[1] J. A. Fleming, *Phil. Mag.*, 1905, ix. 758, and *Phys. Soc. Proc.*, 1905, xix. 603.

The great objection to ebonite thus used is that it is very liable to alter its properties with time. As the deterioration is worst at the surface, it is accentuated by the use of very thin sheets. Its dielectric loss is relatively high.

§ (31) Glass Condensers.—Although not in general suitable for use as standards, condensers with glass dielectric are of distinct value in a number of practical applications.

(i.) *The Leyden Jar.*—The Leyden jar, invented in 1745, is still a convenient condenser for certain purposes. The jar should be made of English flint glass free from bubbles or flaws, and the surfaces of the glass not covered with tinfoil should be coated with shellac varnish and thoroughly dried off. Both inner and outer connections to the tinfoil should make good contact, for a loose connection causes sparking and this is ruinous to the jar. According to Fleming [2] the so-called pint size has usually a capacity of about 0·0015 μF, and the gallon size about 0·003 μF. They will generally stand a potential difference of 20,000 volts. When used with high-frequency currents at high voltages brush discharge occurs at edges of the tinfoil, which increases as the voltage is raised. It acts as an increase of effective plate area and causes an increase of capacity at the higher voltages.

Fig. 18.—Mościcki Glass Condenser (single section).

(ii.) *Mościcki Glass Condensers.*—Mościcki [3] has introduced improved Leyden jar condensers of the form shown in *Fig.* 18, consisting of a long glass tubular flask with a special channelled porcelain or ebonite insulator at the top. In one type the outer conductor is an electrolyte, and another type has both the inner and outer coatings formed by chemically deposited silver strengthened by subsequent electroplating. The inventor found that the tendency to break down is much greatest at the edges of the coatings, and accordingly he protected against breakdown by thickening the glass at the neck of the flask where the edges come. One of the second type, with a height of 120 cm. and surface 200 sq. cm., has a capacitance of 0·01 μF and will work continuously at 10,000 volts (at 50 ∿ per sec.). To obtain larger capacities sets of the tubes are mounted together.

(iii.) *Condensers with Glass Plates in Oil.*—

[2] J. A. Fleming, *Principles of Electric Wave Telegraphy*, 1st ed. p. 59.

[3] I. Mościcki, *Acad. Sci. Cracovie Bull.*, 1904, i. 42; also *Elekt. Zeits.*, 1904, and *Éclairage él.*, 1904, xli. 14.

When exposed to air not artificially dried the surface of glass always absorbs moisture and tends to form a leakage path for electrical discharges. This difficulty is got over by immersing the glass in insulating oil or even by means of a thick layer of vaseline spread over the surface. Oil-immersed glass condensers with metal plates are much used for high voltages at high frequencies. In the type used at the National Physical Laboratory the metal plates are of aluminium 1 mm. thick with all the edges and corners very thoroughly rounded. The plates are cut with lugs as shown in *Fig.* 19, the lugs of alternate plates being at opposite sides. These lugs are clamped together in two sets to leads connected to the terminals. The bundle of plates with sheets of glass between is wrapped with two narrow strips of press-spahn and tightly bound over these with a number of turns of thin tinned copper wire fastened by soldering. The whole is immersed in special paraffin oil (of high boiling-point) which has been dried by many hours' heating above 100° C. Care must be taken to leave no air bubbles between the metal plates and the glass sheets.

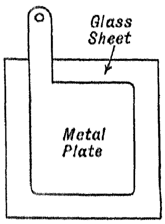

FIG. 19.—Metal Plate and Glass Sheet of Oil-Immersed Condenser.

§ (32) AIR CONDENSERS. — As a dielectric for use in condensers air is superior to solid or liquid substances on account of its freedom from power losses due to leakage and dielectric hysteresis. On the other hand, its dielectric strength and inductive capacity are both lower, for which reason air condensers are relatively very bulky for a given capacitance. There is another very important consideration which prevents the making of very compact air condensers; when the plates are very close to one another the dust particles in the air form dust streaks between the plates, and these leakage paths spoil the good insulation of the condenser. To ensure that this leakage effect shall not occur, the safest way is to lay down the rule that in an air condenser the distance between the surfaces of the conductors should never be less than 2·5 or even 3 mm. At smaller distances there is always risk of leakage due to dust streaks. Such leakage if present can, however, be got rid of by very thorough drying of the air in the condenser, which is best done by means of metallic sodium.

In a condenser with solid dielectric the plates are usually held in position by the dielectric itself, but in an air or oil condenser they must be rigidly supported and kept apart by insulators of solid dielectric. Unfortunately there are very few highly insulating materials that are sufficiently strong and permanent in form to be used for this purpose, since a very small change in the relative position of the plates usually makes a considerable change in the capacitance. Ebonite tends to yield under stress, particularly in warm climates. For the most permanent standards fused quartz or amberite appear to be almost the only suitable insulators. Amberite is reconstructed amber, being made by applying great pressure to amber shavings (wet with ether), which causes them to cohere into a translucent solid. It is an extremely good insulator, and when polished shows very little surface leakage. It is rather brittle, and requires particular care in mechanical working. Fused quartz is harder and has to be ground to shape and then polished. To get the best insulation it should be washed with strong acid after the polishing.

For the purposes of description it will be convenient to consider air condensers in three classes: (i.) Fixed air condensers, (ii.) variable air condensers, and (iii.) condensers with air at high pressure.

(i.) *Fixed Air Condensers.*—The most accurate air condensers are *primary standards* which can be calculated from their dimensions. Forms that have been used for this purpose are either concentric spheres, concentric cylinders with guard rings, or parallel plates similarly guarded. In the determination of "v," the ratio of the electromagnetic to the electrostatic unit of electrical quantity,[1] condensers of these three types have been used by various experimenters. In Rosa and Dorsey's paper[2] will be found fully illustrated descriptions of each of the types. Condensers of this kind are necessarily of very small capacitance, the maximum in the paper just quoted being about 150 $\mu\mu$F.

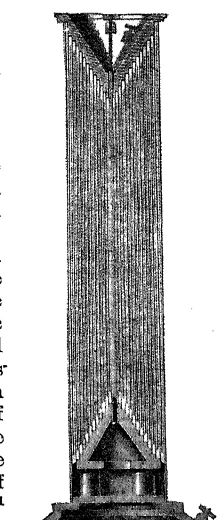

FIG. 20.

For *secondary standards* much higher values are required, and these are obtained by using a large number of parallel plates or concentric cylinders. An illustration of an early example of the cylindrical type is given in *Fig.* 20.

[1] See article on "Electrical Standards."
[2] E. B. Rosa and N. E. Dorsey, *Bureau of Standards Bull.*, 1907, iii. 439.

It was designed by Glazebrook and Muirhead for the Committee of the British Association.[1] In it the two sets of brass cylinders are mounted on stepped brass cones at the top and bottom, the insulation being afforded by three short thick cylinders of ebonite supporting the lower cone. The internal air is kept dry by means of a dish of strong sulphuric acid placed beside these supports. The capacitance is about 0·024 μF.

About the same time Lord Kelvin[2] introduced a portable air condenser with 45 parallel plates, the air-gap distance being 3 mm. The internal air required to be kept artificially dry as the insulating supports were of glass.

More recently improved designs of these two types of air condenser have been brought out by other experimenters. Giebe[3] constructed condensers of both types, but found the plate type superior to that with concentric cylinders. In *Fig.* 21 is shown one of his plate condensers with the case removed. It has a capacity of 0·01 μF, and is built up of seventy-one round plates of magnalium (20 cm. diameter, 1 mm. thick), each of the two sets being mounted with distance pieces on four rods passing through clearance holes in the other set. (Magnalium is a very light alloy of magnesium and aluminium, which is harder than aluminium and easier to work.) The air-gaps are 2 mm., and the solid insulation consists of short amber pillars. The insulation resistance is of the order of 10^9 megohms. When charged to a potential difference of 120 volts, the loss of charge in eight days was less than 5 per cent. The temperature coefficient is about +3 parts in 100,000 per degree C.

FIG. 21.—Giebe Air Condenser (case removed).

Following Giebe's type, Schering and Schmidt[4] constructed a series of air condensers from 0·001 μF upwards, arranged in such a way that, when they are placed one over the top of another in a pile, they are connected in parallel and their capacities add correctly. In *Fig.* 22 is shown a condenser of this additive type made by R. W. Paul. The insulation material used is amberite.

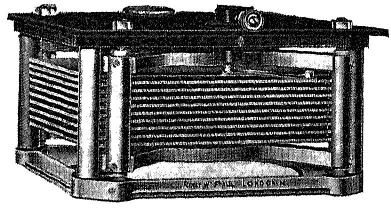

FIG. 22.—Additive Air Condenser (R. W. Paul).

(ii.) *Variable Air Condensers.* (*a*) *Ordinary Type.*—The commonest type of variable air condenser (said to have been invented by Korda in 1893)[5] consists of a set of metal plates fixed parallel to one another on an axle, by which they can be turned so as to lie to a less or greater extent in the air-gaps between a set of parallel fixed plates. The axle carries a pointer which moves over a divided scale, or else a circular scale which is turned past a fixed pointer. The system is shown in plan in *Fig.* 23, in which c is the axis about which the movable plates turn. As the overlapping area a is increased the capacitance rises, its *increase* being approximately proportional to a, and hence also to the change in angular position.

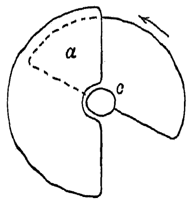

FIG. 23.—System of Variable Air Condenser (in plan).

Fig. 24 shows the working parts of a condenser with a turning scale (divided in

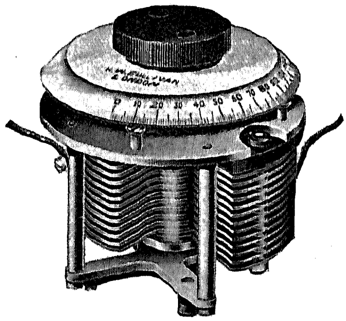

FIG. 24.—Working Parts of Sullivan Air Condenser.

[4] H. Schering and R. Schmidt, *Zeits. Instrumentenk.*, 1912, xxxii. 253.
[5] This type was first used in radio-telegraphy by A. Köpsel (*Dingler's Polytech. Journal*, 1904, xiv. 319).

degrees); in this design the axle has a lower bearing carried by a metal spider rigidly connected to the upper metal plate. This is a much better system than the more common one in which an upper ebonite plate carries the fixed plates and a single bearing for the axle. To ensure constancy of capacitance the bearings should be very well fitted, and the plates should be of good thickness. In making the plates a suitable material (*e.g.* brass) should be used, and great care should be taken to avoid sag due to elastic fatigue. The corners and edges should all be rounded off.

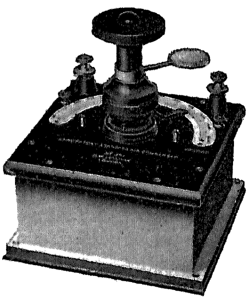

FIG. 25.—Sullivan Variable Air Condenser.

In *Fig.* 25 is shown a Sullivan standard air condenser with fixed scale and moving pointer. The scale reads directly (as all such scales should) in micromicrofarads. A high handle is provided in order to avoid slight errors which sometimes arise when the hand is brought too near the working parts of the condenser. Inside the case there is a metal screen which can be connected when desired to either of the terminals. In general it is best to calibrate the condenser with the screen connected to the movable plates.

The two systems of plates are usually assembled by means of metal rods over which are slipped tubular distance pieces. A more rigid design is that of G. Seibt, in which each set of plates is formed from a single casting, great accuracy in the air-gap spacing being secured by a special system of turning the castings true.

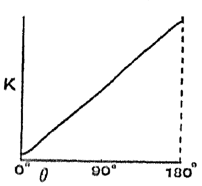

FIG. 26.—Calibration Curve of Turning Plate Air Condenser.

In a well-designed air condenser with semicircular plates the calibration curve, showing how the capacity K varies with the angle θ through which the movable plates have been turned from an initial symmetrical position, is of the form shown in *Fig.* 26. At $\theta=0$ there is a small initial capacity, and as θ is increased, the curve very soon becomes practically a straight line up to nearly 180°, near which the slope usually falls off slightly. Thus over the greater part of the range $K=c+a\theta$, and when the scale is marked to read directly the divisions are uniformly spaced except near the beginning and end of the range.

(*b*) *Square Law Condenser.*—For special purposes the plates of this type of condenser are sometimes shaped so as to give calibration curves of other kinds. For example, for a wave-meter in which the wave-length λ is proportional to the square root of the capacity K, a condenser designed to give K proportional to θ^2 will give an evenly divided scale for λ. Duddell[1] constructed a condenser having this property. The fixed and moving plates have the outlines shown in *Fig.* 27, and one edge of the moving plates follows the polar curve

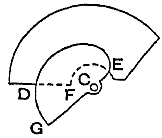

FIG. 27.—Plates of Duddell Square Law Condenser.

$$r^2=4a\theta+b^2, \qquad (101)$$

where the pole is C the centre of the axis of rotation, $r=\text{CD}$, θ(in radius)$=\text{DCE}$, and $b\doteq$ CE the radius of the inner edges of the fixed plates. Then

$$\text{Area DFE}=a\theta^2.$$

Duddell found that when $b=\text{CE}$, with a 1 mm. air-gap and CG about 8·5 cm., the capacitance K in $\mu\mu$F is given by

$$K=\alpha+\beta\theta+\gamma\theta^2,$$

where $\beta\doteq 0{\cdot}25\gamma$. But when b was made equal to 0·87CE, the term in θ was small compared with $\gamma\theta^2$. The range of this square law condenser is short compared with that of the ordinary type.[2]

Occasionally other types of variable air condensers are met with. In some of these one set of concentric cylinders slides within another set; in others the fixed and turning plates of the common type are replaced by two sets of half-cylinders. Here, as in other instruments, rotating systems appear to be handier and more compact than systems involving guided motion in a straight line.

§ (33) EFFECTS OF CAPACITY TO EARTH.—As has already been remarked, when a condenser has small capacitance, it should be enclosed in a conducting screen preferably connected to the moving plates. Unscreened condensers, however, are very often met with, and their readings are frequently affected by errors due to capacity to earth or surrounding objects. Particular care is necessary when the total capacity is below 100 $\mu\mu$F. Orlich's method (§ (5)) is applicable in all cases, by making three measurements (for any given reading). Calling the two sets of plates 1 and 2 and the earth *e* respectively,

[1] W. Duddell, *Inst. El. Eng. J.*, 1914, lii. 275.
[2] See also "Radio-Frequency Measurements."

let the capacitances found be as follows between P and Q

P.	Q.	Capacitance.
1	2 earthed	a
2	1 earthed	b
1 and 2 in parallel	Earth	c

Then $c_{12}+c_{1e}=a,$

$c_{12}+c_{2e}=b,$

$c_{1e}+c_{2e}=c.$

Hence $c_{1e}=s-b,$

$c_{2e}=s-a,$

and $c_{12}=s-c,$

where $s=\frac{1}{2}(a+b+c).$

Thus the "working capacitance"

$$=c_{12}+\frac{c_{1e}c_{2e}}{c_{1e}+c_{2e}}=s-c-\frac{(s-a)(s-b)}{c}. \quad (102)$$

§ (34) Compressed Gas Condensers.—The use of a gas at high pressure as dielectric in condensers was first suggested by Jervis-Smith,[1] and condensers of this type, using compressed air or carbon dioxide gas, were introduced later by Fessenden.[2] The plates in these were discs with an air-gap of 2 to 3 mm. Wien used concentric cylinders with similar distance apart. This type of condenser shows very small dielectric loss even at high voltages, and is specially suitable for radio frequency work. At the higher pressures there is very little gain in dielectric constant (§ (22)), but the dielectric strength is greatly increased, as has been shown by Wolff[3] and (for higher pressures) by Watson. It is roughly proportional to the pressure, and is nearly 300,000 volts per cm. for a pressure of 10 atmospheres, which is at least as high as that of glass. In a well constructed condenser of this kind the air pressure falls very slowly; for example, an initial pressure of 14 atmospheres may fall only 10 per cent in a year.

§ (35) Oil Condensers.—Condensers with oil dielectric are in general similar in construction to air condensers, but with an oil-tight containing vessel. A good oil to use is paraffin oil of high boiling-point; it should be dried by heating for hours above 100° C. before being filled into the container, which should then be closed to prevent absorption of moisture. It has the advantage over air of giving more than double the capacitance for the same size of condenser, but it has slight dielectric loss with alternating currents. There is little change of capacity with frequency.

[1] F. Jervis-Smith, *Nature*, 1893, xlviii. 64.

[2] R. A. Fessenden, *Electrician*, 1905, lv. 795; also M. Wien, *Ann. der Physik*, 1909, xxix. 679.

[3] M. Wolff, *Ann. der Physik*, 1903, xi. 570; and E. A. Watson, *Inst. El. Eng. J.*, 1909, xliii. 113.

Owing to its much greater inductive capacity (4·8) castor oil has been sometimes used in condensers, but it has not proved a success, for, as found by Campbell and Dye,[4] although the dielectric loss per cycle is small at low frequencies, it becomes abnormally high at radio frequencies, even in spite of very thorough drying. The power factor at 800 ∿ per sec. was found to be 0·0005, but at 10^6 ∿ per sec. it was 0·038. The temperature coefficient (−0·4 per cent per degree C.) is also too high. Petroleum behaves far better in all these respects.

It may be remarked here that great care should be taken to have very good connection (whether by flexible conductor or rubbing contact) between the moving parts and terminals in variable condensers, as even a small series resistance sometimes will spoil the otherwise low power factor. Badly insulating ebonite tops are also sometimes responsible for the same effect.

§ (36) Electrolytic Condensers. — Condensers of very large capacity can be constructed[5] without difficulty of metal plates immersed in suitable electrolyte. The metal used must belong to the class known as "valve metals," such as aluminium, magnesium, or tantalum, which have the property, when made the anode in certain electrolytes, of forming on their surface a thin, porous, adhesive layer separated from the actual metal by a thinner layer of gas having an extremely high resistance, which, even with a very small current, allows a high voltage to be maintained. If the applied (direct current) voltage is raised above a certain maximum, which depends on the nature of the electrolyte used, the gas layer breaks down and numerous discharges with sparking occur. For example, for aluminium in solution of sodium sulphate the maximum is 40 volts, whereas in solution of ammonium phosphate it is 460 volts. With aluminium one of the best electrolytes is a saturated solution of ammonium borate $(NH_4)HB_2O_4$. Two sets of plates are immersed in this, care being taken to insulate the conductors as they pass out of the liquid surface; by the application of (say) 100 volts (direct current) for several days to the two sets in parallel against a platinum kathode, the plates are "formed." The two sets are then separated and form an electrolytic condenser which can be used with alternating voltages as high as 90 volts, and with this voltage it shows a power factor of about 0·05. With ten aluminium plates, each having an area of about 160 sq. cm., Schultze thus obtained an effective capacity

[4] A. Campbell and D. W. Dye, *N.P.L. Report*, 1913–14.

[5] C. J. Zimmermann, *L'Éclair. élec.*, 1903, p. 388; and G. Schultze, *Elektrotech. u. Maschinenbau*, 1909.

of about 60 microfarads. The condenser was tested with frequencies up to 800 ∿ per sec., and carried alternating current of the order of 1·5 amperes for a week without apparent alteration. The capacity depends on the forming voltage, being inversely proportional to it (for rising values).

IV. Measurement of Capacity

§ (37) Introductory.—In most of the more modern methods of measuring capacity alternating current is employed, and many of these methods are similar to those used for the measurement of inductance. A full description of suitable sources of alternating current and the measuring or detecting instruments employed will be found in the article on "Inductance, Measurement of." That article also includes descriptions of the resistances and inductances required for the measurements.

Classification of Methods.—The various methods of measuring capacity are best classified according to the chief electrical property in terms of which the unknown capacity is determined. The measurement may be in terms of:

(A) Resistance (including current and voltage);
(B) Another capacity;
(C) Mutual inductance; and
(D) Self-inductance.

The following descriptions of a number of typical methods are given in the order of this classification, some special cases being discussed separately.

(A) *Comparison with Resistance*

§ (38) Impedance Methods.—If a pure sinoidal voltage V applied to the terminals of a condenser gives a current I, then (§ (9)) the capacitance K of the condenser in microfarads is given by

$$K=\frac{10^6 I}{\omega V}, \quad . \quad . \quad . \quad (103)$$

where the pulsatance $\omega=2\pi n$, n being the frequency.

The voltage and current may be measured by ammeter and voltmeter. From Table I. (§ (9)) it will be seen that the ammeter should be a low reading one (*e.g.* of thermal type). The voltmeter should be electrostatic, to ensure that the current taken by it shall be very small. When the capacitance to be measured is small, it is necessary to take account of the capacitance of the voltmeter. This capacitance depends on the deflection [1]; for example, in an Ayrton-Mather voltmeter tested by Campbell the capacitance ranged from 8·1 to 11·9 $\mu\mu$F, corresponding to readings of 500 and 4000 volts respectively. In a Kelvin multicellular voltmeter (to 120 volts) the capacitance at 40 volts is about 70 $\mu\mu$F; in a portable Ayrton-Mather instrument of the same range it rises from about 30 $\mu\mu$F. at zero reading to about 55 $\mu\mu$F. at a reading of 84 volts. In no case should long twisted flexible leads to the voltmeter be used, as they may add more capacitance than the voltmeter itself. The capacitance of the voltmeter must be subtracted from the K obtained by equation (103). If the applied voltage is constant, the correction, if any, may be found by observing the change in the current when the voltmeter is applied to the condenser.

Instead of using an ammeter, a resistance R may be put in series with the condenser, and V_0, the potential difference across this, observed on the voltmeter.

Then $$K=\frac{10^6 V_0}{V\omega R} \text{ (in } \mu\text{F)}. \quad . \quad . \quad (104)$$

Here V and V_0 should if possible be nearly equal. The following examples indicate the order of magnitude of R required:

With $V_1=V_0$,
for $n=50$ ∿ per sec., $R \doteqdot 3180/K$;
for $n=800$ ∿ per sec., $R \doteqdot 200/K$.

If the wave-form of the applied voltage is not a pure sine curve, the current wave-form will be more impure, for the effect of the condenser is to accentuate the harmonics. If the voltage wave-form is known, and the components are V_1, V_3, V_5 . . ., then instead of equation (103) we have

$$K=\frac{10^6 I}{\omega V}\sqrt{\frac{V_1^2+V_3^2+V_5^2+\ldots}{V_1^2+9V_3^2+25V_5^2+\ldots}}, \quad (105)$$

and the same correcting multiplier applies to equation (104).

§ (39) Arnò's Electrometer Method.—In Arnò's null method [2] a sine wave current is sent through the unknown condenser K in series with an adjustable resistance R (*Fig.* 28). The point A is connected to the needle of an electrometer, and B and C to the alternate pairs of quadrants. When a balance is obtained by adjusting R,

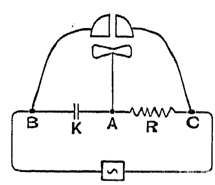

Fig. 28.—Arnò's Electrometer Method.

$$K=\frac{10^6}{\omega R} \quad (\mu\text{F}). \quad . \quad . \quad (106)$$

§ (40) Commutator Methods with Direct Deflection.—Maxwell [3] suggested various

[1] Lord Kelvin, *Roy. Soc. Proc.*, 1892; A. Campbell, *El. Rev.*, 1895, xxxvi.

[2] R. Arnò, *Nuovo Cim.*, 1895, iv. (1), 252.

[3] Maxwell, *Electricity and Magnetism*, 2nd ed. vol. ii. §§ 775 and 776.

methods of determining capacity in terms of resistance by the help of a commutator regularly repeating the process of charge and discharge of a condenser, and various experimenters have developed methods of this kind. In Fleming and Clinton's[1] method a rotating commutator periodically charges the condenser from a battery (of constant voltage) and discharges it through a galvanometer. The commutator is of the secohmmeter type; it is solidly built, and is driven by a directly coupled electric motor, the number of charges per second being determined by a counter geared to the spindle and a stop-watch or chronograph. The commutator consists of three toothed metal discs mounted on the same spindle, but all insulated from one another, the arrangement of the teeth being shown in *Fig.* 29, which gives a view of a portion of the rim. The two discs a and b carry the working contact teeth, while the teeth of the middle disc (shown shaded) are only for the purpose of steadying a contact brush as the other teeth pass under it. This brush (not shown) is of brass gauze and is fixed centrally so as to make contact alternately with a and b as the spindle revolves. Two other similar brushes (c and d) make uninterrupted contact with the sides of a and b.

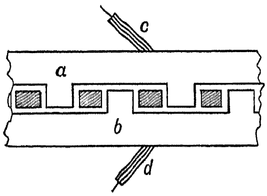

FIG. 29.—Portion of Commutator Rim (Fleming and Clinton).

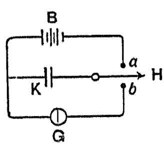

FIG. 30.—Commutator Direct Deflection Method (Fleming and Clinton).

Two systems of working are used:

System (1).—The connections are shown diagrammatically in *Fig.* 30, the commutator H alternately charging the condenser K, through the middle brush, from the battery B and discharging it through the galvanometer G, whose period is long compared with that of the charge and discharge. Accordingly, when the speed is kept steady, the intermittent current (of discharge) will give a steady deflection on the galvanometer. From the ordinary calibration of the galvanometer with steady currents, let this deflection be equivalent to a current I in microamperes.

Then $$K = \frac{I}{nV} \quad (\mu F), \quad . \quad . \quad (107)$$

where V is the voltage of the battery (in volts) and n the frequency of charge.

A moving coil galvanometer only should be used, for reasons to be explained later. The second system is a better one and does not require this restriction.

To ascertain if the condenser has any leakage sufficient to affect the results, the galvanometer is put in series with the battery and a short-circuiting wire put in its place. The galvanometer will now measure the charging current instead of the discharge. If the value of the capacity obtained with the new connections agrees with the former test, there is no error due to leakage.

System (2).—The connections are shown in *Fig.* 30A. Here G and G′ are the equal-acting coils of a special differential galvanometer. Coil G, shunted by S, with a high resistance R in series receives a steady current from the battery B, while the commutator (represented by H), by charging and discharging K, sends an interrupted current in the opposite direction through G′. By adjusting R and S a balance is obtained on the galvanometer, in which case

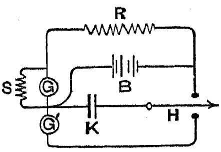

FIG. 30A.—Differential Commutator Method (Fleming and Clinton).

$$K = \frac{(G+S)10^6}{n[R(G+S)+GS]} \quad (\mu F). \quad . \quad (108)$$

As the ordinary type of differential galvanometer with the coils G, G′ wound together does not insulate these coils sufficiently from one another for this method, special galvanometers were constructed. One of these was of moving coil type with the coils G and G′ one above the other, rigidly connected, and on the same suspension, but in separate magnetic fields. Their sensitivities were made equal by adjusting one of the magnetic fields by means of a magnetic shunt of soft iron facing the poles of the magnet.

Leakage can be detected in the same way as in System (1), which is a great advantage in this method. The differential galvanometer method was first used by Klemenčič at Vienna in 1884, and after him by many others. It has recently been used by Rosa and Dorsey[2] in testing guard ring condensers. Their commutator had an extra brush, through which the guard ring was separately charged.

§ (41) MAXWELL'S COMMUTATOR BRIDGE METHOD.—Maxwell[3] described a method in which a reversing commutator periodically

[1] J. A. Fleming and W. C. Clinton, *Phil. Mag.*, 1903, v. 493; and *Phys. Soc. Proc.*, 1903, xviii. 386. See Werner Siemens, *Pogg. Ann.*, 1857, cii. 66.

charges and discharges a condenser in one arm of a Wheatstone's bridge, in which the other arms are resistances. The method, with slight modifications of detail, has been used with great success by many different

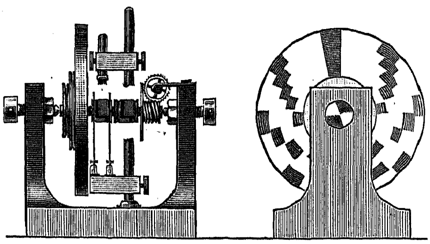

FIG. 31.—Thomson and Searle's Commutator.

experimenters. Instead of a reversing commutator, usually one which merely charges the condenser in the bridge arm and then short-circuits it has been employed. In the earlier experiments the commutator consisted of a vibrator working between two contact pieces, driven by intermittent current from an electrically maintained tuning fork.[1] The vibrating contact maker had certain disadvantages and was replaced by a revolving commutator by Glazebrook [2] and also by Fleming. The revolving type is now in general use. In *Fig.* 31 is illustrated the simple form used by Thomson and Searle [3] in 1890, and in *Fig.* 32 the more elaborate

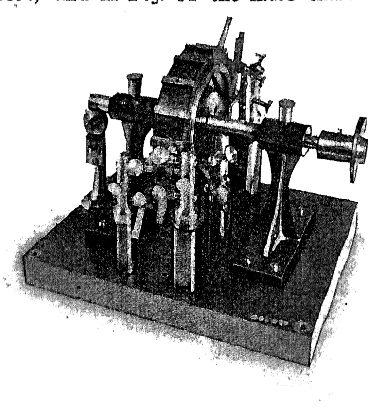

FIG. 32.—Rotating Commutator (Rosa and Dorsey).

type employed by Rosa and Dorsey[4] in 1907. These are both of the three-brush type, similar in principle to that shown in *Fig.* 29, but without the shaded teeth. The middle brush requires careful adjustment; it is advantageous to deaden its vibration by means of india-rubber. For the purpose of determining the speed a small toothed wheel is geared into a screw-thread on the spindle, and closes an electric contact for every fifty or hundred revolutions of the latter. By connection with a chronograph a dot is marked on the recording cylinder exactly at the end of every fifty or hundred revolutions, while at the same time signals every second from a standard clock are also inscribed.

The bridge connections are shown in *Fig.* 33, the middle brush of the commutator being represented by c which is touched alternately by a and b, the first contact introducing K into the bridge arm and the second short-circuiting it.

Let the resistances of the arms be Q, R, S, G, and B, as marked in the figure, and let n be the frequency of charge. By proper choice of R and S and by adjusting Q the deflection of the galvanometer is brought to zero, and then [5] we have

$$K=\frac{S}{nQR}\left\{\frac{1-\dfrac{S^2}{(S+R+B)(S+Q+G)}}{\left(1+\dfrac{SB}{Q(S+R+B)}\right)\left(1+\dfrac{SG}{R(S+Q+G)}\right)}\right\}, \quad (109)$$

where K is in farads if the resistances are in ohms.

This may be written

$$K=\frac{1}{nQ}\cdot\frac{S}{R}\cdot F, \quad . \quad . \quad (110)$$

and by proper choice of the various resistances F may be made a mere correcting factor nearly equal to unity. The battery resistance B can always be kept very small by the use of secondary cells. The ratio R/S should be large, say 1000/10 or 10,000/10, and the galvanometer has usually a moderately high resistance (*e.g.* 500 ohms). When these conditions hold, the correction due to F will in general be less than 1 per cent. It is convenient to tabulate its value for various values of Q and for several values of R and S.

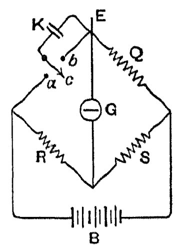

FIG. 33.—Maxwell's Commutator Method.

The resistance in the condenser circuit must be kept as small as possible, as otherwise a correction would have to be introduced due to the condenser not being fully charged in

[5] J. J. Thomson, *Roy. Soc. Phil. Trans.* A, 1883, clxxiv. 707.

each period (see Maxwell, *loc. cit.*). After a test has been made, the condenser is disconnected from its leads and a similar measurement made of the effective capacitance of the leads and commutator. The value obtained is subtracted from that obtained with the condenser, the result giving the capacitance of the condenser alone.

It is best to earth the point E, the outer conductor of the condenser being also connected to that point.

The galvanometer should have a long period of oscillation with good damping. One of moving coil type with a coil having considerable moment of inertia is suitable. A. Campbell found that, when a moving-magnet galvanometer is used, considerable errors may occur unless when at the zero reading the magnet needle is exactly at right angles to the axis of the deflecting coils. The theory of the method assumes that the deflection will be zero when the total electric quantity passing through the galvanometer in each period is zero, that is when the mean current is zero. But if the magnet needle is not perpendicular to the deflecting field, the magnetisation of the needle will not remain constant, but will to some extent rise and fall with the variation of the instantaneous value i of the deflecting current. Thus, instead of the deflecting torque being proportional to i, a certain component of it will be proportional to i^2, and then the zero balance will not be a correct indication that $i_{\text{mean}}=0$. When this source of error is present, reversing the battery gives a change of reading for K, and by taking a mean of the two readings partial correction may be obtained. The effect also may be reduced by shunting the galvanometer with a condenser. In any case it is much better to use a moving coil galvanometer, and even with it care should be taken that the coil is in a position of symmetry for the zero reading, for the square law effect is noticeable in some types of moving coil instruments.

§ (42) MAINTENANCE OF CONSTANT SPEED.—As will be seen from equation (109) the zero balance is for a definite value of the frequency n. If the value of K is constant and the resistances are correct for a given value of n, then if the speed of the commutator is above or below the correct value, the galvanometer will be deflected to the one or the other side of zero. It is therefore necessary to have some means of holding the speed constant. The earlier experimenters regulated it by the help of an electrically driven tuning-fork whose prongs carried screens with overlapping window-slits. A stroboscopic disc on the commutator spindle (as shown in *Fig.* 31) was observed through these slits, and the speed was regulated so as to keep one of the sets of marks on the disc apparently motionless. The regulation was done by the observer applying slight friction with the fingers to the flywheel of the commutator or its driving cord.

About 1902 Campbell introduced a simpler and better method at the National Physical Laboratory. The resistances are first set at appropriate values and the observer controls the speed by simply observing the galvanometer light spot and holding it at zero by friction on the flywheel or other means. The driving motor is set to run normally a little too quick. [The actual speed is determined by a chronograph as already described, the length of run necessary being determined by the accuracy required. For example, if the chronograph can be read to 0·05 second, a run of at least 10 minutes would be required to give accuracy of reading to 1 in 10,000.]

The above method of speed control is not only useful in testing condensers, but affords what is probably the most accurate known system of maintaining a speed constant. At the National Physical Laboratory it has been put to a number of different applications, such as the determination of the frequencies of tuning-forks or of high-frequency sparks, the speed of rotation in the Lorenz method for the ohm, etc. It is only necessary to fix a small commutator on the spindle whose speed is to be held, and to connect it up with a good mica condenser (kept at constant temperature) in a suitable bridge as above described. The accuracy attainable depends on various things, such as the sensitivity of the galvanometer, the inertia of the flywheel, and the constancy of the condenser and the resistance coils used. As the galvanometer must be of relatively long period, small quick changes of speed will not show much on the deflection, and the absolute degree of steadiness must not be estimated too rashly from the steadiness of the deflection.

In similar tests Giebe uses a special automatic speed regulator, which is described in § (6) of the article on "Inductance Measurement."

Effect of Change of Frequency.—If the condenser tested has dielectric loss and capacitance which varies with frequency, then in general a test by the commutator method with frequency n will not give the same result as a test in which sine wave alternating current of frequency n is employed, for in the commutator method the curve of applied voltage is by no means of sine wave form. Campbell[1] attempted to find an empirical relation, but the subject requires further investigation.

§ (43) COMMUTATOR METHOD WITH GUARD-RING CONDENSERS.—When the condenser to be tested has a guard ring the commutator may be duplicated or a second set of brushes added. Rosa and Dorsey ensured that the

[1] A. Campbell, *Roy. Soc. Proc.* A, 1912, lxxxvii. 410.

guard ring should be charged to the same potential as the condenser plate by putting its commutator in a bridge network across the same battery and identical with the main bridge.

(B) *Comparison with another Capacity*

§ (44) INTRODUCTORY.—The older methods of comparing the capacities of two condensers nearly all made use of only a single charge and discharge. By and by, to increase the sensitivity, commutators of the secohmmeter type were introduced so as to obtain a steady condition of periodic charge and discharge (or reversal), still using a direct current source. But since alternating currents have become common in everyday electrical work, the methods have been modified so as to be used with alternating current, and have in this way been rendered on the whole more convenient, more definite, and more sensitive.

§ (45) BALLISTIC GALVANOMETER METHOD.—When a condenser is discharged through a moderate resistance, the greater part of the quantity held by it passes out in a small fraction of a second. To measure the quantity which enters or leaves it at charge or discharge, the most commonly used instrument is a *ballistic galvanometer*,[1] which is simply a galvanometer which has such a slow time of swing that practically the whole charge or discharge quantity has passed through it before the moving part has been appreciably deflected from its zero position. If the angles moved through are small the throw (or kick) of the moving part is very approximately proportional to the quantity that has passed. Thus if q is the quantity (in coulombs) and D the throw (in angle or scale divisions), then

$$q \doteq \mathrm{AD}, \quad . \quad . \quad . \quad (111)$$

where A is the ballistic constant.

If a current of i amperes gives a steady deflection δ, then $i \doteq a\delta$, where a is the steady-current constant of the galvanometer.

Then A and a are connected by the relation

$$Aa \doteq \frac{\mathrm{T}}{2\pi}\left(1+\frac{x}{2}\right), \quad . \quad . \quad . \quad (112)$$

where T is the complete period of the galvanometer (in seconds), and x is the logarithmic decrement of its swings *for one half-period*. [If A has been determined from equation (112), the capacity of a condenser can be found by charging it with a known voltage V and discharging it through the galvanometer. Then $\mathrm{K}=\mathrm{AD}/\mathrm{V}$.]

However, instead of assuming exact proportionality of the scale readings, it is best to calibrate the scale once for all either with known values of i or of q.

To compare the capacities of two condensers each is charged in turn from the same battery and discharged through the galvanometer. Then if the capacities are K_1 and K_2

$$\mathrm{K}_2=\frac{\mathrm{K}_1\mathrm{D}_2}{\mathrm{D}_1}, \quad . \quad . \quad . \quad (113)$$

where D_1 and D_2 are respective throws.

A correction should be applied if necessary from the calibration of the scale.

If the condensers are very different in capacitance, one of the throws will be too small to observe with accuracy, in which case either of the following methods may be used:

(*a*) The condensers are charged with different voltages V_1 and V_2 so that the throws on discharge are nearly equal. The ratio $\mathrm{V}_1/\mathrm{V}_2$ is determined by voltmeter or potentiometer measurement.

Then $$\mathrm{K}_2=\frac{\mathrm{K}_1 . \mathrm{V}_1\mathrm{D}_2}{\mathrm{V}_2\mathrm{D}_1}. \quad . \quad . \quad (114)$$

(*b*) The galvanometer is shunted on the Ayrton-Mather[2] system (which here gives constant damping), and the condensers are charged on the same battery, but the shunt is set in each case so as to make the two discharge throws as nearly equal as possible.

Then $$\mathrm{K}_2=\frac{\mathrm{K}_1 . b_2\mathrm{D}_2}{b_1\mathrm{D}_1},$$

where b_1 and b_2 are the multiplying powers of the shunt in the two cases.

Thus an unknown capacitance can be determined by the use of a standard condenser.

The system of the Ayrton-Mather shunt is shown in *Fig.* 34. A fixed resistance AC is put across the galvanometer terminals. The working terminals are P and Q, and the shunting power is varied by altering the position of B. Thus $(s+r+g)$ is kept constant, which gives constant damping when P and Q are an open circuit.

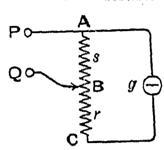

FIG. 34.—Ayrton-Mather Shunt.

For convenience of working the galvanometer should be well damped, and its complete period should, if possible, be about 10 seconds to allow sufficiently deliberate observation of the throws.

The great difficulty in all tests of this kind arises from absorption (see § (8)). When this is present, as it is in all but air condensers, although the greater part of the charge rushes in very quickly when the charging voltage is applied, a small additional amount goes on creeping in, as it were, for a considerable time as long as the charging voltage is maintained. In a similar way for the discharge, after the first rush, in which the free charge quickly comes out, the absorbed charge continues to dribble out for a long time at a gradually

[1] See the article on "Magnetic Measurements."

[2] W. F. Ayrton and T. Mather, *Electrician*, 1893-1894, xxxii. 627.

lessening rate. Thus the value of the capacitance measured by the charge or discharge depends on the amount of time during which either charge or discharge is allowed to continue, and any time elapsing between charge and discharge will allow continued absorption and also affect the result. Thus the discharge is not really quite complete before the galvanometer is appreciably deflected, and so the slow part of the discharge does not have its full effect, and the total quantity indicated depends on the period of the galvanometer used. As an example, *Fig.* 35 shows the effect of varying the time of charge of a standard mica condenser,[1] the variation in apparent capacitance being measured by a galvanometer of 8 seconds' period. It will be noticed that the total variation is of the order of 0·6 per cent.[2] Other materials, such as crown glass or india-rubber, show very much larger absorption effects than this. In all cases, therefore, where capacity is tested by single charge and discharge, it is important that the time conditions should be definitely specified.

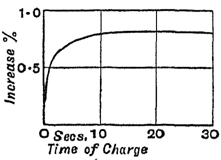

FIG. 35.—Variation of Apparent Capacitance with Time of Charge.

§ (46) THOMSON METHOD OF MIXTURES.—The principle of Thomson's[3] method of comparing two capacities is as follows. If two condensers K and C are charged by different voltages V_1 and $-V_2$ so that their charges are Q and $-Q$ respectively, then, if their corresponding terminals are connected, the charges will annul one another and the condensers will be found to be completely discharged. When this result is obtained

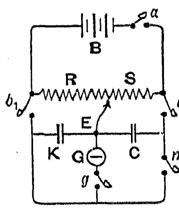

FIG. 36.—Thomson Method of Mixtures.

$$KV_1 = Q = CV_2, \quad \text{or} \quad \frac{K}{C} = \frac{V_2}{V_1}.$$

The connections are shown in *Fig.* 36. At least one of the resistances R and S is adjustable; often they are arranged with a central slider so that the ratio R/S can be varied while (R + S) remains constant. The point E is earthed.

To make the test:

(1) Key *a* is closed, sending a current through R and S, and producing voltages V_1 and V_2 across these resistances, such that $V_1/V_2 = R/S$.

(2) Next, the keys b_1 and b_2 are closed for a definite period and then opened, leaving K and C charged to voltages V_1 and $-V_2$ respectively.

(3) Then the key *m* is closed (for a definite time), which allows the condenser charges to "mix"; and finally the galvanometer key *g* is closed. If a throw is produced on the galvanometer, the ratio R/S is altered and the procedure repeated until by trial the value of R/S is found for which the galvanometer throw is zero. When the galvanometer thus indicates no charge, the condensers have been exactly discharged by the mixing, and then we have

$$K = \frac{CS}{R}. \quad . \quad . \quad . \quad (115)$$

This method has been very extensively used in the testing of electric cables[4] both in the factories and at cable stations. Special keys are generally used to simplify the working of the test. In comparing moderate capacities, Dr. Muirhead recommends a charge of 15 seconds and mixing for 4 seconds. With a long submarine cable of 2000 km. length (about 300 μF capacity), the charge may be for 5 minutes and the mixing for 10 seconds.

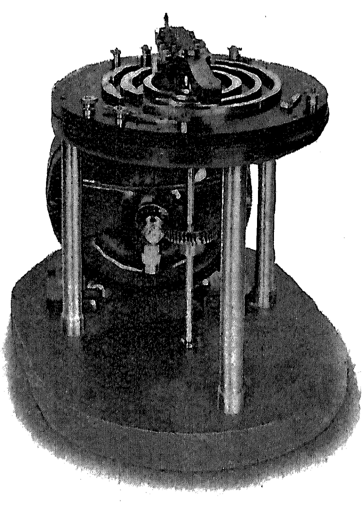

FIG. 36A.—Curtis's Switch for Cyclic Method of Mixtures.

The method has been used by Muirhead, Glazebrook,[5] and others in comparing standard mica condensers against air condensers, and the difficulties due to absorption have been investigated. In order to bring the conditions into a cyclic state Curtis[6] employs a motor-driven switch (shown in *Fig.* 36A) which auto-

[1] Tested at N.P.L. by A. Campbell, 1903.

[6] H. L. Curtis, *Bureau of Standards Bull.*, 1910, vi. 431.

matically performs the operations of the test in a periodic manner until approximately steady conditions are reached.

In all cases when the point E is earthed the battery must be very well insulated.

§ (47) Gott's Method of Comparison.—Another method very largely used in cable work is that of Gott,[1] the connections for which are shown in *Fig.* 37. By closing the key a for a definite time the condensers are charged in series, and the ratio R/S is altered by the slider f until, on closing key b, the galvanometer shows no throw.

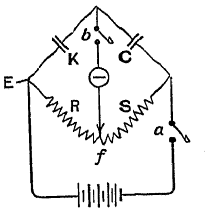

Fig. 37.—Gott's Method of comparing Capacities.

Then $$\frac{\mathrm{K}}{\mathrm{C}}=\frac{\mathrm{S}}{\mathrm{R}}$$

The battery need not be highly insulated, as the point E is earthed. When the condensers are not similar in absorption, difficulties arise just as in the Thomson method. In general the balance on the galvanometer is never perfect, a slight quick kick and a slow drift usually occurring together.

If the galvanometer and battery are interchanged in Gott's method it becomes De Santy's method.

§ (48) Bridge with Alternating Current.—If in one of these last methods (*e.g. Fig.* 37) the battery is replaced by a source of alternating current and the ballistic galvanometer by detector of alternating current, such as a vibration galvanometer or telephone, in most cases it will be found impossible to obtain a balance, and at best only a minimum can be obtained on the detecting instrument. The reason for this is that, unless K and C are both free from absorption and leakage, the impedances of the condenser arms contain both reactance and resistance components. If the leakage and other losses in the condensers are represented by resistances p and q in parallel with them, we have the arrangement shown in *Fig.* 38. The symbolical impedances of the condenser arms are $p/(1+j\omega p\mathrm{K})$ and $q/(1+j\omega q\mathrm{C})$ respectively, and hence, if the bridge balances,

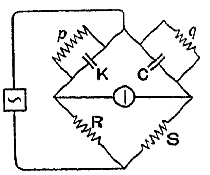

Fig. 38.—Bridge with Leaky Condensers.

$$\frac{p/(1+j\omega/\mathrm{K})}{q/(1+j\omega q\mathrm{C})}=\frac{\mathrm{R}}{\mathrm{S}}$$

or $$\mathrm{S}p(1+j\omega q\mathrm{C})=\mathrm{R}q(1+j\omega p\mathrm{K}),$$

[1] J. Gott, *Soc. Tel. Eng. Proc.*, 1881, x. 278.

which gives the two conditions

$$\left.\begin{aligned}\frac{p}{q}&=\frac{\mathrm{R}}{\mathrm{S}}\\ \text{and}\qquad \frac{\mathrm{K}}{\mathrm{C}}&=\frac{\mathrm{S}}{\mathrm{R}}\end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (116)$$

Thus it is seen that, for a balance, the parallel resistances must be inversely proportional to the capacitances. In general, in comparing two condensers this condition will not be found to hold for the condensers alone, but a balance can always be got by shunting one or other of them by a resistance of the right value (which can be found by trial). If C (taken as the standard) has negligible losses, then $q=\infty$; and if a balance is got when C is shunted by a resistance Q, we have

$$\mathrm{K}=\frac{\mathrm{CS}}{\mathrm{R}}$$

and $$p=\frac{\mathrm{QR}}{\mathrm{S}}.$$

Thus, by equation (68),

$$\tan\phi=\omega\mathrm{K}p=\omega\mathrm{CQ}, \quad . \quad . \quad (117)$$

where $\cos\phi$=power factor of K.

For example, this method was used by Campbell[2] to determine the capacities and leakage resistances of cellulose condensers.

It is clear that an alternating current method of this kind not only may determine the capacity but also the power loss in the condenser (for given current or voltage). Indeed most of the alternating current methods give information regarding the power factor ($\cos\phi$) as well as the capacitance.

Grover,[3] whose paper on the subject contains very complete information, has discussed the more general case of this method, in which both of the condensers have internal loss, and in the bridge are shunted by external resistances P and Q to obtain a balance. Then, as before,

$$\mathrm{K}=\frac{\mathrm{CS}}{\mathrm{R}},$$

but the power factor of K (or its phase displacement θ) cannot be absolutely determined unless the power factor of the standard condenser C is known. The second condition for balance gives

$$\tan\theta_1-\tan\theta_2=\frac{1}{\omega\mathrm{CQ}}-\frac{1}{\omega\mathrm{KP}}, \quad . \quad (118)$$

where θ_1 and θ_2 are the phase displacements[4] of the condensers K and C. Since the power factor $\cos\phi=\sin\theta$, when θ_1 and θ_2 are small, equation (118) gives $(\theta_1-\theta_2)$, which is approximately the difference of the power factors of the condensers. If the unknown condenser K

[2] A. Campbell, *Roy. Soc. Proc.*, 1906, lxxviii. 196.

[3] F. W. Grover, *Bureau of Standards Bull.*, 1907, iii. 371.

[4] See § (14).

has a very small power factor the shunt required on the standard may be inconveniently high (*e.g.* megohms). It is therefore best, as Grover recommends, to begin with K shunted by 100,000 ohms. The use of high resistances is a weak point in the method, particularly when the capacitances of the condensers are small, for the self capacitances of the resistances may cause error. For this and other reasons the next method is to be preferred.

N.B.—The determination of the power factor is of the utmost importance, for it usually is a criterion of the goodness of a condenser. A condenser with small power factor shows little absorption and its capacity usually changes little with frequency.

§ (49) Wien's Series Resistance Method.—In Wien's [1] method the loss in the unknown condenser is balanced by putting a resistance in series with the standard condenser, which is assumed to have zero power factor. The connections are shown in *Fig.* 39, in which p represents the internal loss in the condenser K under test, and Q is an adjustable resistance in series with C, a standard condenser with negligible internal loss. When the vibration galvanometer (or telephone) shows no current,

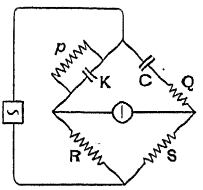

Fig. 39.—Wien's Series Resistance Method.

$$K=\frac{S}{R}\cdot\frac{C}{1+\omega^2C^2Q^2} \quad . \quad . \quad (119)$$

and
$$p=\frac{R}{S}\cdot\frac{1+\omega^2C^2Q^2}{\omega^2C^2Q}; \quad . \quad (120)$$

hence also
$$\omega^2KCpQ=1. \quad . \quad . \quad . \quad (121)$$

If $\cos\phi$ = power factor of condenser K, then

$$\cot\phi=\frac{1}{\omega Kp}=\omega CQ. \quad . \quad . \quad (122)$$

When $\cos\phi$ is small (which is usual in condensers),

$$\cos\phi \doteq \omega CQ \quad . \quad . \quad . \quad (123)$$

and
$$K \doteq \frac{SC}{R}. \quad . \quad . \quad . \quad (124)$$

[Wien used the method not merely to obtain the ratio of K to C, but also to determine both K and C in terms of known resistances and frequency. For this purpose, after making the test giving equations (119), (120), and (121), K is shunted with a known resistance P, and Q is altered to Q_1 to obtain a balance.

Then
$$\frac{\omega^2KCQ_1pP}{(p+P)}=1,$$

which with (121) gives
$$p=\frac{P(Q-Q_1)}{Q_1}.$$

By using this value of p, K and C can be got from equations (119) and (120).]

[1] M. Wien, *Wied. Ann.*, 1891, xliv. 689.

For the comparison the standard C may be an air condenser or a good mica condenser of known power factor. In the latter case the power factor of C will come into the result. It is better then (following Grover) to represent the losses in both the condensers by series resistances ρ_1 and ρ_2, and, in making the test, to use external series resistances P and Q as shown in *Fig.* 40.

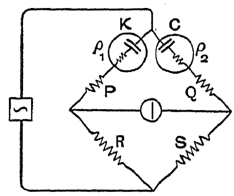

Fig. 40.—Series Resistance Method (Grover).

Then
$$\frac{K}{C}=\frac{S}{R}$$

and
$$\frac{P+\rho_1}{Q+\rho_2}=\frac{R}{S},$$

whence
$$\tan\theta_2-\tan\theta_1=\omega KP-\omega CQ$$
$$=\omega C\left(\frac{SP}{R}-Q\right). \quad (125)$$

As in other bridge methods, it is very desirable to use equal ratio arms (R=S); they can then be interchanged to eliminate want of equality and residual inductances. When very unequal arms are used (*i.e.* when the condensers are not nearly equal), the effects of earth capacities often introduce serious errors, especially with small condensers or at relatively high frequencies. The power factor results are much more affected than those of capacity.

§ (50) Wagner's Earthing Device.—The difficulties due to earth capacities are got over by an ingenious device due to Wagner.[2] As shown in *Fig.* 41, an auxiliary circuit is connected across the alternating source, consisting of a condenser k in series with two resistances r_1 and r_2. The main bridge is first approximately balanced and then, with the point A earthed, r_1 and r_2 are altered until a telephone T shows no current, thus indicating that A and B are at the same potential. The circuit of T is broken, and the main bridge rebalanced more accurately. Then the equality of potentials at A and B is again tried and r_1 and r_2

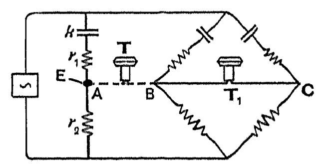

Fig. 41.—Wagner Earthing Device.

[2] K. W. Wagner, *Elektrotech. Zeits.*, 1911, xxxii. 1001: also *Electrician*, 1911, lxviii. 483.

readjusted if necessary. Finally the telephone T is removed, the point A is left earthed, and exact balance on the main bridge is obtained. It will be noticed that since B is at potential zero, when the telephone T_1 shows no current, C is also at zero potential, and so is the telephone, which can therefore be handled without introducing capacity currents to earth. The device ensures that a certain point of the network is virtually at earth potential though not actually connected to earth. It can be used for the same purpose in other methods.

§ (51) Wien's Method.—Wien's series resistance method has been used in a number of important researches. For example, Monasch[1] used it in testing the dielectric losses in glass, ebonite, paraffin, and various kinds of cables at high voltages (up to several thousand volts), using a special air condenser as standard. He showed that the power factors were practically constant over a long range of applied voltage, the losses being exactly proportional to the square of the voltage. Batman[2] used the method with voltages up to 10,000 volts, and employed as detecting instrument a special single-wire (Einthoven) vibration galvanometer in which the wire was of aluminium.

For most purposes the method is one of the best, if good standard subdivided condensers are available.

§ (52) Four-condenser Bridge.—Nernst[3] introduced a bridge in which two condensers were used instead of resistance ratio arms, thus having capacitance in each of the four arms. He used it with radio frequencies up to several million ∿ per sec.

Hertwig[4] used this type of bridge for the measurement of dielectric constants at 10^6 ∿ per sec., arranging it as shown in *Fig.* 42. To avoid as much as possible the inductance of leads, the bridge consists of four similar condensers, two pairs of them having a common plate. The unknown condenser x is put in parallel with K, and is balanced by inserting a sheet of glass between the plates of C. If x shows leakage, this is balanced by the adjustable high resistance Q, which consists of a specially constructed capillary tube containing electrolyte. The source is a quenched spark system, and the detecting instrument a crystal rectifier F and telephone T. Joachim[5] uses a similar bridge with a triode valve source (giving 10^6 ∿ per sec.) and a toothed-wheel interrupter in the telephone circuit.

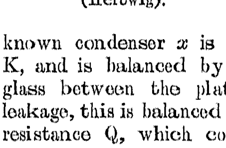

Fig. 42.—Nernst Bridge (Hertwig).

Fleming and Dyke[6] used a four-condenser bridge (*Fig.* 43) in which C, C_1, and C_2 are adjustable air condensers and K is the condenser under test. If p represents the internal loss of K, which is balanced by the series resistance Q, then

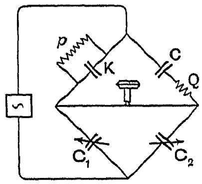

Fig. 43.—Fleming and Dyke's Method.

$$\frac{1}{p}=\omega^2CKQ \quad . \quad . \quad . \quad (126)$$

and

$$\frac{K}{C}+\frac{Q}{p}=\frac{C_1}{C_2}. \quad . \quad . \quad . \quad (127)$$

The condensers were of the order of 0·002 μF.

A high-frequency alternator with a wave-filter furnished a source of pure wave-form, and a telephone was used as detecting instrument.

Hopkinson[7] also employed a four-condenser bridge, but with a quadrant electrometer suitably connected as detecting instrument.

§ (53) Series Inductance Method.—Rosa suggested that instead of balancing the difference of phase for the two condensers by added resistances as in *Fig.* 40, a balance could be obtained by making one or both of the arms R and S inductive, thus avoiding any addition in the condenser arms. The method, as shown in *Fig.* 44, was carried out by Grover,[8] who remarks that it is not so convenient as the series resistance method for condensers over 0·01 μF. If the internal losses of the condensers are ρ_1 and ρ_2, we have

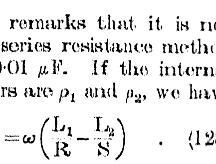

Fig. 44.—Series Inductance Method.

$$\tan(\theta_1-\theta_2)=\omega\left(\frac{L_1}{R}-\frac{L_2}{S}\right) \quad . \quad (128)$$

and

$$\frac{K}{C}=\frac{S}{R}+\omega^2K(L_1\rho_2-L_2\rho_1)$$

$$=\frac{S}{R}\left(1+\frac{\omega L_1}{R}-\frac{\omega L_2}{S}\right). . \quad . \quad (129)$$

Substitution Method.—In both this method and the preceding ones it is sometimes advantageous

to use a substitution method, testing each of the condensers to be compared against a third.

§ (54) DIFFERENTIAL TRANSFORMER METHODS.—Various experimenters [1] have used a differential transformer (inductor), instead of a bridge, for the comparison of condensers. For further information see the article on "Inductance Measurement," § (94).

§ (55) M'CLELLAND'S IONISATION CURRENT METHOD.—M'Clelland [2] has described a simple method of comparing capacities of any magnitude down to a few micromicrofarads or even less. It is based on the fact that the ionisation current that can be got by the use of a radio-active substance like uranium nitrate is extremely constant, and can be made so small that the time taken to charge a condenser by it can be accurately measured. First one of the condensers is charged up to a given voltage by the small constant current, and then the other is in the same way charged to the same potential difference. The time taken is observed in each case, and from the times the ratio of the capacitances may be deduced. *Fig.* 45 shows the arrangement of the apparatus.

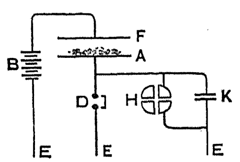

FIG. 45.—M'Clelland's Ionisation Current Method.

A few grams of uranium nitrate are spread on a sheet of paper and placed on a metal plate A, over which is another plate F connected to one pole of a battery B, the other pole of which is earthed. K is one of the condensers, and H is an electrometer across its terminals. The points marked E are earthed. As the voltage across FA is increased, at first the ionisation current increases, but when the voltage is great enough the current comes to a maximum and does not increase further. The voltage required to reach this steady current depends on the distance apart of the plates. It is advisable, however, to be able to reach 200 volts with the battery. To make the test, the earthing switch D, which at first is kept closed, is opened and the time observed which is taken by the electrometer light spot to move a distance of say 100 divisions on the scale. The same process is repeated with the other condenser, and to gain accuracy each may be tested a number of times. If the two condensers have capacitances K_1 and K_2, and if C is the capacitance between F and A, including the electrometer and the leads, then, t_1 and t_2 being the respective observed times,

$$\frac{K_1+C}{K_2+C}=\frac{t_1}{t_2}.$$

To determine C a reading is also taken with the electrometer alone. If t_3 is the time in that case, we have

$$\frac{K_2+C}{C}=\frac{t_2}{t_3},$$

which determines C in terms of K_2 taken as standard. For small condensers an ordinary Kelvin electrometer giving say 60 mm. deflection for 1 volt is suitable; for larger condensers a Dolezalek instrument (giving 5 mm. per millivolt) may be used. The space between the plates A and F should be screened to prevent air currents from blowing away the ionised air. It is better to use uranium than radium or thorium, as it gives off no emanation.

(C) *Measurement in Terms of Mutual Inductance*

§ (56) CAMPBELL'S SIFTER METHOD.—For the determination of a capacity in terms of mutual inductance Campbell's sifter method [3] is the simplest. Two cases arise.

Case (i.) *Condenser free from Loss.*—When the condenser to be tested has zero (or very small) power factor, it is connected with an adjustable mutual inductance m, an alternating source and a vibration galvanometer (or telephone) as in *Fig.* 46. The proper directions to connect the primary and secondary coils of m are found by trial.

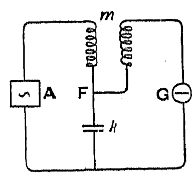

FIG. 46.—Campbell's Sifter Method.

By adjusting m the current in the galvanometer circuit can be made zero, and then

$$k=\frac{1}{\omega^2 m}, \quad . \quad . \quad . \quad (130)$$

where the pulsatance $\omega=2\pi n$, n being the frequency of the alternating source. The capacitance is thus measured in terms of m and the frequency. The frequency may be determined by means of a frequency meter or by measuring the speed of the alternator. When the condenser has power loss, a perfect balance cannot be obtained, only a minimum current being observed on the galvanometer, and the less simple method of Case (ii.) must be used. With good mica condensers, however, Case (i.) is often sufficient.

Case (ii.) *Condenser with Power Loss.*—There are various ways of extending the simple method of Case (i.) so as to obtain an accurate

[1] A. Elsas, *Wied. Ann.*, 1891, xliv. 654.
[2] J. A. M'Clelland, *Roy. Dublin Soc. Proc.*, 1904, p. 168.
[3] A. Campbell, *Phys. Soc. Proc.*, 1908, xxi. 69, and *Phil. Mag.*, 1908, xliv. 155; also *Phys. Soc. Proc.*, 1917, xxix. 350. See also "Inductance, Measurement of," § (84).

balance with an imperfect condenser. *Fig.* 47 shows one of the easiest systems.

In *Fig.* 47 the internal loss in k, the condenser under test, is represented by the series resistance r, m is an adjustable mutual inductance (inductometer), while M_1 and M_2 are mutual inductances whose secondary coils form a closed loop of resistance R and self-inductance L. The coils should be so placed that there is no direct mutual inductance between the primary circuit and the galvanometer circuit other than m. The coils forming M_1 and M_2 should therefore be placed at a good distance from the inductometer m and be turned so as to be conjugate to each other pair and to the inductometer coils.

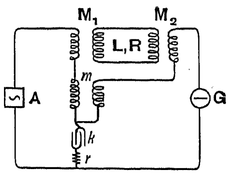

FIG. 47.—Campbell's Method, with Compensation for Condenser Losses.

The current in G can be reduced to zero by adjusting m and M_1 *or* M_2, and then

$$\frac{1}{k\omega^2}=m+\frac{rL}{R} \quad . \quad . \quad . \quad (131)$$

and $$Rr=\left[M_1M_2+\left(m-\frac{1}{k\omega^2}\right)L\right]\omega^2. \quad (132)$$

Hence $$Rr=\left[M_1M_2-\frac{L^2r}{R}\right]\omega^2. \quad . \quad (133)$$

Here M_1M_2 must be greater than L^2r/R, except in the limiting case of a perfect condenser, when $r=0$ and then also $M_1M_2=0$.

From (131) and (132) we obtain

$$r=\frac{RM_1M_2\omega^2}{R^2+L^2\omega^2} \quad . \quad . \quad . \quad (134)$$

and $$\frac{1}{k\omega^2}=m+\frac{LM_1M_2\omega^2}{R^2+L^2\omega^2}. \quad . \quad . \quad (135)$$

When the frequency (and hence ω) is known, these two equations give k and r and $rk\omega$, the power factor of the condenser.

It is best to arrange the auxiliary closed circuit so that L/R is very small, and hence rL/R negligible compared with m. Then by equation (131)

$$k=\frac{1}{\omega^2 m},$$

the same as equation (130) for a perfect condenser. This does not involve a knowledge of r, L, R, M_1, or M_2, and the auxiliary loop circuit now merely introduces a small vector to balance ri_1 without appreciable effect in equation (130).

Power Factor ($rk\omega$).—Also, when L/R is small,

$$r \doteq M_1M_2\omega^2R, \quad . \quad . \quad . \quad (136)$$

and here L need not be known accurately but M_1M_2 must be determined. This can be done directly by adding a known resistance s to the condenser circuit and altering R to R′ to restore the balance.

Then $$M_1M_2\omega^2=\frac{s}{1/R'-1/R}. \quad . \quad . \quad (137)$$

When M_1M_2 is to be determined in this way the loop (LR) may be merely placed over the m inductometer coils if desired.

To illustrate the relative values of the various resistances and inductances required, let us consider the case of measuring the power factor (0·0005) of a good mica condenser of capacitance 0·1 μF at a frequency of 800 ∿ per sec. Since $\omega \doteq 5000$, we have $r=1$ ohm and $m=0{\cdot}4$ henry. For $R=10$ ohms, $M_1M_2 = 4\times10^{-6}$, and so M_1 and M_2 may each be 2 millihenries.

In most cases, however, the Carey Foster method (§ (59)) is the best for the determination of power factor.

§ (57) MEASUREMENT OF FREQUENCY BY CAMPBELL'S METHOD.—Campbell's method affords a very accurate way of measuring frequency, and he has introduced frequency meters working on this principle, in which the inductometer scale is graduated to read the frequency directly or with integral multipliers corresponding to a suitable series of condensers arranged in the instrument. With a long-range inductometer and condensers tested against it by Carey Foster's method, the frequency can be determined with very high accuracy. The value obtained gives the frequency at the instant of balance (which can be set very rapidly), and not the mean frequency over an interval of time such as many other methods give.

For the higher ratio frequencies a telephone forms a convenient detecting instrument for this method. Strong harmonics, if present in the wave-form of the source of current, may somewhat obscure the point of balance, but if the primary self-inductance in the inductometer is kept relatively high, the harmonics cause very little trouble from 200 up to 5000 ∿ per sec.

§ (58) WAVE-FORM SIFTERS.—In *Fig.* 46 it has been seen that if the source gives a current of frequency n, when m (or k) is so adjusted that $mk\omega^2=1$, no current will pass round the circuit G, and this is entirely independent of anything (resistance, inductance, etc.) included in the circuit G. If the current in the first circuit (of A) contains a harmonic of frequency n, then this harmonic will be entirely suppressed in the second circuit. Thus the combination of capacitance and mutual inductance can be used as a wave-form sifter [1] to prevent

[1] A. Campbell, *Phys. Soc. Proc.*, 1912, xxiv. 107.

current of any one desired frequency from passing into a circuit, while allowing currents of all other frequencies not too near n to pass. Other methods in which the balance depends on frequency (*e.g.* that of § (61)) may also be used for this purpose.

§ (59) Carey Foster's Method. (i.) *Theory.*—For the determination of capacitance and condenser power factor by the help of mutual inductance the best system appears to be the method of Carey Foster with Heydweiller's modification.[1] The connections for the most general case are shown in *Fig.* 48, in which K is the condenser to be tested and s represents its internal power loss. R and S are approximately non-inductive resistances having residual self-inductances l and λ respectively. The mutual inductance M may be of fixed value or variable (an inductometer), and P and L are the total resistance and self-inductance of the branch BC, which consists of the secondary coil of the mutual inductance with an added resistance. G is either a vibration galvanometer or a telephone.

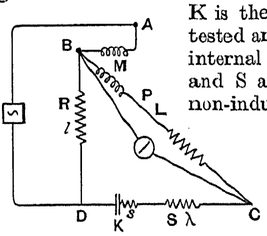

Fig. 48.—Carey Foster Method, Heydweiller's Modification.

In the method as originally described by Carey Foster[2] the branch DC contained only the condenser K, the resistance S being absent, and single make and break (or reversal) of a battery current was used, the condition of balance being that the total quantity passing through the galvanometer should be zero, in which case

$$K=\frac{10^6M}{PR}, \quad . \quad . \quad . \quad (138)$$

where K is in μF when M is in henries and P and R in ohms.

If the condenser is leaky there will be a small steady deflection before the current is reversed, which introduces error.

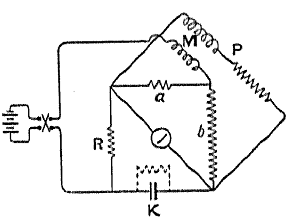

Fig. 48a.—Carey Foster Method, Campbell's Modification.

Campbell (in 1903) got rid of this source of error by the system shown in *Fig.* 48a, in which the resistance a is very small compared to b. By altering the ratio a/b the steady deflection is reduced to zero before the reversal throw is annulled[3] by altering M or P. For the latter balance

$$K=10^6\frac{M}{PR}\left(\frac{a+b}{b}\right)^2. \quad . \quad (138\text{A})$$

For balance at every instant, L should be equal to M.

The original method, however, gives no balance with alternating current. Heydweiller[4] showed that it requires the addition of a resistance S in the condenser branch, which allows two necessary conditions to be satisfied.

When a balance has been obtained (in *Fig.* 48),

$$\frac{10^6M}{K}=PR-\omega^2lL+\omega^2(l+\lambda)M \qquad (139)$$

and

$$M(S+s)=R(L-M)+Pl. \quad . \quad (140)$$

From these two equations K and $(S+s)$ can be determined, and, since S is known, s and hence the power factor ωKs can be found.

Unless ω is large, the terms in l and λ can usually be neglected in (139), which becomes

$$K=\frac{10^6M}{PR}, \quad . \quad . \quad . \quad (141)$$

the same equation as (138).

Sometimes the term in l may be neglected in equation (141), which becomes

$$S+s=\frac{R(L-M)}{M}. \quad . \quad . \quad (142)$$

However, for good condensers in which s is small, to obtain accuracy S should also be made small, and Pl may not be negligible.

(ii.) *Working Conditions.*—In carrying out the method it is best to make R a fixed standard resistance (oil-cooled) of very small residual self-inductance. The final balance may be obtained either (1) by adjusting S and M, or (2) by adjusting S and P.

Case (i.) R *and* P *Fixed,* S *and* M *Variable.*—It will be noticed that P consists of the resistance of the secondary coil of the inductometer (M) in series with an added resistance. It is best to swamp the copper resistance of the secondary coil by making the added resistance very much greater, so that temperature variation may not introduce uncertainty. For the highest accuracy the values of R and P should be measured immediately after a test is made.

The values of R and P should be so chosen as to make PR some integral power of 10. Then K is obtained directly from the observed value of M.

After the reading has been obtained with the condenser in position, the leads should be disconnected from its terminals, and, without disturbing their position, a reading should be taken of their capacitance k. Then the true capacitance of the condenser is $(K-k)$.

Sometimes it is found that no adjustment of S and M will give a balance. Often this is

[1] See also "Inductance, Measurement of," § (85).

[2] G. Carey Foster, *Phil. Mag.*, 1887, xxiii. 121.

[3] Equation (138a) is due to R. Ll. Jones.

[4] A. Heydweiller, *Wied. Ann.*, 1894, liii. 499.

due to L being less than M, in which case a coil must be added in the arm BC to make sure that L is greater than M, otherwise equation (140) cannot usually be satisfied. A difficulty also may arise when M is very small compared with L, for then S may have to be inconveniently large. A lower value of R is then wanted.

A long-range inductometer giving from 0 up to 10 millihenries is suitable for M. In general it is best to earth the point A (*Fig.* 48).

The use of a variable M is extremely convenient in giving a long range of direct-reading measurement, but it has one disadvantage which may sometimes trouble the observer: the adjustments of M and S are not independent and have to be repeated alternately until an *exact* balance is obtained. If it is not perfect, the balance may be a fictitious one corresponding to values of K and S very far from the truth. With a telephone as detector and a current source containing harmonics, in general when the balance is true the harmonics will be silenced almost exactly along with the fundamental (if the condenser is of good quality); if this does not happen, it is often an indication that the approximate balance is fictitious.

Case (ii.) R *and* M *Fixed,* S *and* P *Variable.*—When Pl can be neglected in equation (140), the adjustments of S and P are independent and there is no danger of a fictitious balance. In all other respects, however, the system of Case (i.) is much more convenient.

The modified Carey Foster method has many advantages. With a single inductometer and a few resistance coils to give a series of values of PR, capacities from a fraction of a micro-microfarad up to many microfarads can be directly measured. At the same time condenser power factors can be determined without reference to any standard condenser. When the power factor is very small (*e.g.* 0·0001), L must be known to high accuracy and Pl must not be neglected. The measurement of such a small power factor is difficult by any method, for earth capacities and other small residual effects begin to show themselves, and the experiment often becomes as much a test of the weak points of the apparatus used.

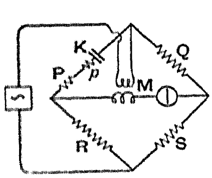

Fig. 49.—Rayleigh's Method.

§ (60) Rayleigh's Method. — Rayleigh [1] has pointed out that the Hughes method can be adapted to the measurement of a capacitance K instead of a self-inductance L. The connections are shown in *Fig.* 49, p representing the power loss in the condenser. The equations for the balance of the bridge, obtained from those of the Hughes method by writing $-1/\omega^2K$ for L, are

$$\frac{M}{K}=QR-S(P+p) \quad . \quad . \quad (143)$$

and
$$\omega^2MK=\frac{S}{(P+p+Q+R+S)}. \quad . \quad (144)$$

Hence
$$\omega^2M^2=\frac{SQR-S^2(P+p)}{P+p+Q+R+S}, \quad . \quad (145)$$

which gives p in terms of M, P, Q, R, and S. By using the value obtained, K can be found from (145).

§ (61) Campbell's Bridge Method. — The arrangement of Campbell's bridge method [2] is shown in *Fig.* 50. The unknown condenser K (with loss represented by p) can be introduced into the arm AB, which contains the secondary coil (P, L) of a variable mutual inductance M. The other arms are non-inductive, Q being adjustable.

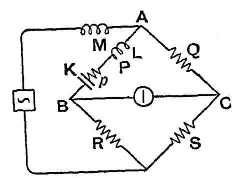

Fig. 50.—Campbell's Bridge Method.

First a balance is obtained without the condenser K, which gives for values M_0 and Q_0,

$$\frac{L-M_0}{M_0}=\frac{R}{S}$$

or
$$\frac{L}{M_0}=\frac{R+S}{S}. \quad . \quad . \quad . \quad (146)$$

Then K is introduced as in the figure, and a balance again obtained with values M_1 and Q_1.

Then
$$\frac{L-1/\omega^2K}{M_1}=\frac{R+S}{S}, \quad . \quad . \quad (147)$$

and hence
$$K=\frac{S}{R+S}\cdot\frac{1}{\omega^2(M_1-M_0)}. \quad . \quad (148)$$

Also
$$SP=RQ_0$$

and
$$S(P+p)=RQ_1,$$

whence
$$p=\frac{R(Q_0-Q_1)}{S}, \quad . \quad . \quad (149)$$

which gives the power factor of the condenser.

This method can also be used for determining frequency or for sifting of wave-form. For this purpose it is better to make it more direct reading by adding self-inductance N in the Q arm so as to make $M_0=0$.

Then
$$M_1K\omega^2=\frac{S}{R+S}, \quad . \quad . \quad (150)$$

and, with K, S, and R fixed, n will be inversely proportional to $\sqrt{M_1}$.

[1] Lord Rayleigh, *Theory of Sound*, 2nd Edition, 1895, vol. i. § 235*q*. See also "Inductance, Measurement of," § (101).

[2] See also "Inductance, Measurement of," § (98).

This method has two advantages over that of § (56): (*a*) the losses in the condenser cause no complication, and (*b*) while in that method very large values of K or M_1 are required for low frequencies, here, by varying the factor $(R+S)/S$, K and M_1 have any desired values. For example, for 100 ∿ per sec. with a value for $(R+S)/S$ of 256, only about 0·01 henry and 1 μF would be required, whereas for the former method with 0·1 henry the value of K would be about 256 μF.

§ (62) Use of Condenser Methods for determining Absolute Value of Ohm.—Any method which determines resistance in terms of mutual inductance can be used to determine the unit of resistance in absolute measure, for the mutual inductance can be referred to a standard calculated from geometrical dimensions alone. (See article on "Electrical Measurements, Systems of.") The methods described above lend themselves to such a determination through the intermediary of a condenser K. If the condenser is first tested at a given frequency by Carey Foster's method, M_1/K is found in terms of resistances. If it is then tested (at the same frequency) by one of the methods of § (56) or (61), M_2K is found in terms of frequency alone, or of frequency and a ratio of resistances, and hence M_1M_2 can be expressed in terms of resistances.

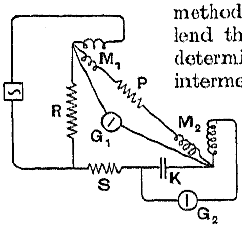

Fig. 51.—Resistance in Terms of Mutual Inductance by Intermediary Condenser (Campbell).

If the first of these methods is used, the two measurements can be carried out simultaneously according to Campbell's system shown in *Fig.* 51. A balance on G_1 is first obtained by adjusting S and M_1 or P with G_2 disconnected. Then G_2 is put in circuit and a balance also obtained on it, and ultimately G_1 and G_2 show a simultaneous balance. Then

$$\frac{M_1}{PR}=K=\frac{1}{\omega^2 M_2},$$

and hence

$$PR=\omega^2 M_1 M_2. \qquad (151)$$

In Rayleigh's method (§ (60)) the intermediary K can be directly eliminated as in equation (145).

§ (63) Determination of Capacitance in Terms of Self-inductance.—The methods for determining K in terms of L are the same as those for L in terms of K, except that usually an adjustable L can be used. A full description of a number of these methods is given in the article on "Inductance Measurement," §§ (106) to (115).

Special Methods

§ (64) Methods for Radio Frequencies.—In general the methods for determining the capacitance or power factor of a condenser at radio frequencies depend upon electrical resonance.

(i.) *Jordan's Method.*—As a typical example may be given Jordan's [1] method of testing the power factors of condensers at high frequencies, as shown in *Fig.* 52. The primary oscillation

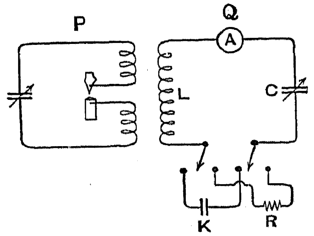

Fig. 52.—Test of Power Factor of Condenser (Jordan).

circuit P consists of a condenser and a self-inductance connected to a Poulsen arc B. To ensure symmetry and thus avoid troublesome earth capacity effects, the inductance consists of two equal coils, and B is connected between them. (The source of current supplying the arc is omitted in the diagram.) A secondary circuit Q is loosely coupled to P, and consists of a self-inductance L, an adjustable condenser C, a high-frequency ammeter A, and a pair of switches which can bring into the circuit either K, the condenser under test, or R, an adjustable non-inductive resistance. First, by setting C, the circuit Q is tuned to resonance, and the reading of the ammeter noted. Then, with R in circuit instead of K, the condenser C is adjusted to give resonance again, and R is altered until the same reading is obtained on the ammeter. The observed value of R gives the effective series resistance of K, and the power factor is ωKR (farads and ohms).

(ii.) *Differential Thermojunction Methods.*—Many null bridge methods are not workable at radio frequencies. The use of differential thermojunctions, however, is the basis of several null methods for high frequencies. For example, Glatzel [2] uses this device in his system of measuring small condensers shown in *Fig.* 53. A circuit A carries current of radio frequency, and two other circuits are loosely coupled to it, containing self-inductances and adjustable condensers K and C.

[1] H. Jordan, *Deutsch. Phys. Gesellsch. Verhandl.*, 1912, p. 451; see also W. Hahnemann and L. Adelmann, *Elekt. Zeits.*, 1907, xxviii. 988, 1010.

[2] B. Glatzel, *Deutsch. Phys. Gesellsch. Verhandl.*, 1907, ix. 151; see also L. Isakoff, *Phys. Zeits.*, 1911, xii. 1224, and A. Hund, *Gen. Elec. Rev.*, 1914, xvii. 981.

A measuring (or detecting) circuit is loosely coupled to the two latter by loops at B and D, with heater thermojunctions at p and q connected in opposite directions to the galvanometer G. By varying K and C a balance is first obtained; then the small unknown condenser c is put in parallel with C, and the capacitance of c determined by the change required in C to bring the galvanometer deflection back to zero.

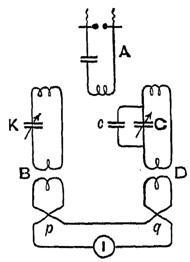

FIG. 53. — Glatzel's Differential Thermojunction Method.

(iii.) *Heterodyne Methods.* — For the measurement of small capacities various observers[1] have used heterodyne methods, in which two separate circuits, containing condensers K and C and inductances, carry currents produced by thermionic valve generators at radio frequencies, which are adjusted to be equal by observing the beats. The unknown small condenser is then put in parallel with C, which is adjusted until the frequencies are again equal. The change in C gives the value of the unknown condenser. In another modification of the method K and C are set to give a difference of frequencies of 1000 ∿ per sec., and the musical note obtained is made to beat against one produced by a third circuit.

§ (65) POWER FACTORS OF CONDENSERS BY WAVE-FORM MEASUREMENTS. — Various observers have deduced the power factors of condensers and the dielectric losses in various materials from determinations of current or voltage wave forms. Two examples may be mentioned.

(i.) Thornton,[2] using a sine wave voltage, took oscillograms of the current and terminal voltage of a number of different condensers (at frequency 39·5 ∿ per sec.); from these he drew hysteresis curves for the various dielectrics used, and deduced the power factor in each case.

(ii.) Nussbaumer[3] determined the quantity and voltage curves for the oscillatory charge (see § (15)) of various condensers, using suitable self-inductances to give frequencies from about 300 up to 2000 ∿ per sec. By means of a Helmholtz[4] pendulum the charging was started and then interrupted after a definitely known short interval (t) of time; the terminal voltage was then read on an electrometer and the charge in the condenser determined by discharging it through a ballistic galvanometer. By repeating the process for a number of values of t, curves of v and q were obtained for one oscillation, and from them hysteresis loops were drawn and the power losses deduced.

§ (66) WATTMETER METHODS.—The power lost in a condenser can be measured by means of a wattmeter, but great care must be taken to avoid errors which easily occur with low power factors. Rosa[5] in 1898 developed a number of methods for this purpose, making use of an electromagnetic wattmeter.

The wattmeter measurements are made much easier by putting in series (or parallel) with the condenser a self-inductance coil of well-stranded wire and having low resistance (R). The combined circuit can thus be arranged to have a power factor not far from unity, and so can be tested with good accuracy. To obtain the power lost in the condenser, the total observed power must be reduced by the amount RI^2, where I is the current in the inductive coil. The series method has the advantage that by means of resonance a high voltage can be applied to the condenser with only a comparatively low voltage on the combined circuit. These methods were used by Rosa and Smith[6] in testing condensers, and they corroborated their results by calorimetric measurements of the actual amounts of heat dissipated in the condensers by the energy losses. Both the series and the parallel inductance systems were used later by Mather[7] in testing the power factors of electric supply cables.

Electrostatic voltmeters have been used successfully for condenser testing by Addenbrooke[8] and others.

§ (67) CAPACITANCE BY MEASUREMENT OF ELECTROLYTIC RESISTANCE.—The electrostatic lines of force in the dielectric of a condenser have the same geometric form as the stream-lines of current produced if the plates of the condenser are immersed in a conducting liquid and a voltage applied to the terminals. Thus the capacitance of a complicated system of conductors (such as a radio antenna) is sometimes determined indirectly by measurement of electrolytic resistance. A properly proportioned model of the conducting system is constructed in metal. This is placed in a large vessel containing a suitable electrolyte of resistivity ρ (in ohm-cm.), and the electrolytic

resistance R between the two sets of conductors is measured. Then the required capacitance K, in microfarads, is given by

$$K \doteqdot \frac{8 \cdot 84 \times 10^{-9} a \rho}{R}, \quad . \quad . \quad (152)$$

where a is the ratio of the linear dimensions of the actual system to those of the model.

V. Properties of Dielectrics and Behaviour of Condensers

§ (68) By the various methods described in the preceding sections many investigations have been made of the properties of dielectrics and the behaviour of condensers. As regards dielectrics, inductive capacity (dielectric constant) has already been dealt with in §§ (17) to (24), and only power loss (or power factor) requires further consideration. In the case of condensers the most important properties are the variation of capacitance with temperature, voltage, frequency, atmospheric pressure, or lapse of time; also power factor and its variations due to these conditions.

§ (69) Mica Condensers. (i.) *Effect of Frequency.*—For mica condensers used with alternating current the capacitance decreases as the frequency is raised, the rate of decrease becoming very small at the higher audio frequencies. (The lower limit which the capacitance thus tends to approach has been called by Curtis the *geometric capacity.*) The amount of change with frequency depends on the quality of the condenser. In a good condenser of very small power factor the variation is very small indeed from low frequencies of the order of 50 ∿ per sec. upwards, as will be seen from *Fig.* 54, which refers to a standard mica condenser (at 15° C.) tested by Campbell at the National Physical Laboratory. For condensers of poorer quality the change over the same range may amount to 3 or 4 parts in 1000.

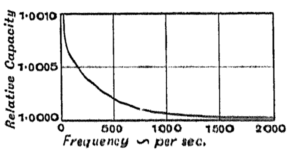

Fig. 54.—Change in Effective Capacity with Frequency (in good Mica Condenser).

(ii.) *Variation of Capacitance with Temperature.*—Mica appears to have a very small positive capacity temperature coefficient,[1] but in most good condensers there is sufficient paraffin wax left along with the mica to give the coefficient a small negative value, which is commonly from −1 to −3 parts in 10 000 per degree C. Condensers made with silvered mica, in which the paraffin does not get between the plates, have a positive temperature coefficient of the order of +1 in 10 000 per degree C.

Curtis [2] has made a very thorough investigation of the behaviour of a number of mica condensers, and for further details the reader is referred to his paper. In *Fig.* 55 are shown the results of some of his tests of a good mica condenser at various temperatures and frequencies. The three upper curves are for single charge of 0·6 sec., and discharge times of 1·0, 0·5, and 0·1 sec. respectively. It will be noticed that these show greater capacities than those for alternating current, and also zero or positive temperature coefficients. The less perfect condensers tested by Curtis show these effects to a much greater degree.

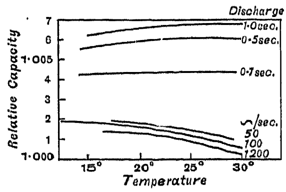

Fig. 55.—Variation of K with Temperature in good Mica Condenser (Curtis).

(iii.) *Alternating Voltage.*—The capacity of a good condenser shows no appreciable change for different alternating voltages of the same frequency. Condensers of silvered mica unfortunately sometimes show slight variation for different voltages; in one case Curtis observed an increase of capacity of 0·1 per cent on raising the voltage from 20 to 100 volts.

(iv.) *Permanence.*—The effect of changes in atmospheric pressure on the capacity of a mica condenser is very slight.

If kept in a room of constant temperature (15° C.) the capacity of a good mica condenser may remain constant to within 1 or 2 parts in 10 000 for years.

(v.) *Power Factors.*—The power factor of a good mica condenser (at 15° C. with 100 ∿ per sec.) is commonly of the order of 0·0003, but in the very best examples values as low as 0·0001 [3] may be found. The temperature coefficient of power factor is positive, and there is decrease with increase of frequency (see Curtis, *loc. cit.*).

The insulation resistance measured with direct current may be as high as 100 000 megohms for a 1 μF condenser.

§ (70) Paraffin Paper Condensers.—Ordinary paraffin paper condensers are as a rule less constant than mica condensers and their power factors are much larger. There are wide differences in quality and behaviour in the types used in commercial work.

(i.) *Change of Capacitance with Frequency.*—The capacitance falls as the frequency is raised, much as with mica condensers, but

[1] W. Cassie, *Roy. Soc. Proc.*, 1889, xlvi 357.

[2] H. L. Curtis, *Bureau of Standards Bull.*, 1911, vi. 431.

[3] This represents a phase displacement of 0·017°.

the variation is much greater. *Fig.* 56 shows the behaviour of a good paraffin paper condenser (of power factor 0·002) at 15° C. The variation with frequency increases as the temperature is raised, and becomes considerable in condensers of large power factor. Very full information on this and the other properties will be found in a paper by Grover,[1] which gives the results of a large series of alternating current tests on fifteen different condensers. Jordan [2] has investigated paper condensers at radio frequencies. In some of them the paper was paraffined, in others it was impregnated with oil.

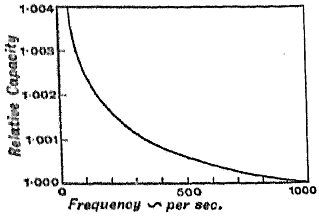

FIG. 56.—Change of Capacity with Frequency in good Paraffined Paper Condenser (Grover).

(ii.) *Variation with Temperature.*—According to Grover, the capacity temperature coefficient of a paraffin paper condenser of small power factor is usually negative and nearly constant, being not more than about −5 parts in 10 000 per degree C. In poorer condensers it is sometimes positive, rapidly increasing at the higher temperatures and lower frequencies (often up to 1 per cent). In other cases it even changes from positive to negative values.

(iii.) *Variation with Voltage.*—Paraffin paper condensers of good make do not appear to vary with change of the applied voltage. For example, a condenser of Mansbridge type tested at the N.P.L. showed constancy of capacitance to within 1 in 1000 for voltages from 10 up to 100 volts (at 100 ∿ per sec.). The power factor was also constant, which is in agreement with the results of Monasch (*loc. cit.* § (51)) and others who have found the power factors of various condensers constant over long ranges of voltage.

(iv.) *Power Factor.*—The power factor depends very much on the quality of the condenser, insufficient drying of the paper during construction causing increased losses. At 15° C. and 100 ∿ per second Grover found values ranging from 0·0017 to 0·017. In general the value rises rapidly at the higher temperatures and lower frequencies. Foiled paper condensers of Mansbridge type, which are now so much used in telephone work, show relatively high power factors. One of these tested in 1912 by Campbell (at 16·5° C. and 100 ∿ per sec.) had a power factor of 0·0084 with a capacity of 2 μF. In this type the resistance of the conducting plates inside the condenser contributes appreciably to the power lost.

According to Fischer,[3] Meirowsky condensers —in which the dielectric is paper impregnated with lacquer—have power factors of about 0·009 at 80 ∿ per second.

§ (71) CONDENSER POWER FACTORS FOR VARIOUS DIELECTRICS.—The power factors of condensers with dielectrics of various other materials have been investigated (for different temperatures and frequencies) by a number of experimenters.[4] The ranges of frequency used in some of these researches are given in Table VII.

TABLE VII

	Frequencies. ∿ per Second.	Temperature ° C.
Hanauer .	128, 256, 512, and 10 000	. .
Monasch .	50 and 86	. .
Fleming and Dyke	920, 2760, and 4600	−18 to 80
	$0{\cdot}5\times10^6$ up to 2×10^6	18
Thornton .	36·5	. .
Wagner. .	500 up to 5000	10 to 50
Austin . .	$0{\cdot}3\times10^6$	. .
Bairsto . .	900 up to 2×10^6	. .

In addition to tests on condensers Monasch also made determinations of the power factors of various cables (for electric supply) with impregnated paper and other dielectrics. Wagner made a very complete investigation of the dielectric constants, power factors, and other properties of various samples of gutta-percha, and of balata and other dielectrics, chiefly in the form of cables, the whole range of telephonic frequency being covered.

The measurements become more difficult at radio frequencies and the results are more uncertain, for in addition to the actual power lost in the solid or liquid dielectric, power losses may often occur due to other causes, such as spraying discharge in the air (particularly near the edges of the conductors). Austin found the power factor to be constant from 4000 up to 20 000 volts in condensers in which spraying is prevented by the nature of their construction; for example, glass plates in oil, oil-immersed jars, etc. But for ordinary Leyden jars in air, between 10 000 and 20 000 volts where brush discharge occurs, the power factors increased roughly in proportion to the voltage. In Fleming and Dyke's experiments very considerable variation in power factor

Proc.*, 1911, xxiii. 117; W. M. Thornton, *Phys. Soc. Proc.*, 1912, xxiv. 301; K. W. Wagner, *Archiv f. Elektrot.*, 1914, iii. 67; L. W. Austin, *Bureau of Standards Bull.*, 1913, ix. 73; G. E. Bairsto, *Roy. Soc. Proc.* A, 1920, xcvi. 363.

was observed in nearly all cases, which appears to have been due to causes of the nature of brush discharge. In work at radio frequencies the dielectric loss is sometimes specified by the logarithmic decrement of the condenser instead of the power factor. If δ is the decrement [1] of the condenser K for a *whole period*, L the resonance self-inductance for pulsatance ω, and R the effective resistance, then $\omega^2 LK = 1$, and

$$\delta = \frac{R}{2nL} = \frac{\pi RK\omega}{\omega^2 LK}$$

$$= \pi RK\omega,$$

or $$\delta = \pi \times (\text{power factor}). \qquad (153)$$

[Sometimes the decrement δ' for *half-period* is used, as in Fleming and Dyke's paper. Then $\delta' = \delta/2 = (\pi/2)RK\omega$.]

In Table VIII. are given a number of values of power factors of condensers according to various observers. As most of the materials are of variable composition, too much stress must not be put upon the absolute values, which must rather be regarded as indicating the order of magnitude to be expected.

TABLE VIII

Balata (15° C.)	Wagner	800	0·005

The materials of the india-rubber and gutta-percha class call for special notice.

Gutta-percha.—Rayner [2] discovered that the

[1] See § (15), equation (93).

[2] E. H. Rayner, *J. Inst. El. Eng.*, 1911, xlvi. 412, and 1912, xlix. 3.

temperature coefficient of the power factor of gutta-percha (at low frequencies) is negative above 10° C. Campbell found that at 800 ∿ per sec. it is still negative. The subject was fully investigated by Fleming and Dyke (*loc. cit.*) over an extensive range of temperature for three different temperatures. As appears from their curves, shown in *Fig.* 57,

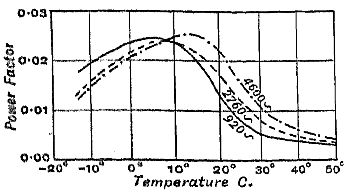

FIG. 57.—Power Factor of Gutta-percha Condenser (Fleming and Dyke).

the power factor has a maximum at a temperature not far from 10° C., the position of the maximum depending somewhat on the frequency. Addenbrooke [1] tested the power factor of gutta-percha at very low frequencies and obtained the values given in Table IX.

TABLE IX

Frequency. ∿ per Second.	Power Factor.
1·5	0·075
3	0·072
6	0·063
12	0·055
46	0·040

Rayner [2] found the power factor of a gutta-percha (cable) condenser at 50 ∿ per sec. to be practically constant from 10 up to 4000 volts.

India-rubber.—As will be seen from *Fig.* 58,

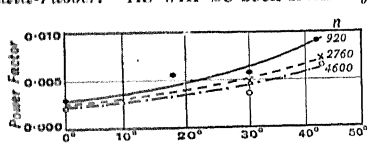

FIG. 58.—Power Factor of Pure Para India-rubber (Fleming and Dyke).

Fleming and Dyke found the temperature coefficient positive for pure Para india-rubber. Wagner's curves indicate a maximum power factor near 30° C.

On the other hand, vulcanised rubber, as shown in *Fig.* 59, has a distinct minimum near 20° C. (Fleming and Dyke).

Balata.—Balata has a much lower power factor than gutta-percha, with a large negative temperature coefficient at ordinary temperatures (Wagner).

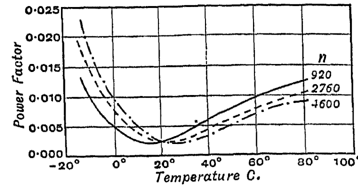

FIG. 59.—Power Factor of Vulcanised India-rubber Condenser (Fleming and Dyke).

VI. USE OF CONDENSERS FOR MEASURING INTERVALS OF TIME

§ (72) An interesting and important application of condensers is their use for the measurement of short intervals of time. If a condenser of K microfarads, with initial charge Q, is allowed to discharge through a resistance R ohms for a time t seconds, then by equation (96)

$$t=10^{-6}\mathrm{KR}\log_\epsilon\left(\frac{\mathrm{Q}}{q}\right), \qquad (154)$$

where q is the quantity left in the condenser at the end of time t.

Or if V and v are the terminal voltages at the beginning and the end of time t, since $\mathrm{K}=\mathrm{Q}/\mathrm{V}=q/v$, we have

$$t=10^{-6}\mathrm{KR}\log_\epsilon\left(\frac{\mathrm{V}}{v}\right). \qquad (155)$$

In 1876 Sabine [3] used a condenser in this way for the measurement of very short intervals of time. In *Fig.* 60 is shown the system as he used it for determining the time of contact of a light hammer H hitting an anvil A. With the key D in the position shown the condenser is charged by depressing key P for a moment. It is then discharged through the ballistic galvanometer G by pressing down key D, the throw measuring the initial charge Q. With key D up, the condenser is again charged, and the anvil hit with the hammer, which is allowed to rebound. The key D is immediately depressed, and the smaller throw now obtained on the galvanometer measures the quantity q left in the condenser. Then t the duration of impact can be obtained by equation (154), Q/q being equal to the ratio of the two throws of the galvanometer.

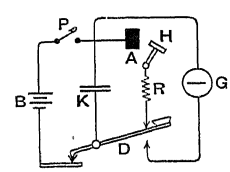

FIG. 60.—Sabine's Method of measuring Duration of Impact.

Radakovič [4] employed the method for the

[1] G. L. Addenbrooke, *Electrician*, 1913, lxx. 673; see also *Phys. Soc. Proc.*, 1915, xxvii. 291.
[2] See *Phys. Soc. Proc.*, 1911, xxiii. 142.
[3] R. Sabine, *Phil. Mag.*, 1876, i. 337.
[4] M. Radakovič, *Wien. Akad. Ber.*, 1900, cix. (II.*a*), 276, 941.

measurement of the speed of bullets. The bullet breaks successively the contacts A and B, which consist of wires (in screens) broken by its passage. The key F is then rocked over to the galvanometer side and the interval between the two breaks of contact determined as already described. Radakovič states that it is desirable to work only with small voltages, and that the best accuracy is got when $Q/q=3\cdot6$.

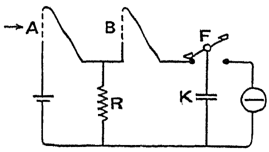

FIG. 61.—Radakovič's System of measuring Speed of Bullets.

Peirce [1] used a similar method to determine the time of contact of a quick tap on a telegraph key, which he found varied from 0·003 to 0·03 second. He worked with time of charge (equation (95)) instead of discharge.

Kennelly and Northrup [2] increased the accuracy of the method by using the method of mixtures (§ (46)) for measuring the charge left in the condenser, setting the resistances so as to give an approximate balance and then reading the small residual throw. They used the method to determine the duration of contact of impacting spheres (chiefly of steel), the time intervals dealt with being of the order of 50 to 300 microseconds.

More recently Klopsteg [3] has used a modification of the method, in which the galvanometer throw for q is made very small by opposing to the voltage of the condenser a nearly equal steady voltage of opposite sign. The system is shown in *Fig.* 62. The two contacts A and B are opened in quick succession at the beginning and end of the short interval to be measured. Then the battery is reversed at D and the key F put down. If the setting of the resistances R and S has been right, the galvanometer throw will be quite small and very exact calibration will not be required. If ΔQ is the small charge indicated by this throw, and V the voltage across (R+S), the interval t will be given by

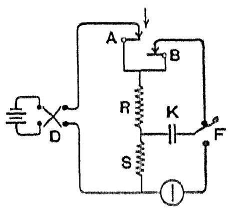

FIG. 62.—Klopsteg's Method of measuring Short Time Intervals.

$$t=10^{-6}KR\log_e\frac{1}{\frac{S}{R}+\frac{\Delta Q}{KV}\left(\frac{R+S}{R}\right)}. \qquad (156)$$

[1] B. O. Peirce, *Am. Acad. Proc.*, 1906, xlii. 95.
[2] A. E. Kennelly and E. F. Northrup, *Franklin Inst. J.*, 1911, xxx. 172.
[3] P. E. Klopsteg, *Phys. Rev.*, 1920, xv. 12.

For example, with a 1 μF condenser, for an interval of 161·5 microseconds R and S were 175 and 70 ohms respectively. Klopsteg investigated the accuracy of the method by the aid of a Helmholtz pendulum, and concluded that in measuring an interval of 250 microseconds the probable error of each observation need not exceed 0·15 per cent. He mentions also a method based on equation (155), in which V and v are measured by means of an electrometer.

Various other experimenters [4] have used similar condenser methods.

§ (73) MEASUREMENT OF RESISTANCE BY LOSS OF CHARGE.—The method of § (72) may be inverted and used to measure an unknown resistance R by observing an interval of time. It is only very high resistances that give t sufficiently long to be observed with accuracy. If R is in megohms and K in μF, equation (155) becomes

$$R\doteq\frac{0{\cdot}4343t}{K\log_{10}(V/v)}. \qquad (157)$$

The high resistance (R) to be measured is put across the terminals of the condenser K in parallel with an electrostatic voltmeter. A charge is given to the condenser so as to make the voltmeter read near the top of its scale, an initial V is observed, and then a number of values of v are read at definite times from the start, as the condenser gradually discharges through R. Both the condenser and the voltmeter must have very high insulation.

The method is sometimes used to find the insulation resistance of a cable, in which case, following equation (154), a ballistic galvanometer may be used, the condenser being the cable itself.

CARBONS FOR ARCS, THE MANUFACTURE OF

§ (1) THE MATERIALS.—The choice of raw materials for the manufacture of arc lamp carbons is governed by the necessity of producing a finished carbon which is of as high degree of purity as possible, and which is also homogeneous in structure and composition. The purest material which can be used is lamp-black, which is obtained by burning creosote oil under conditions which cause the carbon to be separated. The lamp-black, or soot, thus obtained can be produced with as high a degree of purity as 99·7 per cent or 99·8 per cent carbon, the slight impurities that exist being introduced from the walls of the chambers in which it is collected. It is in the form of an impalpable powder, and of a fairly high specific gravity. Carbons can be made from lamp-black alone with the use of a suitable binder, but it is more general to mix with the lamp-black some other form of carbon. It was formerly general practice to use gas retort carbon as the second raw material. This carbon, which is formed on the inside of the gas retorts in the process of gas manufacture, varies greatly in appearance and purity. Pieces of gas retort carbon may contain less than 0·5 per cent of foreign matter, but the foreign matter may easily run up to 6 per cent or 7 per cent. It is therefore necessary, when gas retort carbon is used, to select only the pure varieties; fortunately, this can be comparatively easily done, as the amount of impurity alters the appearance of the retort carbon, and by carefully selecting only those pieces which have the right appearance indicating high purity, it is possible to obtain gas retort carbon in bulk in which the average amount of impurity will not exceed 0·5 per cent. In recent years, gas retort carbon has been largely displaced as a raw material by petroleum coke or pitch coke, the former being the coke residue left after the complete distillation of crude petroleum, the latter the same residue after the complete distillation of gas-tar. Both these materials, if properly prepared, have a very high purity which should in no case exceed 1 per cent foreign matter, and can easily be kept below 0·5 per cent. These materials, more particularly petroleum coke, as obtained commercially, are liable to have a fairly high content of volatile matter, and in this case it is necessary to resort to the process of calcining, which may easily be performed in any suitable furnace, to drive off all volatile contents.

Lamp-black, of course, does not require any grinding before it is used for the manufacture of carbons. It is sometimes calcined or treated in other ways to increase its density, but when a proper quality of lamp-black has been manufactured in the first instance, such processes are unnecessary. Retort carbon, petroleum coke, or pitch coke require to be ground to very fine powder. Any suitable grinding mills may be used for this purpose, but, on account of the extreme hardness of these materials, they cause great wear on the grinding machinery, and precautions have to be taken to prevent the final powder from being too highly contaminated by impurities from the grinding machines. The crude products may be broken up and ground to fairly coarse powder on steel machines, and the final grinding to a fine powder may also be done with such mills, but in this case it is generally necessary to pass the powders through a magnetic separator to remove any particles of steel which may have been introduced. The finer grinding may alternatively be done on emery or carborundum stone mills, in which case magnetic separation will probably be found to be unnecessary.

The finely ground powder is mixed with lamp-black in the desired proportion, and with a suitable binder such as pitch or tar. The highest grade carbons will contain a very high percentage of lamp-black, say in the neighbourhood of 80 per cent. Lower grade and cheaper quality carbons contain considerably less lamp-black, which may be reduced even as low as 20 per cent. The precise percentage of these two materials used is not only governed by the question of quality, but depends to a certain extent on the conditions under which the carbons are ultimately to be used. Where carbons are to be used with large currents at a high current density, somewhat better results are obtained by decreasing the percentage of lamp-black, which

tends to give the final carbon too china-like a structure, which is liable to crack excessively under the great heat of a heavy current arc.

The choice of a binding material depends largely on the machinery and processes of manufacture. Medium soft pitch, which may be still further softened by the addition of a small percentage of creosote oil to the mixture, requires to be worked at higher temperatures than tar, and somewhat different machinery has to be employed. Tar, when used, is always a refined tar, from which the more volatile constituents have been distilled. It is, of course, necessary that the binding material should be as free from impurities as the main raw materials. The mixture of raw materials and binder is worked up into the form of a very stiff dry paste, so dry that it can be crumbled in the hand into dust, but yet with sufficient binding material to bind it together under high pressure. This mixture is formed under hydraulic or other mechanical pressure into large blocks, often called "cheeses" on account of their resemblance in shape to a large cheese, and these are then pressed in hydraulic presses through a die of the requisite diameter to form a rod of carbon of the desired size. The rods, as they issue from the die, are cut up into lengths suitable for further handling. Where cored carbons are required, the rod, instead of being solid, is in the form of a tube, the hole being formed by a suitable steel needle in the die. The rods are formed at very great pressure, in the neighbourhood of five tons to the square inch.

When the carbons have reached this stage in their manufacture, the final quality has been largely determined, the importance of purity in all the materials has already been emphasised, and there follows, of course, the necessity for preventing contamination during the various processes of grinding and mixing. The fineness of the powder and the thoroughness of the mixing, particularly the thoroughness with which the binding material is distributed throughout the mass, naturally control the final homogeneity of the carbon. The composition of the binder, the temperature and pressure at which the rods are formed, control the percentage of binding material used, and this in its turn largely determines the final porosity of the finished carbon.

§ (2) Baking.—The rods, as they come from the press, are tied up into bundles for calcining. Great care must be taken to keep the rods, which at this stage are rather flexible, as straight as possible throughout the baking process. In the case of the larger carbons, it is usual to perform some of the finishing processes, such as pointing one end and flatting the other end of the carbon, on the green carbon before it is baked, but in the case of the smaller carbons, and often also the larger ones, these processes are carried out after baking. The bundles of rods are packed in suitable fireclay crucibles and surrounded by carbon powder or some other refractory powder, to prevent air getting to the carbons themselves during baking. They are then slowly calcined up to a temperature of about 1200° C.

The baking process must be carried out with great regularity and slowness, the temperature being steadily raised to maximum, and as steadily, though somewhat more quickly, dropped. The process drives off the whole of the volatile material and leaves behind a coke formed from the pitch or tar which has been used as a binder, which cements the whole carbon together, and the baked rod is hard and china-like in character.

Many special types of furnaces have been designed to carry out the baking process, which, however, can be performed in any furnace where there is complete control of the rate of rise of temperature. The differences in design of furnaces only affect the accuracy and economy with which this control can be exercised, and, of course, the economy in the handling of the carbons during baking. The baked carbons, if they are not already cut and pointed, have to pass through this process after baking. Cutting is really a process of breaking the carbons through; pointing and grinding the end flat is done on carborundum or emery stones. A further mechanical process to which the baked carbons must be submitted is that of sorting to eliminate any carbons which have become crooked in baking, and the carbons must also be examined to take out any which are defective in other ways, such as being blistered or cracked or having similar faults.

§ (3) The Core.—At this stage the solid carbons are finished unless they have to be coppered, to which reference will be made later. The cored carbons, namely, those which are in the form of a tube, have to have the core canal filled. The cored carbons which are used in ordinary open type or enclosed type lamps, for the so-called pure carbon arc, have the core canal filled with a mixture of carbon and potassium silicate. The carbon is in the form of a very fine powder, which is mixed with a solution of potassium silicate until it has the consistency of a fairly thick cream. This mixture is then injected into the core canal, which it completely fills, and the carbon is then dried at a temperature sufficiently high to drive off all the moisture in the coring mixture. The core is then in the form of a dry powder held together in its place by the dry silicate of potash. The function of the silicate of potash is not only to act as a binding material, but to lower the resistance of the arc and, as has been ex-

plained elsewhere, to centralise the arc at the end of the carbon. For flame arcs, suitable chemicals are introduced in the form of powder into the coring mixture; calcium fluoride is used when a yellow flame arc is required: cerium fluoride for a white flame arc: other compounds can be used for producing special colours.

§ (4) Conductivity.—The conductivity of the finished carbon is not very high, and varies of course to some extent with its composition. The resistivity is from 0·06 to 0·09 ohm per centimetre cube. Where the diameter of the carbon is small for the current to be carried, or where, as in some types of flame lamps, the length of carbon from the carbon holder to the arc is great, it is necessary to increase the conductivity in order to avoid too large a voltage drop along the carbon. This is effected by copper-plating the carbon electrolytically, sufficient thickness of copper being deposited to give the required conductivity. In long flame carbons another method for lowering the resistance is to introduce metal—generally brass—wire into the body of the carbon: a separate hole parallel to the core canal and about 1 mm. diameter is formed in the carbon when pressing, and the wire is introduced into this after baking, and is generally waved so that it makes contact with the carbon at short intervals throughout its length. Various devices are employed to make direct contact to this wire in the carbon holder of the lamp.

§ (5) Flame Carbons.—Mention has already been made of the flame carbon in which flame-producing material is introduced into the core. The original flame carbon had the flame-producing material distributed throughout the mass of the carbon, the ingredients being introduced into the original mixing before pressing. Experience showed, however, that in open type flame lamps better results could be obtained by concentrating the ingredients in the core. In recent years, however, the development of the enclosed type flame lamp, where the carbons burn in an enclosure from which the air is largely excluded, have necessitated the manufacture of a flame carbon in which the ingredients are introduced into the original mixture, and which is therefore homogeneous throughout its section. Carbons burning under these conditions naturally do not taper to a point but burn with a practically flat end, and it is therefore necessary for the flame-producing material to be evenly distributed instead of concentrated in a central core. Open type lamps have also been recently developed for which the most suitable type of carbon is one consisting of an outer shell of pure carbon with an inner solid carbon containing flame-producing material. To manufacture such carbons, the two parts are prepared separately and the inner rod inserted in the shell, either before or after baking, and suitably cemented to it.

The design of a carbon to be used for a special purpose depends mainly on the lamp and conditions of burning. These determine the diameter and length of carbons required; whether the carbon has to be cored or solid; if cored, the size of the core; and for flame carbons the percentage of flame-producing material which has to be incorporated. These factors, combined, of course, with efficient manufacture, determine the steady and even burning of the carbons. M. S.

DIELECTRICS

§ (1) MATERIALS USED AS DIELECTRICS.—A dielectric is a type or condition of matter or space in which it is possible to produce and maintain a continuous state of electric stress with little or no supply of energy from outside sources.

Substances are commonly divided into conductors and non-conductors. Non-conductors are often termed dielectrics when their particular function is to separate neighbouring conductors which are at different potentials. Dielectrics may be solid, liquid, or gaseous. Those in common use include such substances as mica, glass, paraffin, porcelain, varnished materials such as papers and cloth, wood, oils, gases at ordinary temperatures, vacuum. The distinction between a dielectric and a conductor is that in the space between two conductors, separated by a dielectric, a state of electric stress can exist without the continuous supply of energy from without the system, whereas in the case of a conductor an appreciable and often very large amount of energy is required to maintain the condition of electric stress. There is no hard and fast line between conductors and dielectrics. Probably all dielectrics allow a very minute current to pass through them, though this may be far beyond the sensitiveness of ordinary measuring apparatus to detect.

Many materials which are efficient dielectrics at ordinary temperatures gradually alter as the temperature is raised, and change imperceptibly to a conducting state. This is common with a number of substances of a mineral nature such as glass, porcelain, oxides of the type used in the Nernst lamp. In fact, at about 2000° C. or less, it may almost be said that insulating materials cease to exist. When conductivity commences in such materials it increases at a relatively very great rate with increase of temperature. It may increase twofold for every few degrees rise.

Many materials when pure, such as water and soluble salts, have the properties of dielectrics, but when mixed become conductors. The work of Faraday on the effect of an electric current passing through solutions of salts gave an insight into the properties of matter in solution and indicated the possibility that a quantity of electricity might not be infinitely divisible, but be found to be of an atomic character. The knowledge derived from observations on electrolysis, osmosis, and vapour pressure of solutions has afforded a more satisfactory basis of an electrical theory of matter in a state of solution than we have possessed of the physical nature of electric stress in materials which are non-conductors. The work of the last thirty years on gases has also given more insight as to the passage of electricity through them than we have of the process of the passage of an electric current through non-conducting solids.

§ (2) DYNAMICS OF ELECTRIC STRESS.—In the article on "Units of Electrical Measurement" definitions have been given of various terms which we shall have to employ. The electrostatic unit of electricity has been defined as the quantity which if concentrated at a point in air—more strictly *in vacuo*—will repel an equal quantity concentrated at a second point 1 cm. away with a force of 1 dyne.[1] The electric intensity at any point of an electric field is the force which would act on unit charged placed at that point without altering the distribution of the field. This quantity we denote by R. The quantity

[1] It may be convenient to recollect that a force of 1 dyne is approximately equal to the weight of 1 milligramme. More strictly, weight of 1 milligramme = ·981 dyne.

$KR/4\pi$ has been defined, for a medium of specific inductive capacity K, as the induction in the field. For air in which K is unity this becomes $(1/4\pi)R$, and we have seen [1] that this quantity measures σ, the surface density of distribution over a conductor at any point of which the intensity of the field is R, so that $R=4\pi\sigma$.

The direction of R is normal to the surface. If the conductor be a plane sheet, then it has been shown that the equation becomes $R=2\pi\sigma$. In these expressions R is measured in electrostatic units, *i.e.* by the fall per centimetre of the electrostatic potential. We have seen that one electrostatic unit of potential is equal to 3×10^{10} electromagnetic units or $3\times 10^{10}\times 10^{-8}$ volts, and this is equal to 300 volts. Hence the electrostatic unit of intensity is equal to 300 volts per centimetre.

Experiment shows that the maximum value possible for R in air is about 100 (which is equivalent to $100\times 3\times 10^{10}\times 10^{-8}$ or 30,000 volts per centimetre). We therefore see that in air and at a distance from other conductors the surface density of charge on a sphere or cylinder cannot exceed $100/4\pi$ or about 8, while in the case of an infinite plane it may theoretically reach double this value. As a plane must in practice have edges, the only way of obtaining values approaching this would be to encase the edges in insulating material of higher electric strength than air.

§ (3) MECHANICAL FORCES ACTING ON CHARGED SURFACES.—The normal mechanical force acting on a charged surface is represented [2] by $F=\frac{1}{2}R\,.\,\sigma$, R being the intensity of the field at the surface. This is equivalent to

$$F=\frac{R^2}{8\pi}=2\pi\sigma^2.$$

Since R has a maximum value of about 100 in air the greatest mechanical force that can be exerted by electrification is about $100^2/8\pi$ or 400 dynes per sq. cm., which is equivalent to the weight of about 0·4 gm. Forces up to something of this order are therefore available for the measurement of voltages.

If a condenser with air as the dielectric has a capacity C, this will be increased by substituting most other dielectrics for the air. If the resulting condenser has a capacity KC, K is termed the *Permittivity*; it is commonly known as the *specific inductive capacity.*

Conductors immersed in a dielectric of permittivity K have the force reduced [3] to 1/K of the value when air is the dielectric, if the electric *charge* is constant. When the electric *voltage* is constant the force is increased K times to $KR^2/8\pi$.

[1] See "Units of Electrical Measurement," § (13); "Electrostatic Field, Properties of," § (4).
[2] See "Electrostatic Field, Properties of," § (5).
[3] "Units of Electrical Measurement," § (11).

In the construction of electrostatic voltmeters and similar apparatus for high voltages there is a direct gain in the forces available in immersing them in paraffin or similar oils (K=2). There is a still greater gain possible in that R can be considerably increased above what is practicable in air, so that KR^2 for good oils may have a working value 20 to 50 times what is practicable in air.

The value of K for air is about 1·0006, for hydrogen 1·0003, while all solid and liquid materials vary from about 2·0 upwards.

The following list, taken from Kaye and Laby's *Physical and Chemical Constants,* which may be consulted for further information, gives the values for a few materials:

SUBSTANCE.	k.
Solids :	
Calcite	7·5-7·7
Ebonite	2·7-2·9
Fluorite	6·8
Glass, Crown	5-7
,, Heavy Crown	7-9
,, Flint	7-10
,, Mirror	6-7
Ice	93·9
Indiarubber	2·1-2·3
Mica	5·7-7
Paper, dry	2-2·5
Paraffin wax	2-2·3
Pitch	1·8
Porcelain	4·4-6·8
Quartz	4·5
Resin	1·8-2·6
Rock Salt	5·6
Selenium	6·1
Shellac	3-3·7
Silica, fused	3·5-3·6
Sulphur	3·6-4·3
Vaseline	2·2
Liquids :	
Alcohol, methyl	35·4/13·4°
,, ethyl	26·8/14·7°
,, amyl	16·0/20°
Aniline	7·30
Benzene	2·29/18°
Carb. bisulphide	2·62
,, tetrachloride	2·25/18°
Ethyl acetate	6
Glycerine, λ=200	39·1/15°
Oil, castor	4·6-4·8
,, olive	3·1-3·2
,, paraffin	4·6-4·8
Petroleum	2·0-2·2
Toluene	2·3
Turpentine	2·2-2·3
Vaseline oil	1·9
Water, λ=∞	81
,, λ=3600 cm.	3·32*
,, λ=1200 cm.	2·79*
	76 cm. Hg.; λ=∞.
Gases :	
Air	1·000586
Hydrogen	1·000264
Helium	1·000074
Nitrogen	1·000581
Carbon dioxide	1·000985

* Beaulard, 1908.

Shellac, oils, rubber, ebonite, have values between about 2 and 3; glass and micas 6 to 9. Many liquids are much higher, water being about 80 at ordinary temperatures, but at very low temperatures the value seems to become constant at 2 to 3 for a variety of

liquids which are widely different at ordinary temperatures.

§ (4) ENERGY STORED IN DIELECTRICS WHEN ELECTRIFIED.—It has been shown [1] that in an electrified dielectric there is stored in it a quantity of energy $KR^2/8\pi$ per unit volume, where R is the electric intensity, *i.e.* volts per cm. $\div 300$.

The fact that the establishment of an electric field requires a definite amount of energy is of great importance in physical phenomena and technical applications.

(i.) *Energy in Space near the Earth's Surface due to Potential Gradient.*—There is usually a vertical electric field [2] in our atmosphere which commonly has a value of about 1 volt per centimetre, and since 1 volt$=1/300$ electrostatic unit, the energy per c.cm. is therefore $1/300^2 \times 8\pi$. In a cubic metre the quantity is about $\frac{4}{9}$ dyne-centimetre. In a cubic kilometre the quantity is $10^9 \times \frac{4}{9}$ dyne-cm.$=4{\cdot}5$ kilogram-metres, or 33 ft.-lbs.

(ii.) *Energy stored in Space in an Overhead Transmission System.*—A very important case of storing of energy in space occurs in the case of high-voltage transmission lines. It is commercially economical to build these up to a length of 200 miles and voltages up to 200,000 where fuel is expensive and water-power is available.

Take as an example a transmission line of 100 kilometres in length, working at 150,000 volts. For simplicity consider a single phase circuit of two wires of 1 cm. radius, 300 cm. apart, supported so high that the capacity to earth may be neglected in comparison with the capacity between the wires. The capacity per cm. of the circuit is $1/(4 \log a/b)$, where a is the distance apart, and b is the radius of the wire, and this is equal to $1/(4 \times 5{\cdot}7)$.

The length of the line is 10^7 cm.

The voltage is $150{,}000 \div 300$ or 500 E.S. units, the peak value of which is $500 \times \sqrt{2}$.

The energy stored in space, when the voltage reaches its highest value, is

$$\tfrac{1}{2}CV^2 = \tfrac{1}{2} \times \frac{10^7}{4 \times 5{\cdot}7} \times (500 \times \sqrt{2})^2 \text{ dyne-cm. (ergs)}$$

$$= 11 \text{ kilowatt-seconds}$$

$$= 1100 \text{ kilogram-metres.}$$

This energy has to be supplied to the line twice every period to keep it charged when no energy is being taken out at the receiving end. A large part of the energy is restored again as the voltage falls; it is therefore of an oscillatory nature, given by an expression of the form ($E \sin \omega t$),[2] and the plant supplying it has to be sufficient to supply the necessary charging current. Suppose the frequency is 25 alternations per second, so that $\omega = 2\pi \times 25$, the effective charging current is $CV\omega$ or $10^7 \times 500 \times 2\pi \times 25/(4 \times 5{\cdot}7)$, and this is $3{\cdot}45 \times 10^{10}$ electrostatic units, which is equal to $(3{\cdot}45 \times 10^{10})/(3 \times 10^{10})$ or $1{\cdot}15$ electromagnetic units. Thus the effective charging current is $11{\cdot}5$ amperes.

The apparent power supplied to the line is $150{,}000 \times 11{\cdot}5$ volt amperes or 1700 kilovolt-amperes. Such a line requires, therefore, plant of the capacity of nearly 2000 kilowatts to be connected to it, even when the load to be supplied is negligible. If a 2000-kilowatt machine were supplying power to such a line it could supply a real load of over 1000 kilowatts as well as the charging current. The kilovolt-amperes would then be

$$\sqrt{1700^2 + 1000^2} = 1950.$$

Actually such a circuit would be capable of transmitting some 50,000 kilowatts.

(iii.) *Energy stored in Insulation of Machinery.*—Similarly in the case of alternating current plant there is an appreciable storing of energy and subsequent emission from the insulating material twice every cycle.

Take, for example, the insulation of a machine working with a mean effective voltage between the copper winding and the iron of 10,000 volts. Suppose the insulation is mainly of mica, 0·33 cm. thick, and that $K=5$. The potential gradient is $10{,}000/0{\cdot}33$ and $R = 10{,}000/0{\cdot}33 \times 300 = 100$.

The energy stored in the insulation will be $(5 \times 100^2)/8\pi$ or 2000 dyne-cm. per c.cm. If the copper circuit is inserted in the iron of the armature in 50 slots, 100 cm. long, there being 2 conductors per slot, and the mean circumference of the insulation is 10 cm., then the volume of the insulation will be $50 \times 100 \times 2 \times 10 \times 0{\cdot}33$ or 33,000 c.c. The total energy stored will be $2000 \times 33{,}000$ dyne-cm. or 0·66 kilogram-metre. This is equal to 4·8 ft.-lbs. If the frequency is 50 cycles per second, the energy is stored up and released 100 times a second, and the 4·8 ft.-lbs. is stored up in 1/200 sec., or at the mean rate of 960 ft.-lbs. per second. There is, therefore, nearly 2 horse-power of oscillating energy in the system irrespective of any loss which may be due to the imperfect qualities of the dielectric. Just as in any mechanical oscillating system energy must in practice be supplied to compensate for losses due to various kinds of friction, so in all dielectrics there must be some electrical loss. This loss appears as heat, which increases the temperature of the dielectric. In some materials such as air, when not over-stressed, the supply of energy required is negligibly small, less than 1/10,000 of the oscillating energy. At the other end there are many materials with large technical applications, such as varnished fibrous in-

[1] See "Electrostatic Field," § (6).

[2] See also "Atmospheric Electricity and Thunderstorms," § (1), Vol. III.

sulations, with values of 5 per cent or more, as mentioned later. The energy absorbed and appearing as heat commonly rises rapidly with increase of temperature and may reach 50 per cent.

It is interesting to note that materials with a moderate dielectric energy absorption have a distinct value when arranged as insulating material in suitable locations in a high-voltage system. Their property of absorbing energy and only giving out an appreciably smaller fraction after the voltage wave has passed, enables them to be of use in absorbing electrical shocks and surges which are inevitable on power systems, such "transients" being commonly caused by short circuits or lightning or by defective plant connected to the system. Materials of this nature act in a manner analogous to air reservoirs and safety-valves on hydraulic pipe systems, which help to prevent excessive pressures which might otherwise be set up by "water hammer" action.

§ (5) Applications of Dielectrics.—Every use of electricity requires conductors at different potentials. The separation of these is effected by the interposition of a dielectric. The qualities of importance in a dielectric depend upon its application.

(i.) *Mechanical Separation of Conductors at Low Voltages.*—In some cases its main function is the mechanical separation of a number of conductors in which the electric stress in the dielectric is relatively low, the necessity for mechanical strength governing largely the thickness chosen. The dry-core telephone cable is an example. In such cables each wire is spirally wrapped with paper ribbon. Two wires which are to be used together are spiralled together, and this process is repeated with pairs, the "lay" or pitch of spiral being modified in the different circuits so as to avoid troubles from inductance.

The voltage is low, not exceeding about 30 volts. Cables may contain 300 or more pairs of wires, and the individual circuits are distinguished by a colour scheme. They are always lead-covered. The dielectric efficiency is dependent on the dryness of the paper, which is dried out, after the cable is laid and jointed, by forcing dried air through it.

Another similar case arises in the submarine telephone and telegraph cable. The insulation is stressed electrically to a very low value. Mechanical strength must be adequate and largely governs the design of the cable, since continuity of service is of first importance. The materials used, gutta-percha and similar substances, have not as good dielectric qualities as mica, paraffin wax, and certain types of mineral oils; but they alone have the necessary mechanical properties such as toughness and flexibility combined with the rare property of being unaffected by salt water, for almost an indefinite time, even under very intense hydrostatic pressures.

For electric circuits such as house-wiring, for lighting and power, india-rubber is largely used as the foundation for the dielectric. The thickness is governed by mechanical considerations. The dielectric is usually protected by braiding which is treated with a wax preparation.

(ii.) *Insulation for Moderate Voltages.*—For machines up to 500 volts a foundation of fibrous materials such as paper and woven fabrics is very largely employed. These in themselves are very poor insulators, and cannot be used alone, as they are not waterproof. If a machine were started up after being cooled below the dew-point, as often happens in practice, it would be full of water in the interstices of the winding. This would result in sufficient electrolytic damage to cause a short circuit. Such fibrous materials must be made waterproof by being suitably impregnated. Shellac, oxidised linseed oil, and varnishes containing bituminous and similar compounds are largely used.

The impregnating is carried out *in vacuo.* After the air is pumped out the hot impregnating compound is run into the vessel and immerses the part of the machine, then air is admitted and forces the material into the interstices.

Synthetic varnishes promise to have a wide application. They are commonly made from phenolic compounds, which condense to more complex substances when treated with aldehydes. The action is brought about by catalysts and heat. In an intermediate stage a form soluble in alcohol may be obtained, which permits of varnished papers and fabrics being made. These may be wrapped in several layers on conductors or laid on one another to form flat insulation of any desired thickness. On being subsequently heated they become hard and waterproof. They resist heat better than materials of a shellac nature, which are liable to soften at high temperatures.

(iii.) *Insulation for High Voltages.*—Though fibrous material is very largely used for low-voltage plant, 500 volts, in which the thickness is often governed more by mechanical than electrical requirements, it is also largely used when the thickness is governed by the electric stress that has to be dealt with. Not only is this the case in such plant as transformers (2000 to 130,000 volts) but also in transmission cables in which the insulation consists of paper saturated with a material such as highly refined mineral oil.

For the electrical circuit of high-voltage moving machinery, such as dynamos driven by steam turbines, it is essential that the insulation should occupy as little space as possible. The high speeds necessary, which are directly fixed by the frequency of supply, put a very definite limit to the diameter of

the rotating part. From a magnetic point of view space occupied by other materials than copper or iron is wasted, and a larger machine is required than otherwise would be the case. The insulation must therefore be as thin as possible and also withstand temperatures of the order of 150° C. Mica possesses the desired properties in the highest degree. Its main disadvantage is that it has to be used in small pieces. In covering the copper conductor of a high-voltage machine a large number of flakes of mica, each of which is one or two thousandths of an inch thick, are cemented together with a varnish to form a large sheet, which can be wound round the copper to the desired thickness. Heat and pressure are used to solidify the wrapping. Sometimes, for convenience of construction, the mica is attached to paper to make the wrapping process easier, the paper being wound on to the bar with the mica. In such cases the paper adds little to the electric strength of the insulation, as it is much inferior to an equal thickness of mica. The best course to adopt depends on general design and method of manufacture.

Mica insulation of this class is far from homogeneous. This is, electrically speaking, a disadvantage, but its use is essential for modern high-power generating plant. Without it designs would have to be seriously modified. There is strong economic inducement to transmit large amounts of power at the highest practicable voltage, which is largely governed by the limitations of the transmission cable and its insulation. The direct generation of high voltages demands an increased amount of insulating material in the plant as compared with the production of the same amount of power at lower voltages. This is of special importance in prime generators, such as turbo-alternators, as it leaves less room for copper and iron, just where it is most valuable. It is therefore not economical to generate power directly at very high voltages; but to wind the machines for any convenient economical voltage, and to transform up to the transmission voltage by static transformers

Generating voltages in such cases depend on local conditions. About 10,000 volts have been frequently used, where there is a local demand which can be fed at this voltage. Distant supplies can be carried out simultaneously by stepping up to 70,000 or 120,000, according to circumstances. These pressures are used for overhead transmission. For underground work 6600 and 11,000 are most common, 22,000 and 33,000 systems are increasing, and 66,000 is being installed.

One of the most valuable commercial dielectrics is mineral oil. As mentioned above, it is used very extensively for impregnating the paper used in power cables. It is also used in very large quantities for insulating transformers and for the immersion of the operating contacts of high-voltage switches. For these purposes it is commercially obtainable with an electric strength of 20,000 to 40,000 volts as the breakdown pressure between half-inch spheres 0·15 inch apart, while by special purification the value may be raised to 80,000.

Fibrous insulating materials may often be used in oil immersed transformers without impregnating materials such as varnishes, the oil performing the function of the varnishes which are necessary if fibrous material is used exposed to the air.

§ (6) Characteristics of Dielectrics.—All solids and liquids fall short of perfection as dielectrics.

(i.) *Leakage Resistance.*—A perfect dielectric would withstand electric stress indefinitely, so that two conductors immersed in it and charged to a definite difference of potential would maintain this difference for an indefinite time. In practice the difference of potential will diminish more or less quickly. In the case of very good insulators the rate may be very slow, condensers may be made so as to lose only a small fraction of their charge in a day when in a dry atmosphere if insulated by amber, quartz, or soapstone. In the case of other dielectrics such as treated fabrics the leakage may be immensely greater.

(ii.) *Dielectric Hysteresis.*—Gases such as air are practically perfect dielectrics if not stressed too highly.

In addition to very high resistance to leakage, it is for very many purposes of the first importance that the energy stored up in a dielectric, when stressed electrically, should be recovered as far as possible when the electric stress is reduced to zero. Just as a definite amount of energy is absorbed in iron when the magnetic field in which it is situated is altered and brought back to its initial value, so a definite amount of energy is required when the electric stress in a dielectric is altered in a similar manner.

In the case of magnetism[1] the energy absorbed per cycle is represented by $\int BdH$. In dielectrics the energy is $\int IdV$ when I is the polarisation and V the voltage. The form of the hysteresis curve naturally differs from that of iron, which is complicated by the great range of permeability. The electrical hysteresis figure is composed of two nearly straight lines meeting at the ends and slightly bowed from one another in the middle. This dielectric hysteresis becomes important when the power available is very small, when the frequency of alteration of the electric stress is high, and when the distance of transmission is long. These conditions hold particularly for

[1] See "Magnetic Hysteresis."

telephone and telegraph transmission, especially when cables are used. The fact that every periodic alteration of the electric stress absorbs a certain amount of energy, requires this energy to be provided by the generating plant (a telephone transmitter, for example) over and above that required by the ohmic resistance of the conductors. The extra energy required may be simulated by connecting the conductors together by an impedance of suitable value, the loss in which is equivalent to the hysteresis loss in the dielectric.

It is to be noted that the energy absorbed in losses of this nature is approximately a constant value per cycle, and therefore the power required to supply this energy absorption is proportional to the frequency. The importance at telephonic frequency (800 cycles per second) with a small amount of power available may therefore be very great, if dielectrics of unsuitable character or condition are employed. At radio frequencies, 10^6 per second, the effect may be so pronounced as to very rapidly raise the temperature, and even set on fire insulating materials which are quite suitable for the same voltages at frequencies, such as 50 per second, in common use for power transmission.

The accurate measurement of the properties of dielectrics is therefore a matter of great importance, especially as the actual ohmic resistance is no guide to the value of dielectric hysteresis. The power absorbed for a given alternating voltage is often many thousand times that which would be the case under constant steady stress of the equivalent value.

§ (7) Dielectrics surrounding Long Cylindrical Conductors. (i.) *Homogeneous Dielectrics; Cables.*—Economy in the transmission of large amounts of power requires high voltages to be used to save copper. The saving of copper is important as a matter of prime cost and standing charges, and also on account of the impracticability of transport and laying of cables of very large section. Cables have to be wound for transport on drums which must be large compared with the diameter of the cable. A limit is set by the size of drum that can be handled and by the cost of making the joints which have to be made after laying. The joints increase in number if heavy cable, which can only be handled in short lengths, is used.

The commercial importance of employing high voltages for power transmission is therefore great, and for underground work the limit is fixed by the efficiency of the dielectric insulating the conductors in the cable.

For the great majority of cases where high-voltage transmission is used three-phase currents are employed, three insulated conductors being covered by a cylindrical lead sheath. Paper wound spirally in strips about 1 inch wide and thoroughly impregnated with an insulating oil is used as the insulation. The number of layers of paper used depends upon the voltage. The successive layers are wound so as to "break joint," and the narrowness of the strip permits of the cable being wound on and off the drum without damage, the layers sliding over each other slightly when the cable is bent.

When the insulation surrounding a cylindrical conductor is thick the electric stress at the inner surface is higher than at the outer, if the insulation is electrically homogeneous. To take a plain concentric cable as an example, the electric intensity at P due to a difference of potential V, between the inner and outer conductor is inversely proportional to the distance, r, of P from the centre (*Fig.* 1). Hence k being a constant we have

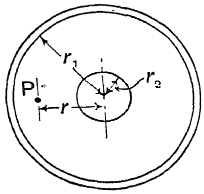

Fig. 1.

$$\frac{dV}{dr}=k\frac{1}{r}, \quad dV=k\frac{dr}{r},$$

$$V=k(\log r_1-\log r_2),$$

$$k=\frac{V}{(\log r_1-\log r_2)},$$

$$\frac{dV}{dr}=\frac{1}{r}\frac{V}{\log r_1-\log r_2}=\frac{1}{r}\frac{V}{\log (r_1/r_2)},$$

(see left side of *Fig.* 2). Suppose $r_1=2r_2$, then dV/dr near the inner surface of the dielectric $=V/r_2 \log 2=V/r_2\times 1{\cdot}44$, and near the outside surface it is $V/2r_2 \log 2=V/r_2\times 0{\cdot}72$.

The mean gradient is V/r_2, so that the maximum stress is 44 per cent above the mean.

For a given outside diameter of the dielectric the electric intensity diminishes with thickness of the dielectric until the radius of the inner conductor reaches a definite fraction of the outer diameter of the insulation. For

$$\frac{dV}{dr}=\frac{V}{r_2}\frac{1}{\log (r_1/r_2)}.$$

This expression has a minimum value when $r_1/r_2=e=2{\cdot}718$. In this case we find at once $dV/dr=V/r_1\times 2{\cdot}718$.

The values of the gradient for $r_1/r_2=2{\cdot}5$ and $r_1/r_2=2{\cdot}9$ are, however, less than 1 per cent in excess of the minimum value. The question whether it is economical to give so much space to insulation at the expense of the size and carrying capacity of the inner conductor is a technical one which will considerably modify the design of the cable.

If the cross-section of the inner cable is increased three times, for instance, so that its radius becomes $r_1\sqrt{3}/2{\cdot}718$, the potential gradient at its surface is only increased some

30 per cent above the minimum value. It is also to be remembered that increasing the thickness of insulation keeps the inner conductor at a higher temperature, which directly limits the current carrying power. The temperature gradient in the insulation is considerable, and if the material used has an appreciable rate of change of permittivity or other characteristic due either to its physical condition or mode of manufacture, the potential gradient will be seriously modified from that indicated by the theory outlined.

(ii.) *Grading of Cables.*—If the inner layers of insulation of a concentric cable are constructed of a material of a higher permittivity than the outer layers, the potential gradient in the space it occupies will be reduced below

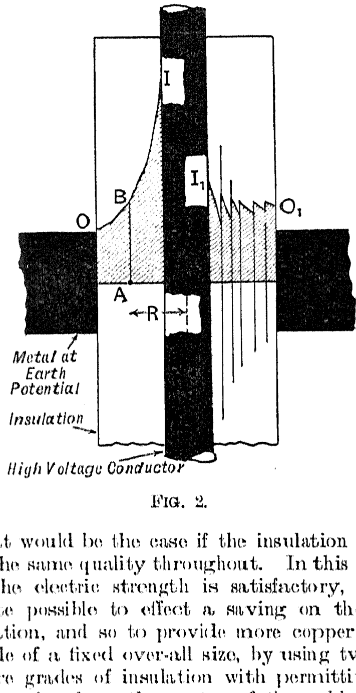

FIG. 2.

what would be the case if the insulation were of the same quality throughout. In this way, if the electric strength is satisfactory, it is quite possible to effect a saving on the insulation, and so to provide more copper in a cable of a fixed over-all size, by using two or more grades of insulation with permittivities decreasing from the centre of the cable outwards, the values of the permittivity being roughly inversely proportional to the radius.[1] The general nature of the result is illustrated in *Fig.* 2.

§ (8) DIELECTRICS SURROUNDING SHORT CYLINDRICAL CONDUCTORS.—The discussion of the case of a long cylindrical dielectric stressed radially shows that the only practicable method of reducing the stress near the inner surface is to increase the value of the permittivity relatively to that of the outer parts.

When the length of a dielectric of cylindrical form is short, not more than a few diameters long, the potential gradient through the dielectric may, however, be equalised by a suitable distribution of conductors embedded in it. Such cases arise when high-voltage conductors have to pass through the metal casings of switches, transformers, etc. When the insulation is thick compared with the diameter of the hole this method becomes of great technical importance.

If a plain cylindrical insulation be used, the potential gradient at any point A across it will be represented by the height AB of the ordinate of the curve IO at A.

The curve has the form AB × R = constant. The potential gradient at the inner surface will be greater than that at the outer surface in the ratio of r_1/r_2. As the inner surface will naturally be the hotter, the material will be considerably weaker, electrically speaking, if made of varnished paper, such as is often used.

It is, therefore, very desirable to equalise the gradient. This can be done when the axial length of the conductor is not very long, by embedding a series of cylindrical metal conductors in the material, of a size so graduated that the capacity between two neighbouring ones is constant, assuming that they are separated by equal radial thicknesses of insulation. As the capacities in series are equal the potential gradient between successive layers will be practically equal. There will be a negligible difference in the exact shape of the curve depending on the radius.

The potential gradient curve takes the form of the saw-toothed line, I_1, O_1, the area of the two shaded portions being equal. It is desirable to connect the inner conductor to the innermost metal foil, and the outer one likewise to the outermost foil. This avoids any danger of brush discharge and surface leakage which is otherwise liable to occur and to damage the material when contact between metal and insulation is imperfect.

As insulation of all kinds depends for its efficiency on being kept dry, it is especially desirable to expose as little as possible of the "end grain" of tubular insulators made of materials of the nature of paper. When they are made of porcelain and moulded materials, insulators are commonly made somewhat taper in shape. This should not be done in the case of paper tubes, which should be of full diameter to the ends. "Condenser" insulators of this type are being used for plant carrying very large amounts of power at high voltages. They have the great advantage over porcelain in not being brittle and they can be made by plant commonly available in electrical works.

To achieve the equality of the successive condenser elements they must be made of equal area and, therefore, the axial lengths must be inversely proportional to their radius—

[1] A. Russell, *The Theory of Electric Cables and Networks.* Constable.

that is, their lengths must follow the ordinates of the curve OI of potential gradient for the homogeneous dielectric.

The lengths need not be symmetrical vertically. If one end is immersed in oil, as will often be the case, it may be more economical to allow most of the tapering to be carried out at the upper end. In practice many more cylinders more closely spaced are used than are shown in the diagram.

The above is only a first approximation to the design of insulators of this type. There is an additional effect due to the part of the central conductor beyond metal cylinders. It has an appreciable capacity effect with the outside areas of the longer cylinders.

§ (9) Limitations of the Application of Dielectrics by the Type of the Electric Stress.—An important technical application of dielectrics is their use for improving the power factor of alternating circuits in which the current would naturally lag behind the voltage, as occurs when induction motors are connected to the circuit. The line current can be reduced by bringing it into phase with the voltage, or approximately so, by connecting to the motor end of the circuit a condenser of suitable size. Such condensers are commonly made of paper, the Mansbridge type being very largely used. Each condenser may be only capable of withstanding a few hundred volts, so that a number have to be put in series to deal with several thousand volts. If they have the same value the voltage will divide itself evenly between them.

Such an arrangement is perfectly suitable for alternating voltages, but is quite impossible for continuous voltages of similar values. If a steady continuous voltage is applied to a number of equal condensers in series, the first effect will be that they will divide the voltage equally between them. The leakage across each condenser will then come into play, and as their resistances will inevitably vary, the voltage across the most leaky one of the chain will gradually fall, increasing the average voltage on the rest. The same effect will go on as regards the remainder, leaving the condenser with the highest resistance to take a very large part of the whole voltage, under which it will fail. Assuming this one to be practically short circuited by such failure the rest will suddenly have an increase in voltage applied to them. The same cycle is gone through, the condensers failing one after another, leaving the most leaky one till the last, other things being equal. Under alternating stress there is no time for this leak to affect the voltage distribution, the capacity current being very much greater than the leakage current.

Condensers for low voltages can only be used in series for high continuous voltages, if subsidiary arrangements are made to prevent the operation of the differential leakage above described. One way of doing this is to short circuit each condenser by a conductance which is fairly large compared with its own conductance. In many cases a megohm or more across each condenser would prevent the voltage distribution becoming seriously uneven if the resistance of the most leaky condenser were several megohms. If such a method is inadmissible it is necessary to design the condenser units so that each will withstand the whole voltage. The Mosciki condensers are made especially suitable for such purposes. They are of tubular form, glass being used as the dielectric, and they can be made to withstand high voltages.

High-voltage D.C. is used in the Thury system of power transmission. A certain design of high-voltage cable may be suitable for alternating current, but unsuitable for high continuous voltages, such as is used in the Thury system of power transmission. The body of the insulation may be considered as equivalent to a number of condensers in series separated by infinitely thin metal laminae. The voltage distribution will be definite under alternating stress, but under continuous potentials it may be quite different, as it will depend to a very important extent on the relative ohmic resistance of the various layers. If this varies with temperature, for instance, the potential gradient will be different when the inner conductor is hot from what it is when it is cold.

Suggestions have been made for controlling the potential gradient across cable insulation, by dividing it into concentric cylinders with thin metal foil between them. The various metal foils are connected to different points of a potential divider which may be a high resistance connected across the whole voltage. The function of the resistance is identical with that of a leak across each of a number of condensers in series previously described.

§ (10) Methods of Measurement of the Properties of Dielectrics.—The investigation of a dielectric requires electric stress to be applied to it by conductors charged to a suitable potential difference. For many purposes dielectrics are used in flat sheets, such as mica and paraffined or varnished paper. These may be conveniently made up into condensers by interleaving them with sheets of tinfoil, alternate sheets being connected together into two groups forming the conductors by which the electric stress is applied. In other cases, as in many details of high-voltage plant, such as the terminals of transformers, machines, and switches, cylindrical forms are used. In such cases internal and external metal coverings can be applied.

For making measurements two principal

methods are commonly used. They are (i.) Bridge methods and (ii.) Wattmeter methods.

§ (11) BRIDGE METHODS FOR TESTING DIELECTRICS.—A condenser constructed of the insulating material to be tested forms one part of a bridge.

(i.) *Direct Current Tests.*—If it is tested by using a battery as a source of power as in *Fig.* 3, T being a detector such as a high resistance galvanometer, the value of the apparent resistance will be given in the usual way, Res. of D = (B/A)C. For a majority of dielectrics made from organic materials, R will increase with the time of application of the electric stress, at first rapidly and later more slowly. It is customary to take the value after one minute's electrification as a criterion; but without a knowledge of the form of the time-resistance curve such an arbitrary figure has not much value.

In practice, measurements of this nature are not usually carried out by bridge methods, as it is impracticable to make a galvanometer, T, sufficiently sensitive. Direct deflection

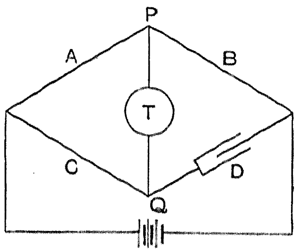

FIG. 3.

methods are employed. Such tests at steady potentials give little or no idea of the performance of an insulator under alternating potentials.

(ii.) *Low Frequency Alternating Current Tests.*—The arrangement shown in *Fig.* 3 cannot be balanced for alternating currents. If A and B are similar resistances or impedances, and D is the condenser under test, C must be given characteristics similar to those of D to obtain a balance, T being a detector sensitive to alternating currents, such as a telephone or vibration galvanometer.

If a variable air or other condenser with practically perfect insulation be substituted for the resistance C (*Fig.* 4), a close approximation to a balance may be obtained if the dielectric of D is of good quality; but in order to obtain a complete balance the power loss in C must be made equal to that in D, assuming A and B are equal. The currents in C and D will then be equal and in phase, so that the potentials at the ends of T are the same at every instant. A and B must be similar. They may be resistances or capacities or inductances. Their function is to act as a potential divider.

The power loss in C may be made equal to that in D by two methods:

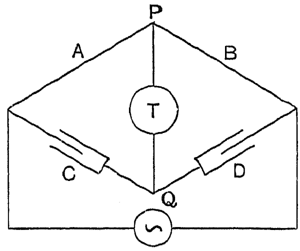

FIG. 4.

(1) By the addition of a resistance in series with C, R_s (*Fig.* 5).

(2) By a resistance in parallel with it, R_p (*Fig.* 6).

The relation of these is such that the power absorbed by the charging current passing

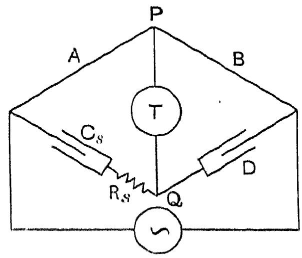

FIG. 5.

through R_s, I^2R_s is equal to the V^2/R_p loss, where V is the voltage on C, either being equal to the power expended in D. In practice R_s will often be small, a few ohms, while R_p will be several thousand ohms. The value of

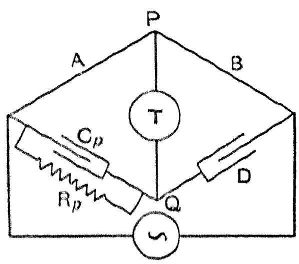

FIG. 6.

capacities C_s and C_p will be slightly different in the two cases.

If A and B are resistances, C and D being condensers with small power loss, it is to be noted that though the voltage across PQ may be zero at every instant, the current in A and

B is very different in phase from the current in C and D. The two currents are approximately in quadrature.

(iii.) *Tests at Audio Frequency.*—Bridge methods of this type are particularly suitable for audio frequencies, a telephone being used as a detector. The impedance of the telephone should be of the same order as that of the bridge arms. These methods are also specially suitable for low voltages and for materials which have very small losses. Condensers made of paraffined paper generally have an energy absorption of 2 per cent or less of the apparent power (voltage × current) passing through them. Mica condensers are often considerably under 1 per cent. The ratio of power absorbed to apparent power is termed the power factor.

In such cases the value of R_s, the resistance in series with a perfect condenser, which is required to produce a balance is quite small and the corresponding value of R_p very large.

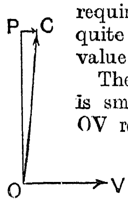

Fig. 7.

The vector, when the power factor is small, is shown in *Fig.* 7 where OV represents the voltage and OC the current vector. The direction of OC differs from OP, the normal to OV by 2° or 3°. The power is PC, parallel to OV, and the apparent power is OC. The power factor is PC/OC.

In such cases OP and OC are practically equal, which is equivalent to considering C_s and C_p equal. Let their values be called K.

The relation of R_s and R_p for equal power losses may be obtained as follows: Let V be the voltage on C or P and I the current passing. Then the power expended in $R_p = V^2/R_p$. The power expended in $R_s = I^2R_s$ and $I = KV\omega$, where $\omega = 2\pi n$; so the power in $R_s = K^2V^2\omega^2R_s$. Eliminating V we have $K^2\omega^2R_sR_p = 1$. The power factor is $V^2/R_pV \, . \, KV\omega = 1/R_pK\omega$, and is also equal to

$$\frac{I^2R_s}{V \, . \, KV\omega} = \frac{(K \, . \, V\omega)^2R_s}{KV^2\omega} = R_sK\omega.$$

To take a numerical example. Suppose a condenser of 0·01 microfarad is being tested against an air or other condenser of negligible power absorption, the frequency being about 800 so that $\omega = 2\pi n = 5000$, and suppose the series resistance R_s required to effect a balance is 400 ohms, then the power factor is

$$R_s \, . \, K \, . \, W = 400 \times 0{\cdot}01 \times 10^{-6} \times 5000 = 0{\cdot}02,$$

i.e. 2 per cent. The same result would be obtained if a resistance of a megohm in parallel with the air condenser were found to be required, for in this case the power factor

$$1/R_pK \, . \, \omega \, . \, \frac{1}{10^6 \times 0{\cdot}01 \times 10^{-6} \times 5000} = 0{\cdot}02.$$

In many cases it is preferable to use the series resistance rather than the parallel resistance arrangement. Smaller values are required, and the error due to the self-capacity of high resistances when used in this manner is avoided. This error is liable to be serious, as it may be an appreciable fraction of the value of the other capacities of the circuit.

A very important precaution which is necessary in all work of this nature is to guard against errors due to distributed capacity between the various parts of the circuit and the earth. This can be avoided by "virtually" earthing certain points of the system by such methods as that suggested by K. W. Wagner.

§ (12) Wattmeter Methods of Testing Dielectrics.—For measurements at high voltages 0·5 to 100 kilovolts or more, Bridge methods become unsuitable and dangerous, especially when working near the voltage at which the insulation breaks down. In addition the power factor changes very rapidly under such conditions, and it is impossible to obtain accurate measurements requiring a double adjustment of condensers and resistances.

A better method is to measure the power directly by means of a wattmeter. For considerable lengths of high-voltage cables it is possible to use a dynamometer wattmeter,[1] having a current coil of a large number of turns designed to carry currents of the order of 0·1 to 1·0 ampere.

A more universal instrument is the electrostatic wattmeter, which can measure the power over a very wide range of currents by simply varying the resistance through which the current passes. By immersing the instrument in a suitable oil, high voltages up to 60 kilovolts have been applied directly to the instrument itself.

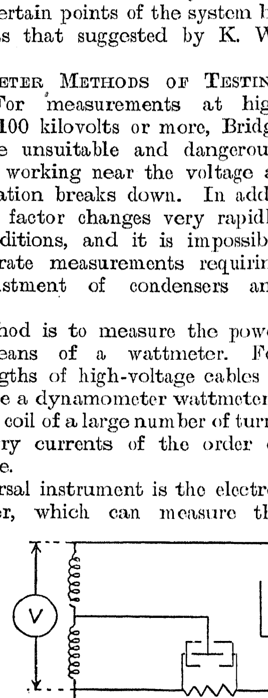

Fig. 8.

One of the most suitable methods of using an electrostatic wattmeter is to supply the needle with a potential equal to half of that applied to the dielectric (*Fig.* 8).[1]

Many types of insulating materials such as fabrics treated with varnishes and gums show great increase of energy absorption under alternating stress as the temperature rises. Wattmeter tests will show that starting from a certain atmospheric temperature the power absorbed rises to commence with, as the temperature rises. If the cooling conditions are suitable, the condition may become stable

[1] See "Alternating Instruments, Wattmeter," § 20.

and the insulation may be able to withstand the electric stress for several hours or days. An increase of atmospheric temperature may, however, so increase the dielectric losses that the temperature stability is no longer possible, more heat being evolved than the cooling conditions can cope with. The temperature will then rise continually, the increase of dielectric power absorbed increasing rapidly all the time, so that failure finally occurs. With the assistance of the indications of a wattmeter the temperature may be so finely adjusted that the stable condition will change to the unstable by increasing the temperature one or two degrees. In such cases the upward tendency of the amount of power absorbed may give an indication of inevitable failure an hour before it actually occurs. Stability or instability of temperature condition may be brought about by starting or stopping an electric fan circulating the air in the neighbourhood of the specimen. If the fan be stopped and the temperature commence to rise at a continually increasing rate, it may be checked and, if not gone too far, the stable condition may be re-established by starting the fan again. The insulating materials, such as varnished cloths, which are largely used for electrical plant, have a much larger power factor than paraffined paper or mica. The power factor may be from 5 per cent to 20 per cent or more. At ordinary temperatures, 15°, the power absorbed is approximately proportional to the frequency, at ordinary commercial frequencies, such as 50 ∿. This proves that the loss is of the nature of a hysteresis effect, the polarisation lagging behind the electric field, as in iron when the magnetic induction lags behind the magnetic field. At higher temperatures, when the loss is very much greater, the loss is only slightly affected by frequency, the energy due to the very great diminution of ohmic resistance of the material becoming a relatively, if not predominantly, important factor.

Information on this point can be obtained by measuring the resistance to continuous potentials while the material is subjected to alternating potentials of several thousand volts. The arrangement is shown in *Fig.* 9. A battery B and a D.C. ammeter A are placed in series with the alternating supply. The battery B may be about 50 to 100 volts, and A is preferably a micro-ammeter, which will only respond to continuous currents. It has to carry a superposed alternating current many times its rated value as a D.C. ammeter. The needle may vibrate under the oscillating torque; but the instrument can be made to give no material deflection under the influence of the alternating current alone. The current supplied by the battery B has to traverse the high-voltage winding of the transformer supplying the power, but its resistance will be negligible compared with that of the insulation under test. Before applying the alternating voltage the ammeter A will give a negligible reading if the insulation is cold. When alternating voltage is applied a measurable continuous current may result, from which and from a value of the voltage of the battery an estimate of the resistance of the insulation to direct currents can be made. This resistance will be found to account for only a small part of the power indicated by the wattmeter to commence with, but as the material warms up a great increase in the ammeter reading occurs, and when the material is nearly at the point of failure the resistance computed from the direct-current readings will, in certain materials, account for practically all the power indicated by the wattmeter.[1]

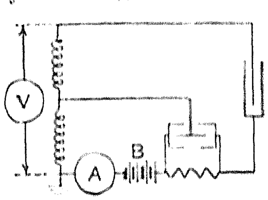

Fig. 9.

§ (13) Measurements at Radio Frequencies.[2]—Accurate measurements at radio frequencies, 10^4 to 10^7, are very difficult, partly because the ear loses its sensitiveness at about 10^4 and direct telephonic methods are no longer available, and also because the distributed and residual capacity and inductance errors increase greatly. It is impossible to make inductances free from resistance or distributed capacity; resistances likewise have inductance and capacity. Condensers are easier to make "pure" than either resistances or inductances. Radiation may also play a serious part in such measurements.

Probably the most suitable method is to measure the energy absorbed thermally. The dielectric may be subjected to a known voltage as measured by an electrostatic voltmeter and its increase in temperature measured thermometrically. With a knowledge of the necessary thermal quantities the dielectric losses may be estimated.

§ (14) Routine Tests on Insulation of Electrical Plant. A.C. Tests.—It is important to subject the insulation of electrical plant to an adequate, and yet not excessive, electric stress before it is put into service. The object of such a test is to prove that construction has been carried out properly and that there are no serious accidental weaknesses in the insulating material. The design of the apparatus ought to provide adequate insulating material, and except in special circumstances, such as the proving of a new

[1] Rayner, *J.I.E.E.* xlix. 47.
[2] See "Radio-frequency Measurements," § (19).

design, the electric stress test should be regarded as a construction—rather than a design—test.

A suitable ratio between the test voltage and working voltage depends upon various factors. In the case of low-voltage plant, 100 to 500 volts, the thickness of the insulation is largely governed by mechanical considerations, and the thickness required ought generally to withstand 2000 volts. A failure under this voltage indicates mechanical weakness such as cracks, imperfect impregnation by insulating varnish, etc. A factor of 10 or 20 may seem large; but a lower test voltage may not reveal important defects. Alternating voltage at 25 to 100 cycles per second is always used, largely on account of its simplicity of production. For plant designed for higher voltages a relatively lower test voltage suffices, and values from 2 to 3 times the working voltages are commonly used. It is generally recognised as reasonable that individual component parts, such as insulators alone, should be capable of withstanding somewhat more than the finished apparatus of which it forms a part, and that a test on an assembly of finished plant such as dynamos, switchboards, transformers all together, should not be subjected to the full pressure applied to each individual apparatus.[1]

The time of application of a test voltage is commonly 1 minute. Sometimes more than 1 minute is required, but there is a distinct danger that, if the time of application is unnecessarily prolonged, the insulation may be appreciably weakened, though the voltage applied may be materially less than what would produce failure, except after a very long time of application. The types of insulation of electric plant are so diverse, and are affected in different ways by high electric stress, the effect of which is also largely dependent on design, that it is practically impossible to say definitely what time of application of a given voltage will prove harmful. It is therefore wise to reduce the time to the shortest which may be considered reasonable. One of the factors to be kept in mind is the possible production of "Corona," *i.e.* ionised air surrounding conductors at high voltages. This may occur under the test voltage while not at the working voltage. The ionised air has highly oxidising properties and organic insulating materials should not be subjected to its action unnecessarily.

Many individual pieces of insulation of electrical plant cannot be tested to destruction in air. The discharge will pass round over the surface before going through. In such cases it is usual to immerse the whole in mineral oil, by which means much smaller pieces can be tested than when in air.

[1] For further details of such tests see the specifications of the British Engineering Standards Association relating to Electrical Machinery.

§ (15) D.C. Tests. Low Voltage up to 1000 Volts.—The measurement of the resistance of the insulation of plant is a very important test. It is made for the purpose of proving the continuity of the insulation and of determining whether it is in a fit state to be operated at the working voltage. If the insulation is damp, its resistance will be a small fraction of what it will be if properly dried. It is frequently impossible to prevent the temperature of electrical plant being below the dewpoint, especially during erection and before being put into service. In such cases the insulation may be thoroughly soaked for days together. Such a condition will generally be indicated by low resistance, and the plant should be dried out before being put into service. If this is not done, permanent damage might be done to the insulation at the working voltage, even though the leakage current were insufficient to produce obvious failure.

For tests of this nature 500 or 1000 volts are commonly used, special insulation resistance measuring instruments being employed giving a direct indication of the resistance. They are provided with a hand-driven magneto generator, and read from about 10,000 ohms to 20 megohms, and specially sensitive types are made to read up to 1000 megohms using generators giving up to 2500 volts.

§ (16) D.C. Tests. High Voltage.—The thermionic valve affords a simple and valuable method of obtaining D.C. voltages, and is used for this purpose in testing electrical plant. Power cables are tested in the makers' works in short lengths, usually by alternating current. After being laid, it is not always a simple matter to provide the necessary portable A.C. testing plant, especially if it is a question of testing long lengths, requiring a large charging current.

The ohmic resistance of the insulation of such cables is high, and only a small amount of power is required to provide the leakage current. Quite a small high-voltage transformer may be connected to such a cable through one or more thermionic rectifying valves. The cable will be gradually charged up by the passage through the valve of the current from alternate half-waves of the A.C. supply, until the value of the D.C. potential applied reaches approximately the peak value of the A.C. voltage wave. Such a method of testing provides a convenient means for proving the absence of serious damage or defective joints in cables after being laid.

DIRECT-CURRENT INDICATING INSTRUMENTS

§ (1) INTRODUCTORY.—The Indicating Instruments at present in use for the measurement of Direct Current are almost entirely of the Moving-coil or Moving-iron types. The earlier forms of instrument, such as the Siemens' Dynamometer and Ayrton and Perry Spring Ammeter, are now only of historical interest.

Both types of instruments, in order to measure the current, make use of the magnetic field, produced by the current to be measured when flowing in a coil of suitable form.

In a voltmeter this coil is one of high resistance; the current circulating in it is a small one, and the instrument measures the voltage applied to its terminals; many turns of fine wire are employed.

In an ammeter used to measure currents of moderate amount the whole current may pass through the coil; its resistance is low, being wound with comparatively few turns of coarse wire.

For larger currents the whole current does not pass through the coil but through a shunt of known resistance made of a resistance alloy having a very small temperature coefficient, so that the heating due to the current does not produce an appreciable change in the resistance. The voltage drop between the terminals of the shunt is measured on a voltmeter, or rather a millivoltmeter, an instrument of comparatively high resistance which, since the voltage drop is proportional to the current in the shunt, can be graduated in terms of this current.

In all types of indicating instruments the moving part has a pointer attached which moves over a graduated scale, and hence indicates the applied voltage or the current.

(i.) *Moving-iron Instruments.*—In the moving-iron type the coil in which the current to be measured flows is fixed, and to actuate the pointer use is made of the attraction between this coil and a piece of soft iron of suitable form and suitably mounted. The motion of the pointer is controlled, in some cases by gravity acting on the moving iron, in others by a spring. The equilibrium position of the pointer in any case is that in which the electromagnetic attraction due to the current just balances the control force;[1] the current is thus measured. Many of the requirements described in the sections which follow dealing with moving-coil instruments apply equally to the other type.

(ii.) *Moving-coil Instruments.*—For the highest grade instruments, both for ordinary switchboard use and for precision measurements, the moving-coil instrument is employed.

The current to be measured traverses a coil which is suitably suspended in the field due to a permanent magnet. When a current flows in this coil it experiences a couple tending to set it with its plane at right angles to the lines of magnetic force due to this magnet; this couple is resisted by a spring control, and the pointer attached to the coil takes up a position in which the effect of the current just balances that of the spring; thus the deflection becomes a measure of the current.

The principle of a coil moving in a permanent magnetic field was used by Kelvin in his siphon recorders and by D'Arsonval in a galvanometer.[2] Weston developed the system, and in 1888 produced the first moving-coil ammeters and voltmeters.

This system is now used in the construction of instruments by makers in all parts of the world, and, while there has been considerable general improvement in detail and some

[1] See "Switchgear," §§ (25)-(27).
[2] See "Galvanometers," § (7) (ii.).

difference in design among the various makers, the essential principles of the original Weston instruments are retained. With the exception of the long-scale instruments, described later, a maximum angle of deflection of 90° is generally used, although instruments with an angle of 120° are now being introduced.

The every-day type of instrument consists of a U-shaped magnet (some makers use a horse-shoe pattern), to which are fixed pole-pieces of soft iron, the opposite faces of which are shaped cylindrically. A round core of soft iron is supported in the centre of the pole-pieces, and the coil moves in the annular gap between them. By this means the lines of magnetic force are rendered nearly uniform over the whole surface of the pole-pieces, and consequently the deflection of the coil

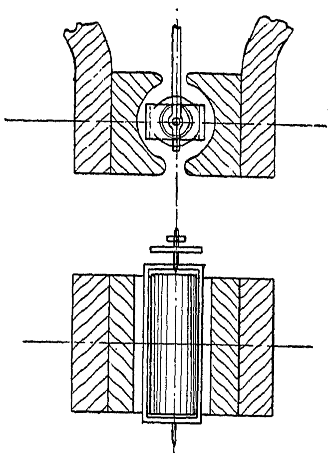

FIG. 1.

is nearly proportional to the current flowing through it. The control is effected by means of springs made of non-magnetic material, which serve also to lead in the current to the moving coil. In some cases one spring only is used, the second connection being made by means of a thin flexible strip connection which exerts little control; but, in general, two springs are employed, wound in opposite directions, thus compensating to a large extent for changes in their mechanical properties or due to variations of temperature.

Steel pivots are fixed to the moving coil, and these work in jewelled bearings fixed usually to the pole-pieces.

A typical moving-coil system is shown in *Fig.* 1, in which the upper figure gives a horizontal and the lower a vertical section through the coil and magnet poles.

§ (2) MAGNETS.—Since the accuracy of a moving-coil instrument depends on the constancy of the permanent magnet employed, the steel must be carefully selected and aged. Most makers employ systems of artificial ageing, and observations, extending over a large number of years, show that a high degree of constancy is obtained. Since it is desirable that the working forces should be large, the magnet should be as long and large as possible and the length of air-gap small. The ratio of the length of the magnet to its cross-section and the section of the air-gap to its length should be as great as possible. Edgcumbe [1] states that the product of this ratio usually varies between 150 and 500, and that it should in no case be less than 100; Fitch and Huber [2] give figures ranging from 190 to 505 for eight types of American-made instruments. The flux density depends on the size and magnetic quality of the steel and the size and shape of the air-gap. A. Campbell [3] gives values for (*a*) an Evershed Ammeter as 700, and (*b*) for a Weston Voltmeter of 870, and considered the latter to be a very high value. Edgcumbe (*loc. cit.*) states that the value in practice ranges from 500 to 2500, and Fitch and Huber (*loc. cit.*) give values ranging from 213 to 2790. The improvement shown in the more recent figures is due to improvement in the steel and the design, particularly in the direction of reduction of the air-gap.

§ (3) MOVING SYSTEM.—The moving coil is almost invariably of copper wire wound in one or two layers on a light copper or aluminium former. The shape of the coil is sometimes round, but more usually rectangular. The dimensions of the system, both former and winding, will, of course, depend on the torque required and the size of the air-gap.

In view of the comparatively large pressure per unit area on the small area of the bearings and the inertia of a heavy moving system, it is desirable that the weight should be reduced as much as possible consistently with mechanical strength and suitable torque. Modern practice has tended to the use of light-moving systems, the requisite torque being obtained largely by decrease of the air-gap. This has the further advantage that the damping, due to the eddy currents set up in the former, is supplemented by the viscous resistance of the air in the gap. But it requires that the workmanship should be exceedingly good, since the slightest contact between coil and magnet pole, or the smallest amount of foreign matter between them, makes the instrument unusable. In practice the advantages of this instrument are, however, so very great that it is satisfactory to note that in the Weston and some other makes, the

[1] *Industrial Electrical Measuring Instruments*, p. 145.

[2] *Bul. Bur. Stds.* vii. No. 3, 420.

[3] *Phil. Mag.*, 1899, xlvii. 1.

moving system is very light and robust, the air-gap very small, and the general behaviour of the instrument most satisfactory.

The actual weight of some moving elements given by Fitch and Huber (*loc. cit.*) ranges for voltmeters from 1·64 grammes to 3·5 grammes, and for millivoltmeters (ammeters) 2·17 grammes to 4·66 grammes. These, however, are all switchboard type instruments: the weight of the moving system of a precision type, such as the Weston or Elliott Standard instruments, would be much less than this, and in some cases probably nearer one gramme.

The size of the windings of moving-coil instruments may vary according to whether the instrument is to be used as an ammeter or a voltmeter. In the case of a millivoltmeter intended to be used with a shunt for the measurement of current, since the current passing through the moving coil is dependent on the pressure drop of the shunt, which must be small, the turns have to be low in resistance, while, in the case of a voltmeter where the current is controlled by a series resistance, the use of a larger number of turns of fine wire gives additional torque and at the same time keeps the total resistance of the instrument high, and reduces the power consumption. Some makers take advantage of this and use different types of coils for ammeters and voltmeters, but others find it possible to use a standard type of coil which will satisfy the requirements of both types of use.

§ (4) Ratio of Torque to Weight.—Janus [1] considered the ratio of turning moment (torque) to the weight of the moving system to be an essential consideration in moving-coil instruments. He took the case of a steel pivot ground to an angle of 60° working in a sapphire bearing, and states that for a deflection of 90° the ratio Torque/Weight should be approximately 0·17.

Fitch and Huber (*loc. cit.*) measured the torque exerted by the moving system and obtained values for the ratio ranging from 0·08 to 0·55. These refer to switchboard instruments, and it is probable that in the case of precision instruments, where the cost allows of better workmanship, the actual values would be considerably higher.

Edgcumbe states that the torque expressed in cm.-grammes for a deflection of 90° should be not less than 0·05 of the weight of the moving system expressed in grammes.

§ (5) Damping.—Efficient damping is one of the essential requirements of a good instrument. The term "damping" is sometimes used in connection with the number of swings which a moving system will pass through before it comes to rest at a definite point. In the use of an instrument, however, it is essential that the pointer should follow small variations rapidly, and since this condition will depend partly on the number of oscillations, and partly on the natural period of the moving system, it is more general to express the quality of the damping in terms of the time required to settle to a definite reading. The time will naturally vary with the size of the instrument, since in a large instrument having the same torque as a small one the free period will be longer, owing to the increased inertia of the long pointer and heavier moving system. This, of course, could be compensated for by increase of the working forces and the control, but the working forces are generally standardised so as to obtain interchangeability, and, in consequence, it is usual to allow a longer damping time for a larger instrument. The damping in moving-coil instruments is effected mainly by means of eddy currents in the metal former, on which the coil is wound, but it is assisted to a certain extent by the fluid friction of the air and also, in the case of ammeters, where the coil is connected across a shunt of low resistance, by the current generated in the coil when moving in the magnetic field. For this reason the damping time for millivoltmeters will apply only when the instrument is connected to the shunt with which it is to be used.

The specification No. 49, 1918, of the British Engineering Standards Association requires (clause 27), that:

"The motion of the pointer of every indicator shall be damped sufficiently to cause it to settle to a definite indication within a reasonable time"; and in an appendix gives a definition of a "reasonable time," based on a large number of tests made at the National Physical Laboratory, as follows:

With a scale not exceeding 4½″ in length, 2½ seconds.
" " 7 " 3 "
" " 12 " 5 "

Fitch and Huber (*loc. cit.*), giving results for a number of typical American moving-coil ammeters and voltmeters, find that in eight types of voltmeters the time varies from 0·8 to 4·6 seconds, and for a similar number of ammeters, from 1·1 to 5·8 seconds. (The actual length of pointer is not given for these cases, but it is probably from 6″ to 8″.) Edgcumbe (*loc. cit.*) gives values for moving-coil instruments of 0·6 sec. for a portable instrument, 2 secs. for an 8″ switchboard instrument, and 6 secs. for a large sector pattern instrument. It should, however, be noted that the figures given do not apply to the best modern types of precision instruments, where it is usual to find that the pointer goes straight to its reading, or, at most, only swings once through it, the time required to take up the final position being considerably less than one second. The same applies in a lesser degree to the better types of switchboard instruments,

[1] *Elektrotechnische Zeitschrift*, xxvi. 561.

in which in general the final position will be taken up in about one second, and the pointer will not swing more than once through its final position.

§ (6) Control Springs.—Control springs are a most important part of a moving-coil system. It is of course necessary to use a non-magnetic material, and hence phosphor bronze is generally used on account of its high elasticity. The series of alloys generally called phosphor bronze have a comparatively high resistivity, and while this does not affect a voltmeter in which there is a large swamping resistance, it may affect the sensitiveness of the low-resistance millivoltmeter considerably, since the resistance of the spring will be comparable with that of the coil, with the consequent loss of working force. For this reason alloys other than phosphor bronze have been, and are still, used in some cases, while in others a low-resistance bronze is used. Edgcumbe (*loc. cit.*), discussing the question, states that "the resistivity of phosphor bronze may be taken as about 10 times the resistance of copper, and that of a high conductivity bronze as about twice that of copper."

Edgcumbe discusses the dimensions of control springs, and states that the stress (of flexure) for ordinary phosphor bronze must not exceed 600 kgs. per sq. cm. if any tendency to permanent set is to be avoided. This limits the thickness of the spring in proportion to the length, and he states that the length should be at least 1500 times the thickness for a deflection of 90°. Increase of torque, therefore, must be obtained by increasing the width of the spring. Janus [1] describes a series of tests made with springs of various types and shows that with phosphor bronze the stress due to flexure may be taken up to 530 kgs. per sq. cm. without permanent set; but he considers that a limit of 280 kgs. per sq. cm. is advisable for instrument work. For a low-resistance bronze having a resistivity of 2·5 microhm-cm., Janus gives the following figures as a basis of calculation for a spring:

Turning moment (90°) = 0·4 dyne-cm.
Temperature coefficient of resistance = 0·35 per cent for 1° C.
Modulus of elasticity = 1,260,000.
Maximum strain of flexure = 200 kgs. per sq. cm.
Resistance of spring = 0·67 ohm.
Breadth = 0·18 cm.
Thickness = 0·0058 cm.
Length (in 8 turns) = 28·5 cm.

Thus the ratio thickness : length is in this case nearly 5000.

For hard-rolled copper Janus considers that the stress due to flexure should not exceed 180 or 200 kgs. per sq. cm.

Existing data regarding materials for springs are by no means complete, and an investigation to determine the elasticity, resistivity, and other constants of the alloys suitable for use as control springs appears to be urgently required.

[1] *E.T.Z.* xxvi. 562.

§ (7) Resistance and Energy Losses.—For moving-coil voltmeters the actual loss of energy involved in the measurement of the pressure is very small. The over-all resistance of a voltmeter is generally of the order of from 50 to 100 ohms for 1 volt, and the actual loss of energy on a 500-volt circuit need not be more than 5 watts.

The resistance of the moving coil itself will vary with different makes of instrument from 3 ohms to 50 ohms, a resistance of about 10 ohms being used by a maker who is employing a standard type of coil for both ammeters and voltmeters. The standard-type instruments made by such firms as Weston and Elliott Bros. have a resistance of approximately 100 ohms per volt, and, in most cases, such instruments will work with a pressure drop of 0·03 volt, or even less, for full-scale deflection, and are thus equally satisfactory for use with shunts as ammeters. The resistance of switchboard-type voltmeters of British manufacture is of the same order, and the figures given by Fitch and Huber (*loc. cit.*) for eight types of American voltmeters, range from 50 ohms to 120 ohms per volt.

In the case of the millivoltmeters used as ammeters, the standard practice in Britain is as defined in the Specification No. 49, 1918, of the British Engineering Standards Association, as follows:

"First Grade and Second Grade Instruments (suitable for Switchboard Industrial use) 0·075 volt; the resistance of the connecting leads specified is 0·025 ohm, and for sub-standard instruments either 0·0005 or 0·001 volt per division of the scale of the indicator, the connecting leads in this case having a resistance of 0·05 ohm."

This apparently allows a large range of pressure drop for sub-standard instruments, but since the use of a 150-division scale for such instruments is almost universal, it amounts in practice to a pressure drop of either 0·075 volt or 0·15 volt for a sub-standard instrument. The resistance of the moving system of the millivoltmeter varies largely with various makes, the values ranging generally from 1 ohm to 5 ohms for switchboard instruments, and from 1 ohm to 10 ohms for sub-standard instruments. The millivoltmeters examined by Fitch and Huber, when they are all reduced to a basis of 0·075 volt drop, had resistances varying from 1·4 to 5·9 ohms. Occasionally instruments have a resistance which is lower than 1 ohm, but since the contact resistance of the connections to the shunt has to be included in the circuit, it is desirable that the resistance of the instrument should be as high as possible.

§ (8) Pointer.—The pointer of a moving-coil instrument is almost invariably made of fine aluminium tube with a flat or knife-edge end, depending on the type of instrument. For precision-type instruments, the pointer is of the knife-edge pattern, the upper edge being painted black or red. A mirror, coming generally to the edge of the scale, serves to eliminate errors due to parallax. For switchboard-type instruments, the tip of the pointer is generally of palm-leaf shape, although some makers use slightly different shapes. Some typical shapes in general use are shown in *Fig.* 2.

To meet the case where a precise reading is required, and, in addition, visibility at a distance, Messrs. Elliott Bros. introduced the type No. 5 (*Fig.* 2). The thin portion of the pointer here moves over the scale fitted with the usual mirror, while the flat circle enables

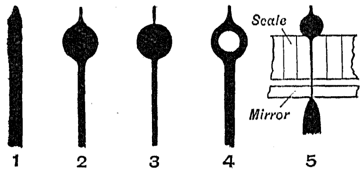

Fig. 2.

an approximate reading to be made from a distance.

The movement of the pointer is restricted by small stops, supported on springs, usually fixed to the scale or magnet. The stops allow the pointer to deflect over the full length of the scale, but serve to prevent damage should an excess current be passed through the instrument. These stops are generally insulated with glass tubing or rubber; of these glass or a similar material is to be preferred, since the rubber perishes and may become sticky with age. The British Engineering Standards Association Specification No. 49, clause 25, requires that the pointer shall be insulated from the electric circuit of an instrument unless the scale plate and stops are so insulated, and that it should be so shaped as to lend itself to ease and accuracy of reading. It specifies further that:

"If an instrument is not provided with means for avoiding errors of reading due to parallax, the clearance between the portion of the pointer which traverses the scale and the scale itself shall be not more than 1/100th part of the length of the scale for all instruments having scale lengths of 150 mm. and upwards, and not more than 1·50 mm. for scale lengths less than 150 mm.

"In the case of First Grade and Second Grade instruments the pointer shall be of such a length that it extends over more than one-half, but not over more than two-thirds, of the length of the shortest scale mark."

The requirements regarding distance of pointer from the scale have not always been adhered to, but the limits specified can be worked to in instruments of good manufacture with a consequent improvement in accuracy and ease of reading.

§ (9) Pivots and Bearings.—The use of two steel pivots, each working in a jewelled bearing is almost universal, although in one or two cases makers use a single bearing of phosphor bronze, or a jewel, the other end of the coil being suspended on fine-strip ligaments on which the coil is hung. Edgcumbe (*loc. cit.*) states that while there is some divergence of opinion as to the best form of pivot, an angle of about 60° is commonly employed. Laboratory (precision) instruments will have a fine point, while with industrial instruments a more obtuse angle is preferred. He also states that sapphires should always be employed for the bearings.

§ (10) Scales.—Examination of a large number of instruments shows that there is great diversity of opinion as to the best type of division and length of it. Not infrequently the dividing lines are far too long, with the result that at a comparatively short distance away the spaces between the lines cannot be distinguished, and it is most difficult to read the instrument. Kelvin drew attention to this malpractice many years ago, and showed that the length of a dividing line should be equal to or not more than 1·5 times the width of the space between two lines. The British Engineering Standards Association Specification deals fully with the question and specifies types of scale suitable for most types of instrument, and particularly for the moving-coil type, where the scale divisions are uniform. The Specification states, clause 22:

"(*a*) Value of Divisions.—The value of each scale division shall be either 1, 2, or 5 of the units measured; or any decimal multiple or sub-multiple of these numbers.

"(*b*) Width of Divisions.—For all Sub-standard instruments and portable type First Grade instruments the angle subtended by a scale division shall be not less than 0·5°. For all First Grade and Second Grade instruments other than those of the

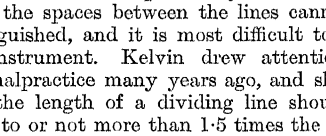

Fig. 3.

portable type the angle subtended by a scale division shall be not less than 1·0°.

"(*c*) Construction of Scale.—The scale shall be divided throughout its effective range and consistently with the requirements of section (*b*) of this clause, with scale marks arranged in accordance with one of the two systems illustrated in *Figs.* 3 and 4 (see also Appendix I.).

"*Fig.* 3 shows a scale formed of the necessary

number of groups of marks, each group consisting of a long mark followed by four normal marks; with a long mark at the end. Scales of this type shall only be used for indicators in which the scale divisions represent 1 or 2 of the units measured, or decimal multiples or sub-multiples of these numbers.

"*Fig.* 4 shows a scale in which a short mark subdivides each of the scale divisions of *Fig.* 3;

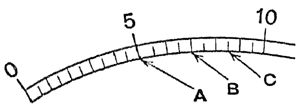

FIG. 4.

thus forming a series of groups of ten divisions followed by a long mark at the end. Scales of this type shall only be used for indicators in which the scale divisions represent five of the units measured or a decimal multiple or sub-multiple of 5.

"(*d*) Figuring.—The figuring of the scale, except in the early part of a non-uniform scale, shall be by steps of 1, 2, or 5, or a decimal multiple or sub-multiple of any of these.

"The figures shall be of such shape as to minimise the risk of different figures being confused with one another; and so spaced as to render individual groups clearly distinguishable from adjacent groups.

"In the case of scales subtending an angle of not more than 100° the figures shall be disposed symmetrically and similarly throughout the scale marks to which they refer.

"Scales of the type shown in *Fig.* 4 shall be figured at every long mark or at every alternate long mark.

"Normal and short-scale marks shall in no case be figured.

"Scales of the type shown in *Fig.* 3 should usually be figured at every alternate long mark, but may be figured at every long mark if the divisions represent 2 units (or a decimal multiple or sub-multiple of 2), and the figures are of such a size that the requirements of the preceding paragraph of this clause are complied with. They may also be figured at every long mark when the value of the divisions is 1 (or a decimal multiple or sub-multiple of 1) if in the absence of such figuring there would be less than one group for every 30 degrees of scale.

"Appendix I.

"Scales.—The following is recommended as the ratios of the lengths of the marks on scales:

Normal marks	. . . .	1·0
Long ,,	. . . .	1·7 to 1·8
Short ,,	. . . .	0·6 to 0·7

"It is also recommended that the length of the normal mark should be not less than 0·8 nor more than 1·5 times the distance between the scale marks defining the widest scale division over the useful range."

The thickness of the dividing lines is not specified; generally, on scales of precision instruments they will be as fine as possible, while with switchboard instruments a bolder line is more usual, and most frequently the lines at the main divisions are much thicker than the others.

§ (11) FIGURING.—Considerable attention has been given to the question of the shape of the figures used to denote the main divisions on a scale, particularly with a view of avoiding confusion between two nearly similar figures, such as 3 and 8. Trotter[1] describes the various systems in use and shows a set of

12345678 0

FIG. 5.

numerals designed to give maximum legibility. This is illustrated in *Fig.* 5.

§ (12) MOVING-COIL INSTRUMENTS WITH NON-UNIFORM OR SET-UP SCALES.—The greater number of moving-coil instruments in use have evenly divided scales graduated from 0 to the maximum value, but in some cases this arrangement is varied to suit the requirements of use. The non-uniform scale instrument has been devised to meet special conditions, such as those arising from the ordinary use of a battery where the normal (10-hour) rate would probably be about one-fifth of the maximum discharge rate, with the result that while the instrument is required to read up to the maximum, under the more normal working load conditions the load is too small to permit of readings being taken to the required accuracy. The ammeters for this special purpose have the zero mark at, or near, the centre of the scale, and the moving system is so arranged that the deflection from a given current at, or near, the zero mark is about three times the amount for the same current value at the upper part of the scale. This is generally effected by shaping the magnet poles so that the coil swings partially out of the field. Consequently, the working forces are decreased and the increase in the size of the lower-scale division is obtained largely by the sacrifice of the controlling forces.

A more common instrument is the voltmeter with a portion of the scale suppressed, so that the visible scale represents only a portion of the total movement of the control springs. In this case the springs are set back so that the pointer is forced back against the stops, and does not move until the pressure across the terminals of the instrument exceeds the value of the suppressed portion of the scale. The reading portion of the scale will be evenly divided, but since the increase of scale length can only be obtained either by increasing the working forces or decrease of control with consequent loss of torque, the extent of the suppression is generally limited. Edgcumbe

[1] *Journal I.E.E.* liv. 273.

(*loc. cit.*) considers that the suppressed portion should be not greater than twice the value of the visible part of the scale, and the Specification of the British Engineering Standards Association requires that

"the suppressed portion of the scale shall be not more than seven-tenths of the maximum scale value."

A usual case is that of a voltmeter for use on a 220-volt circuit, where the scale will be graduated from 180 volts to 240 volts. Voltmeters of this type have the disadvantages that the bending of the spring is much larger than for the ordinary type of instrument, and that there is no zero or other fiducial mark to which the pointer can be set to take up small changes in the spring. It is therefore usual to check them at frequent intervals and to calibrate by means of an adjustable rim or screw.

§ (13) Zero Adjustment.—The provision of an adjustment whereby small changes, due as a rule to the springs, can be adjusted for is most convenient to the user, and the provision of such a device is called for by the British Engineering Standards Association Specification in the following terms:

"A suitable device, accessible from the outside of the case, shall be provided for adjusting the pointer to zero or other fiducial mark, without risk of damage to any of the working parts of the indicator. This clause shall only apply to spring-controlled sub-standard and First Grade instruments.

"On circuits carrying pressures exceeding 250 volts, this device shall be such that it can be employed with safety to the operator when the circuit is alive.

"Any instrument not complying with these conditions shall bear a warning to the effect that the adjustment shall not be made unless the instrument is entirely disconnected from the circuit."

The device usually takes the form of a screw connected to the arm which carries the spring. The screw head is accessible from the outside of the case, a slight turn being sufficient to reset the pointer.

§ (14) Calibration.—The calibration of moving-coil instruments is generally carried out by adjusting the resistance which is in series with the moving coil; other means of adjustment are the variation of the length of the control springs and the more modern practice of using a small piece of iron fixed to one of the magnet poles, which can be moved so as to shunt a portion of the magnetic circuit.

§ (15) Accuracy Characteristics.—Moving-coil instruments are capable of adjustment to a high degree of accuracy. In the highest grades of precision instrument the error is frequently not greater than $\pm 0{\cdot}1$-scale division (150-line scale), while with the more robust switchboard pattern the error with a new instrument does not generally exceed ± 1 per cent of the full-scale reading. The British Engineering Standards Association Specification No. 49, which was drafted by a Committee comprising makers, users, and testing authorities, requires for sub-standard (precision) instruments that the maximum error from full-scale value to the lower limit of the effective range expressed as *a percentage of the maximum scale value* shall not exceed for

	+ or −.
Voltmeters	0·2 per cent
Ammeters (self-contained with shunt permanently connected)	0·5 „
Ammeter indicators (for connection to separate shunts)	0·3 „

The possible sources of error in these high-grade instruments are probably—

(1) Error in calibration;
(2) Inaccuracy of scale drawing;

and, in general, the limits set out meet the case very well, although it is unusual in practice to find a new high-grade ammeter with an error as large as 0·5 per cent of the maximum scale value. For the first grade and second grade (switchboard or portable) instruments a different basis of permissible error is required, since a wider limit can reasonably be allowed for errors of calibration. If, however, for this case the errors over all parts of the scale were expressed as a percentage of the full-scale reading, it would result in limits far too wide for the lower readings on the scale, since with an ammeter having a permissible limit of error of ± 2 per cent the permissible error at half-load would be 4 per cent, and at quarter-load 8 per cent. Therefore, for these instruments the limit of error for the lower half of the scale is only one-half of that allowed for the upper portion, the exact specification being as follows:

Limits of Error in Ammeters and Voltmeters.

Instrument.	From Full-scale Value to Middle Point, expressed as a percentage of the Indication.		From the Middle Point to the Lower Limit of the Effective Range, expressed as a percentage of half the Maximum scale Value.	
	First Grade.	Second Grade.	First Grade.	Second Grade.
	+ or −	+ or −	+ or −	+ or −
Voltmeter, self-contained	1·0	2·0	1·0	2·0
Ammeter, self-contained	2·0	4·0	2·0	4·0
Ammeter, indicator of, permanent magnet, moving-coil type	1·0	2·0	1·0	2·0
Ammeter, indicator of, other types	2·0	4·0	2·0	4·0

In an appendix the Specification indicates the use and class of accuracy for various types of instrument,

and although this table deals with instruments other than those dealt with in this article, it is convenient to reproduce it here to provide comparison of various types.

The following table serves to indicate the class of accuracy which may reasonably be expected with indicating ammeters and voltmeters of different types:

Type.	Class of Accuracy of which capable.	Conditions.
Permanent magnet, moving coil, single range	Sub-standard first grade or second grade	On direct current.
Permanent magnet, moving coil, portable, multi-range, self-contained	First grade, or second grade	On direct current.
Moving-iron . .	First grade or second grade	On alternating current at or about a given frequency.
Moving-iron . .	Second grade	On direct current.
Dynamometer . .	Sub-standard first grade or second grade	On direct current or alternating current at ordinary frequency.
Hot-wire . . .	Second grade	On direct current or alternating current at ordinary frequency.
Induction . . .	Second grade	On alternating current at a given frequency and temperature.
Electrostatic—		
Low tension .	First grade	On direct or alternating current at ordinary frequency.
High tension. .	Second grade	On direct or alternating current at ordinary frequency.

§ (16) TEMPERATURE COEFFICIENT. (i.) *Voltmeters.*—The temperature coefficient of a moving-coil voltmeter is usually so small that it can be neglected for instruments of a moderately high range, say above 30 volts. The actual effects produced by a change of temperature of 1° C., according to Brooks,[1] are—

(*a*) The strength of the spring is reduced by 0·04 per cent.

(*b*) The magnetic flux density in the air-gap is reduced by about 0·02 per cent (this figure represents the average of six instruments of three makes, the individual values ranging from 0·01 per cent to 0·03 per cent).

(*c*) The increase of resistance of the moving coil of 0·4 per cent for 1° C.

To these may be added—

(*d*) The temperature coefficient of the series resistance.

Thus, the effect of temperature on the spring and the magnets produces effects which tend to correct each other, while change in the resistance of the coil, which in itself is only a small portion of the total circuit, can be balanced by the change in the series resistance, which is generally constructed of copper-nickel alloy having a temperature coefficient of about $-0·02$ per cent. Thus, although the limits of variation allowed in the British Engineering Standards Association Specification are 0·1 per cent for a change of 1° C. for sub-standard voltmeters and 0·2 per cent for first grade instruments, the actual variations found in practice for moving-coil voltmeters are very much lower. In a well designed and constructed voltmeter of the sub-standard (precision) type it is difficult to detect any change in the reading for a change of temperature of 20° C., and for first grade or (switchboard) type instruments Fitch and Huber (*loc. cit.*) give values for American instruments ranging from $-0·01$ per cent to $+0·02$ per cent, values which confirm results obtained with a large number of British instruments.

(ii.) *Ammeters.*—In the case of the millivoltmeters used with shunts as ammeters, the temperature coefficient is generally large, and various ingenious devices have been used to eliminate it. The pressure drop required for full-scale deflection—that is, across a circuit comprising the coil and spring only—is of the order of 0·03 volt. A series resistance of material having a small temperature coefficient is used to bring the pressure drop up to the standard values of 0·075 volt or 0·15 volt. So for a switchboard-type instrument the actual change of resistance of the circuit for a variation of 1° C. would be

$$\frac{0·03 \times 0·4}{0·075} = 0·17 \text{ per cent,}$$

while in the case of a sub-standard instrument, using the high-pressure drop, the value would be of the order of 0·08 per cent. These values may be taken as being a fair average of the results of examination of a large number of British-made instruments, which are not provided with additional means for compensation, although with the larger types of switchboard instrument, where larger forces are required to actuate the movement, the temperature coefficient may be as high as 0·3 per cent for 1° C. Fitch and Huber give five values, ranging from 0·08 per cent to 0·32 per cent, for American-made ammeters, and the British Engineering Standards Association

[1] *Trans. I.E.E.* xxxix. 495.

Specification allows variations of 0·1 per cent for 1° C. for sub-standard ammeters, 0·2 per cent for first grade and 0·4 per cent for second grade instruments.

(iii.) *Methods of Compensating for Temperature Coefficient.*—The methods in common use for compensating for changes due to temperature are—

(*a*) The patent springs used by the Edison & Swan Electric Co., the strength of which decreases with increase of temperature to an extent sufficient, or nearly so, to compensate for the change of resistance of the coil.

These have been used almost entirely on switchboard-pattern ammeters, and while they are apparently satisfactory for that purpose, there is no definite information as to their suitability for the higher degree of accuracy required for sub-standard instruments.

(*b*) The method of shunting the magnet with a piece of Guillaume steel, a material the permeability of which has a large magnetic temperature coefficient, was used in some French instruments about 1902. Edgcumbe (*loc. cit.*) states that "the change of permeability with temperature is not large, so that, without shunting the working flux to an excessive amount, sufficient compensation cannot well be obtained." Tests of an actual instrument, however, over a temperature range of from 10° C. to 30° C. showed that the degree of compensation was extremely good, and the same device has been used on ampere-hour meters with very satisfactory results.

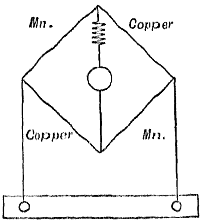

FIG. 6.

(*c*) Campbell [1] perfected a device which allowed of complete compensation for temperature errors in ammeters. The method consists of the arrangement as shown in *Fig.* 6, the millivoltmeter being connected to one pair of opposite corners of a Wheatstone bridge network and the shunt to the other corners. For practical temperature compensation it is usually convenient to make the opposite bridge arms of equal resistance, one pair having a high temperature coefficient and the other negligible. If the total resistance of the millivoltmeter and its series resistance is a, that of the two copper arms na, and if the resistance of these arms is b times that of the manganin arms, then for complete compensation

$$\frac{b^2-1}{b}=\frac{2n(1+a)}{a}.$$

Campbell gives the following practical example: "Let the resistance be in proportion to the numbers shown on *Fig.* 7, those marked 1 being of manganin and the other three of copper, then

$$a=b=3,$$
$$n=1,$$

and it will be seen that these values satisfy the equation for the condition of complete compensation."

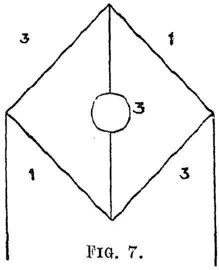

FIG. 7.

(*d*) Another method consists, as will be seen from *Fig.* 8, in shunting the moving coil M, and a portion a of the series resistance $R(=a+b)$ which has zero temperature coefficient by another copper resistance S.

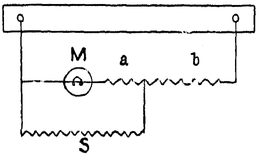

FIG. 8.

The following method of arriving at the conditions for exact compensation is due to R. S. Spillsbury.

Let $r=M+a$,

then the total resistance of instrument and shunt S is

$$\frac{bS+bM+ba+Sr}{S+M+a},$$

and the current through the instrument is proportional to

$$\frac{S}{bS+(a+M)(b+S)}.$$

The differentiation of this with regard to temperature gives

$$\frac{(dS/dT)\{bS+(a+M)(b+S)\}-S\{b(dS/dT)+(a+M)(dS/dT)+(b+S)(dM/dT)\}}{\{bS+(a+M)(b+S)\}^2}.$$

For the temperature coefficient of the instrument to be zero the numerator must vanish. That is, since $dM/dT=M/S(dS/dT)$,

$$ab-MS=0.$$

Thus, if $a=1:b=2$ and $M=1$, the equation is satisfied and exact compensation secured if $S=2$, and even for values of S considerably different from 2 a very close degree of compensation is still obtained.

It should, however, be noted that both of these resistance methods of compensation require that the resistances should be at

[1] *Journal I.E.E.* xxxv. 197.

exactly the same temperature as the moving coil, and therefore should be inside the instrument and as near to the moving coil as possible. If this requirement is not observed, differences of temperature between the compensating resistances and the moving coil may result in errors larger than if the ammeter were not provided with compensation. Further, the types of compensator described are not suitable for use with instruments which are used both for current and pressure measurements, unless provided with special switches, as with the Elliott instrument, for cutting out the compensator when the instrument is used as a voltmeter. Otherwise, the compensator would introduce an error due to temperature when the instrument was used as a voltmeter.

§ (17) LONG-SCALE INSTRUMENTS.—In the instruments previously described the pointer moves over an angle of approximately 90°, but in two cases, by a special arrangement of magnet poles, a scale extending over about 300° has been used. Davis [1] described a special arrangement of magnet poles and coil, designed to give a very long scale, the actual deflection of the pointer being over an arc of from 210° to 270°. The magnet poles were arranged (see *Fig.* 9) to give a long and uniform air-gap, and the rectangular coil, pivoted on one side, was placed with one limb through the centre of the core and the other moving through the air-gap, as shown in *Fig.* 10. Very few of these instruments were made, but later

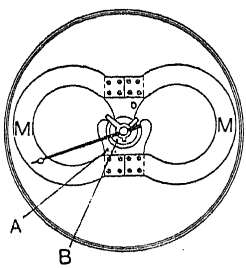

FIG. 9.

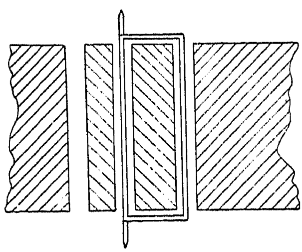

FIG. 10.

Record introduced an improved form. The magnet system and the coil of this instrument is shown in *Fig.* 11, from which it will be seen that extension plates are fitted to both poles of the magnet; the plate from one pole is placed between the two plates fixed to the other pole; the spaces between the inner and outer plates forming the air-gap in which the coil moves. It is claimed for this arrangement that since the two air-gaps are in parallel and not in series, as is the case with the ordinary instrument, more effective use is

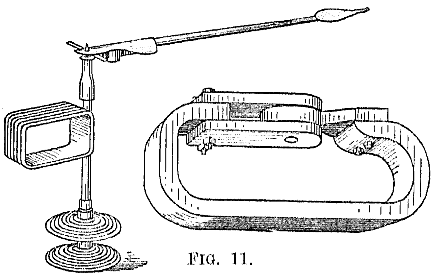

FIG. 11.

made of the magnet. One link of the moving coil passes through the centre of the cores and the other rotates through the air-gap shown in *Fig.* 12.

As the coil embraces a flat plate, the length of the vertical limbs is small, and, in conse-

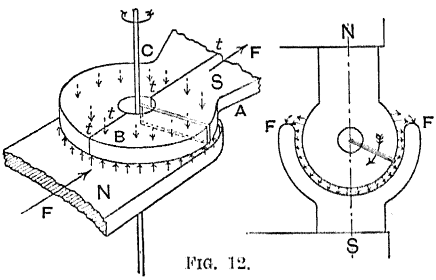

FIG. 12.

quence, the magnetically idle portion of the coil is reduced to a minimum.

The data furnished for an ammeter of this type is as follows:

Weight of movement . . .	2·85 grammes
Torque for deflection of 270° .	0·5 gramme-cm.
B in air-gap, estimated . .	1600
Maximum error due to external magnetic field of 10 gausses .	0·35 per cent

Actual tests gave the following results:

Resistance of instrument and connecting leads . . .	1·42 ohms
Moving coil only . . .	0·39 ohm
Pressure drop for full-scale deflection.	0·075 volt
Temperature coefficient . .	0·25 per cent for 1° C.
Time for pointer to settle to a given reading	2·5 seconds.

The instrument was maintained at full-scale deflection for 18 hours, when it was found that the change of reading was only 0·1 per cent of the full-scale reading.

[1] *Proc. Physical Society*, 1897, p. 425.

The ratio Torque/Weight based on the figures given above has nearly the value 0·17 mentioned by Janus.

§ (18) Other Requirements.—The British Engineering Standards Association Specification specifies a number of other requirements for moving-coil instruments.

(i.) *Insulation.*—" The insulation resistance between all the electrical circuits of an instrument coupled together and the containing-case, or other metal not intended to be insulated from the case when the instrument is in use, shall be not less than 5 megohms."

Where suitable insulating materials are used, there is no difficulty in complying with these requirements.

(ii.) *Polarity.*—Practice, as regards polarity of terminals, has varied considerably, in most instruments the left-hand, or, in the case of terminals fixed one above the other, the bottom terminal has been the positive (*i.e.* connected to the positive pole of a battery or supply pressure), but in many cases the reverse has been the practice. The specification now requires that the left-hand or the bottom terminal, as seen from the front of the instrument, shall be the positive terminal.

§ (19) Variations due to External Magnetic Fields.—Although moving-coil instruments, owing to the large magnetic flux, are affected less than most types of instrument by external magnetic fields, large variations are produced unless due precaution is taken. With an unshielded instrument of the precision-type variations of $\pm 0{\cdot}1$ per cent can be obtained, due to the effect of the earth's field. The effect of an external field, however, only affects the reading of the instrument to an appreciable extent when the direction of the external field is approximately parallel to that of the magnetic flux in the instrument. Precision instruments which are unshielded, therefore, are generally used with the axis of the magnet pointing north and south.

In practice, the effect of the external field due to the current in neighbouring conductors and of placing instruments in close proximity is much greater than that due to the earth's field. Thus, if the instrument is placed at a distance of 1 foot from a straight conductor carrying 1000 amperes, the resultant field would be of the order of 10 gausses as compared with the 0·2 gauss of the earth. The great majority of instruments are therefore fitted with a magnetic shield, this being in most cases formed by making the case of soft iron, and in a few by retaining the non-magnetic case and fitting a shield of soft iron. Even with this protection, however, the effect is not entirely eliminated. In the case of precision instruments used to measure large currents it is usual to provide leads sufficiently long to enable the instrument to be placed at a safe distance, which can always be determined by disconnecting the instrument from the shunt and passing a small current through it from a battery. The effect of the stray field due to the main current circuit is then ascertained by noting the reading of the instrument when turned through a right angle or by switching the main current on and off. For switchboard instruments, however, where these may have to be placed near conductors carrying large currents, it is usual to provide heavy iron cases. The British Engineering Standards Specification provides that

" The variation in the maximum indication of an ammeter or voltmeter indicator, which is intended to be permanently fixed in any position, shall not exceed 3 per cent of that indication, when the indicator is exposed to a magnetic field of 10 C.G.S.[1] units in the direction which produces the maximum error in the instrument readings. For alternating-current instruments the disturbing field shall be alternating and in phase with that in the coil of the indicator.

" Portable First Grade instruments, not purporting to comply with the above requirements, and all Sub-Standard instruments shall bear a statement of the precautions necessary to eliminate or avoid any error due to external fields."

Fitch and Huber[2] obtained values of from 1 per cent to 3 per cent for voltmeters, and from 1 per cent to 4 per cent for ammeters; and Farmer,[3] for the same external field, finds values of from 0·75 per cent to 1·75 per cent for shielded instruments, and 3·5 per cent to 5·5 per cent for unshielded.

§ (20) Shunts. (i.) *Construction.* — The shunts used with moving-coil millivoltmeters are usually made of strips of copper-nickel alloy soldered into brass or sometimes copper lugs. Wires are sometimes used,[4] particularly by German makers, but this form of construction is apparently too expensive, although it possesses many advantages. Tubes also have been used which, when erected in a vertical position, tend to increase the cooling. The thickness of the sheets varies somewhat with different makers, but in a large shunt with many sheets it will be of the order of 1 millimetre. Up to, say, 500 amperes there is little difficulty in making a satisfactory shunt, but the measurement of larger currents presents difficulties (which are not always satisfactorily overcome) in the design of the ends. The effect of stream-line distortion is largely dealt with in the article " The Potentiometer System of Measurement." The points which affect the design of standard resistances apply also to shunts. In the latter, however,

[1] 800 ampere turns will produce a field of approximately 10 C.G.S. units at or near the centre of a plane circular coil 100 cm. diameter.

[2] *Bul. Bureau Standards*, vii. No. 3, 420.

[3] *Book Electrical Measurements in Practice*, p. 54.

[4] See article on " The Potentiometer System of Measurement."

the required accuracy is not so high, but differences sufficiently large to affect the accuracy of a switchboard ammeter can be obtained by slight variation of the method of connecting the main current leads. In the case where a heavy current shunt is

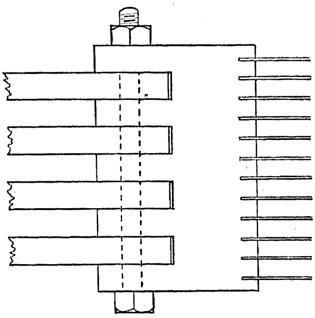

FIG. 13.

designed expressly to fit a certain type of laminated bus-bar, as in *Fig.* 13, it is probable that, if the correct method of connection is strictly observed, there will be no appreciable error due to distortion of stream-lines, but in other cases, and particularly where the lug is in the form of a wide flat plate to which connection may be made on either or both sides, errors of as much as 2 per cent have been found, due to the manner of connecting. The reason for this difference is usually due to the fact that the lugs are not sufficiently long to enable the stream-lines of the current to become uniform. In the case of portable instruments, where weight is a consideration, the case can be met by suitable slotting of the lugs. In the case of large shunts, however, which are intended for permanent connection in bus-bars, it is not easy to understand the reason for the irregularity. Shortening the length of the shunt lugs will reduce the cost of the shunt, but since this has to be made up by an equivalent length of bus-bar, the saving in this respect is not altogether valid.

(ii.) *Shunts for Large Currents.*—The design of shunts for large currents, say for 5000 or 10,000 amperes, presents special difficulties. In the more usual type, as shown in *Fig.* 13, in addition to the shape and size of the ends, it is difficult to ensure that each and every strip is properly soldered into the lug. Field [1] described a multiple-unit shunt which appears to be particularly suitable for measurements of heavy currents. The shunt is built up of a number of units, each bolted to a bus-bar, as shown in *Fig.* 14. Any effect of the resistance of the bolted joints is very largely corrected for by the equalising leads shown in the figure, the resistance of which must be in the same proportion as that of the individual units of the shunt. Field shows that with this arrangement the distribution of current in the individual shunt units may be widely different without appreciable effect on the instrument reading, and gives the result of some tests made by Moore, where four shunts, each for 150 amperes and of a resistance 0·000505 ohm, were connected in parallel to bus-bars.

Each potential terminal was connected to a star-point by a 10-ohm equaliser, and as will be seen

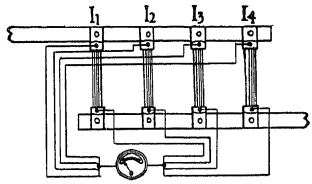

FIG. 14.

from the table below, even when one or more of the shunts is entirely disconnected from the bus-bar, the instrument reading is only slightly affected. In practice the shunts would be bolted tight to the bus-bars, and if this is carried out, as in *Fig.* 14, the current distribution will be approximately equal. Similar results were obtained with equalising leads of much lower resistance, more nearly 0·1 ohm.

Total Current.	P.D. on Shunts, Millivolts.				Mean Shunt P.D.	P.D. between Star-points.	Current calculated from Star-point P.D.
	(1.)	(2.)	(3.)	(4.)			
Amps.							Amps.
A 502·5	64·87	65·67	61·25	61·78	63·39	63·4	502
B 502·5	81·2	80·9	86·1	5·7	63·47	63·4	502
C 502·5	10·8	94·8	86·4	63·5	63·9	63·4	502
D 502·5	79·3	0·0	87·87	86·8	63·51	63·4	502
E 502·5	79·1	0·0	87·75	86·8	63·41	63·4	502

A. All the shunts were clamped tightly on to the copper bus-bars.
B. Shunt No. 4 was just laid on the bars.
C. All the shunts were just laid on the bars.
D. Shunt No. 2 was isolated from one bar and tight on the other.
E. Shunt No. 2 was isolated from both bars.

Another arrangement designed to meet the case of multiple bus-bars is shown in *Fig.* 15.

(iii.) *Testing Sets.*—For testing sets and for

[1] *Journal I.E.E.* lviii. 660.

instruments for laboratory use a number of volt ranges are obtained by means of a series resistance divided at points appropriate to the range required and controlled by a switch. For various current ranges an instrument is usually provided with a number of separate

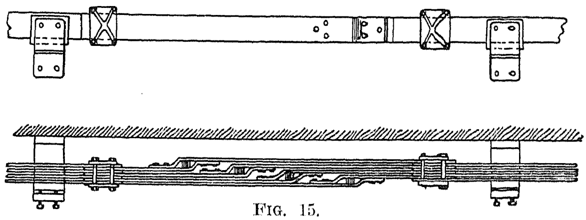

FIG. 15.

shunts which are connected according to the range required. A much more convenient method, however, is that based on the Ayrton-Mather Universal Shunt, in which the millivoltmeter is connected directly across the ends of a shunt and the current led in at the desired point by means of a switch. See *Fig.* 16.

With a small shunt-box of this type eight ranges from 0·15 ampere to 30 amperes are provided. Change from one range to another is effected by movement of the switch, and it will be noted that the contact resistance of the switch does not affect the accuracy of the reading.

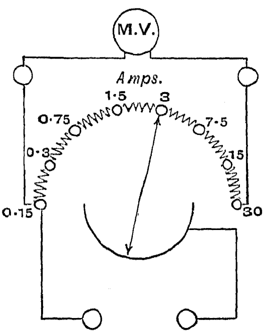

FIG. 16.

In designing a shunt of this kind it is necessary first to determine the total resistance R required for the lowest range I; the value of the intermediate ranges R_1, etc., will then be in the inverse proportion to the current I, *i.e.*

$$\frac{R_1}{R}=\frac{I}{I_1}.$$

Thus, taking a millivoltmeter requiring a pressure drop of 0·1 volt and having a resistance of 10 ohms, the value of R for a range of 0·1 ampere will be 1·01 ohm. For a range of 10 amperes the resistance will be 1·01/10, and so on for the other ranges.

(iv.) *Heating of Shunts.*—The heating of a shunt made up of a number of thin sheets is most irregular, the hottest portion being at the top edge of the central strips. The middle of the shunt will be hotter than the ends, where considerable cooling will take place by conduction along the connecting leads. At full-load variations of temperature of the order of 25° C. are found with large shunts.

(v.) *Thermo E.M.F.*—The copper-nickel alloy generally used as a resister has a thermo E.M.F. of the order of 45 micro-volts for 1° C., and thus a difference of temperature of 17° C. between the two ends will affect the pressure drop across a shunt by 1 per cent. Much larger differences of temperature than this are found in practice, actual measurements showing a difference of temperature between the ends of approximately 30° C., due to Peltier effect only. This may be still greater if the shunt is erected in a vertical position—that is, with one lug above the other—the lower end being connected to the negative of the supply. In this case the increase of temperature at the positive pole of the shunt will be accentuated by the convection currents; thus it is unsafe to connect a shunt in a vertical position unless the positive pole is at the bottom.

The usual method adopted by instrument makers to eliminate thermo E.M.F. is to include in the circuit of the connecting leads strips of the same alloy as the shunt metal. One end of these strips is connected to the potential screws on the shunt, and if of sufficient length to ensure that the other ends are at nearly the same temperature, provide quite satisfactory compensation.

An extension of this method is that generally specified by the Admiralty, in which small lugs of the same material as the shunt are soldered into the end blocks, as shown in *Fig.* 17, the connecting wires being soldered to the curled ends of the strips.

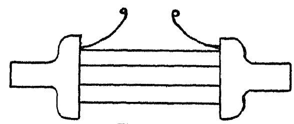

FIG. 17.

The British Engineering Standards Association requirements for shunts are as follows:

"No part of a shunt shall rise in temperature more than 80° C. above the temperature of the surrounding air after carrying the current corresponding to the maximum scale value of the indicator for two hours.

"The main terminals of the shunt shall be so constructed that slight variations in the method of connecting it to the circuit shall not alter the indication of the instrument by more than 0·25 per cent.

"The construction of the shunt and connecting leads shall be such that no thermo-electric force is produced sufficient to alter the indication of the instrument by more than 0·25 per cent."

An appendix gives the following recommendations:

"*Erecting Shunts.*—A shunt dissipates the heat generated when current is passing more by conduction than by radiation. It is therefore necessary to ensure that the ends of the shunts, and any bars to

which the shunts are connected, are of such section and area as to permit of good contact being made, and thus to prevent any rise in temperature due to insufficient section or bad contact.

"When a shunt is built up of a number of sheets, the maximum cooling is obtained when it is erected in a horizontal plane with the sheets in a vertical plane, so as to permit the maximum amount of ventilation between the sheets.

"If by reason of the design of the switchboard it is necessary to erect the shunt with its terminals one above the other, the lower end of the shunt should be connected to the positive pole.

"When the shunt ends consist of flat connecting plates machined either on one or both surfaces, it is essential to ensure that the whole of the surfaces are in contact with the bars to which connection is to be made in order that the lines of flow of current shall not be unduly distorted."

§ (21) Recording (Graphic or Chart) Instruments. — The instruments used for obtaining a graphic record of volts or amperes on a direct-current supply are almost invariably of the moving-coil type, but owing to the comparatively large amount of power required to move a pen over a moving chart with which it is in contact the energy losses are larger and the accuracy lower than in the case of indicating instruments. An ammeter of this type requires a pressure drop of the order of 0·2 volt to operate the pen; such a pressure drop allows of little, if any, swamping resistance, and in consequence the temperature coefficient will be about 0·4 per cent for 1° C. For a recording voltmeter the resistance will be of the order of 20 ohms per volt. An additional source of error is that due to variation of the amount of ink in the pen: this affects the balance of the moving system and may modify the reading considerably.

The Specification No. 90 of the British Engineering Standards Association has the following clauses, which apply particularly to moving-coil recording instruments.

Case or other Protection.—"The recorder shall be contained in a suitable case, of sufficient strength to afford adequate protection against injury when reasonably used, and to exclude dust from the working parts; the accessory apparatus shall be suitably protected when necessary to ensure permanence of the accuracy of the indications. The design shall be such, that complete safety to the operator is ensured when the case is open for the purpose of changing the chart or filling the pen."

Clock or Driving Mechanism.—"Suitable means, easily accessible, shall be provided whereby the timing of the clock or other driving mechanism can be regulated so as not to have an error exceeding 5 minutes in 24 hours."

Chart Ruling.—"The scales on charts employed in conjunction with recording ammeters, voltmeters, and wattmeters shall be divided into 40, 50, 60, or 75 divisions.

"The value of each scale division shall be either 1, 2, or 5 of the units measured, or any decimal multiple or sub-multiple of these.

"A piece of the chart shall be permanently attached to the instrument in such a position as to permit of a ready comparison between the ruling on it and the ruling on a new roll of paper."

Pointer and Pen.—"The pointer and pen shall be insulated from the electrical circuit of the recorder."

Pen to Paper Friction.—"Suitable means shall be provided, when necessary, whereby the pressure of the pen on the paper may be adjusted to prevent variations of pen to paper friction from introducing inaccuracy beyond the limits laid down."

Damping.—"The moving system of a recording instrument shall be provided with means for damping its movement suitably for the conditions in which the instrument is used. Such means shall be independent of the friction between the pen and the paper."

External Shunts.—"The drop in pressure across the terminals of a shunt to which a permanent magnet moving-coil recorder is connected shall not exceed 0·2 volt with the maximum indication on the recorder."

Limits of Error.—"The error in the reading of a recorder, when tested over the effective range at the standard temperature, or at the temperature marked on it, and at ordinary frequency, or at the frequency marked on it, and, with the exception of a wattmeter, when placed in any position in a magnetic field not greatly exceeding that of the earth, and with the pen approximately half full of ink, shall not exceed the limits given in the following table. In the case of voltmeters and wattmeters the pressure shall have been applied for 30 minutes before the test is made."

Description.	Limits of Error expressed as a percentage of the Maximum-scale value.
	+ or −
Voltmeter with free zero	2·5
Voltmeter with partially suppressed zero . .	1·5
Ammeter . . .	3·0
Wattmeter . . .	3·5

Variations in the Indications due to Changes in the Amount of Ink.

"The variation in the indication of a recorder caused by varying the quantity of ink from pen full to pen empty shall not exceed ±3 per cent of the maximum-scale value."

In most of the recorders in general use the pen moves across the paper in the arc of a circle and the paper is ruled accordingly. An exception to this, however, is the "Murday" instrument made by Messrs. Evershed & Vignoles, in which case the pen is pivoted and moves in a straight line across the paper.

Where a record is required to a high degree of accuracy, the "Thread" recorder, described in the article[1] on "Thermocouples," is used. This consists of a suspended galvanometer, the pointer of which swings freely over the paper. A blackened thread is interposed between the

[1] See "Thermocouples," § (16), Vol. I.

pointer and the paper, and a mechanism operated by clockwork forces the pointer down at regular intervals on to the thread, which makes a dot on the paper corresponding to the position of the pointer. In this way the pen-to-paper friction is totally eliminated. An instrument of this kind is sufficiently sensitive to allow of its use in conjunction with a potentiometer with the consequent increase in accuracy. S. W. M.

Direct Current Machines, advantages of. See "Dynamo Electric Machinery," § (11).
Design of. See *ibid.* § (4).

Directional Wireless: the determination of the direction from which signals come in wireless telegraphy. See "Wireless Telegraphy Transmitting and Receiving Apparatus," § (11).

Disc Discharge, The: an arrangement for producing sparks of a definite audible frequency, for transmission in wireless telegraphy. See "Wireless Telegraphy Transmitting and Receiving Apparatus," § (2).

Discharge through Gases, general theory of. See "Electrons and Discharge Tube," § (7).

Displacement Moment: the torque (per unit current) tending to displace the moving system of a galvanometer. See "Vibration Galvanometers," § (21).

Distortion in Telephone Transmitters,
Electrical: incorrect translation of sounds by a transmitter, due to electrical causes. See "Telephony," § (15).
Mechanical: incorrect translation of sounds by a transmitter, due to mechanical causes. See *ibid.* § (15).

Distribution Networks for Electric Power. See "Switchgear," § (40).

Distributor, High-tension: the component of a magneto, which transmits the sparking voltage from the secondary winding to each spark gap in turn. See "Magneto, The High-tension," § (11) (v.).

Dolezalek Alternator, for audio-frequency work. See "Inductance, The Measurement of," § (6).

Double Current Working. In telegraphy, a system in which signals are transmitted by the reversal of a current. See "Telegraph, The Electric," § (7).

Double-plate Sounder: a telegraphic receiver which emits a characteristic sound for each unit of the code employed. See "Telegraph, The Electric," § (6).

Doublet, The Hertzian: two equal stationary charges of opposite sign, varying in magnitude harmonically with time. Radiation of energy by. See "Wireless Telegraphy," § (4).

Fundamental Principles of. See *ibid.* § (3).

DYNAMO ELECTRIC MACHINERY

§ (1) Electromagnetic Transformations of Energy.—The purpose of dynamo machinery is to convert mechanical energy into electrical energy, or *vice versa*, the machines used, in the first case, being known as "generators," and, in the second case, as "motors."

The transformation of energy can be effected in two ways, the first, and one which has very little practical application, being by electrostatic action, while the second, and much

more general method, is by electromagnetic forces, or forces which depend on the interaction of electricity and magnetism. A conductor carrying a current in a magnetic field has a force [1] acting on it when at rest, while if moved across the lines of magnetic force it has an E.M.F. set up in it, and this occurs even if there is initially no current in the conductor. These both depend on the strength of the field, which is measured by the number of lines of induction traversing a unit area placed at right angles to their direction, and on the rate of motion of the conductor. The electrostatic effect referred to is employed in such a machine as the Wimshurst influence machine, but the power available is so small that the electromagnetic effect has been adopted to form the basis of all dynamo machines for practical purposes.

As an example of what can be achieved by this electromagnetic action, with copper, iron, and some insulating material such as cotton, a copper rod of about the same diameter and length as a lead pencil, carrying as much current as it can without getting too hot, when in a position at right angles to the lines of induction of a magnetic field, such as can be obtained by the use of iron, will experience a force of from $1\frac{1}{2}$ to 2 lbs., in a direction at right angles both to its own length and to the direction of the field. A motor armature, say, 7 in. long and 7 in. in diameter could carry about sixty such conductors, each insulated with cotton and connected in proper sequence round its periphery. Such an armature, if run at a speed of about 1500 r.p.m., would be capable of exerting from 7 to 8 horse-power.

Electromagnetic action takes place in accordance with laws first discovered by Faraday, and which may be stated thus : [2]

I. A conductor carrying unit current placed in a magnetic field of unit induction or unit flux density (one line per square centimetre), in a direction at right angles to that of the field, experiences a force of 1 dyne per centimetre of its length, in a direction at right angles both to the conductor and to the field.

II. A conductor moving with a velocity of 1 cm. per second, at right angles to the lines of force of a magnetic field of unit induction or unit flux (one line per square centimetre), has, induced in it, unit electromotive force per centimetre of its length.

In order to calculate either the force on the conductor, in the first case, or the electromotive force, in the second case, it is necessary to know the strength of the magnetic field, which is given by the number of lines of induction per square centimetre. This strength of the magnetic field is defined as its magnetic induction or flux density, and since, in most cases, the field is obtained with iron which is magnetised by the action of a current of electricity, it is necessary to determine the relation between the magnetic flux and the magnetising force produced by this current.

If, as is usual, the current is flowing in a wire which is bent into the form of a solenoid, round a mass of soft iron, the magnetising force (H) in C.G.S. units is given by the expression

$$H = 4\pi n i,$$

where i is the current and n is the number of turns of wire per unit length of the solenoid.

In this formula the current is measured in absolute units, which are ten times the value of the practical unit of current, the ampere. Thus, if I be the current in amperes,

$$H = \frac{4\pi}{10} \cdot nI,$$

where the product nI is the number of ampere turns per unit length of the solenoid, and the magnetising force is given in C.G.S. units.

The relation between (B) the magnetic flux density and (H) the magnetising force in C.G.S.

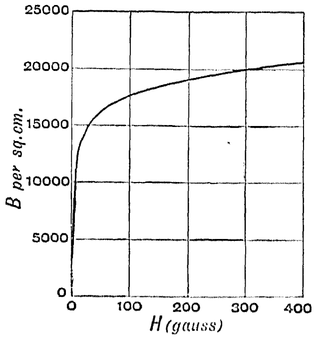

FIG. 1.

units is expressed in the form of a curve which is determined for the material in question by direct experiment [3] (see *Fig.* 1).

The ratio of B to H is defined as the magnetic permeability and is generally denoted by the symbol μ ; its value clearly depends on H.

The two laws previously given may be stated in somewhat different form, which, although easily recognised as equivalent, for certain purposes is more convenient, thus :

(I.*a*) A closed circuit carrying a current, when placed in a field of magnetic flux, is acted on by a force which tends to set the circuit in such a position as to link with itself the maximum amount of flux.

The force in a given direction, measured in dynes, is equal to the product of the current and the increase of the amount of interlinked

[1] See "Electromagnetic Theory," § (9).
[2] See *ibid.* § (12).

[3] For the method of doing this see "Magnetic Measurements," § (18) and following.

flux which would result from a unit displacement of the circuit in the direction specified. In the case of angular displacement the resultant action will be a couple.

(II.a) If there is any variation in the magnetic flux which is linked with a closed circuit, an E.M.F. is induced round the circuit which is equal to the rate of decrease of the interlinked flux.

It should be noted that, provided that the magnetic flux density is measured in absolute units (number of lines of induction per square centimetre), the electromotive force is also given in absolute units. In practice the E.M.F. is measured in volts; and 1 volt $= 10^8$ absolute C.G.S. units.

According to Law I. the mechanical force on a conductor is at right angles to the flux and to the current; the positive directions of the three are related as shown in *Fig.* 2, in which Oz drawn upwards represents the direction of the flux, and Oy horizontal and towards the observer represents the direction of the force. Ox drawn horizontal and towards the right represents the direction of the current. If the current or the on flux be reversed, the direction of the mechanical force is also reversed.

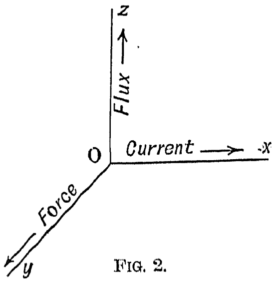

Fig. 2.

§ (2) The Magnetic Field due to a Conductor.—The following method of illustrating the action referred to is also useful.

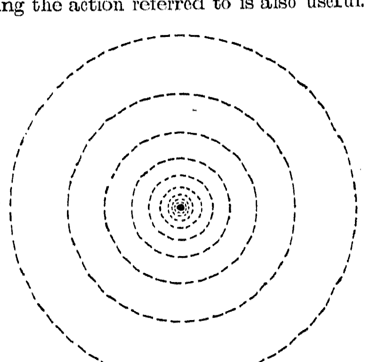

Fig. 3.

In a straight conductor, in air and carrying current, lines of force will surround the conductor symmetrically in the form of concentric circles, as shown in *Fig.* 3.

If another conductor is arranged close to and parallel to the first conductor (*Fig.* 4), and current is also passed through this second conductor, then, if the currents in the two are in the same direction, there will be a differential action in the intervening space, so that the magnetic field will be weak, whereas the total

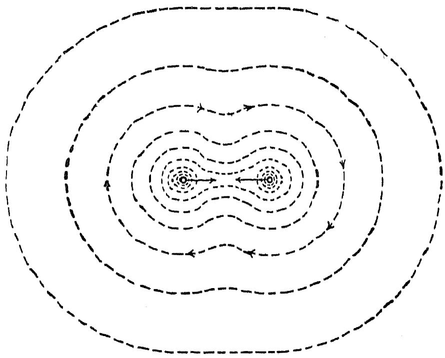

Fig. 4.

field surrounding the two conductors will be increased. If the magnetic lines are assumed to be in tension, then they will tend to draw the conductors together. Similarly, if the conductors carry currents in opposite directions (*Fig.* 5), then the field strength between them

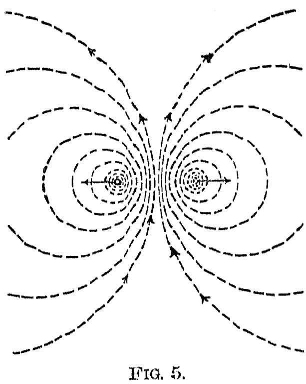

Fig. 5.

will be increased, and the total field surrounding them will be reduced, and the conductors will, therefore, tend to move away from one another. If a single conductor be placed in a magnetic field at right angles to the direction of the magnetic lines, the effect of its own field will be to cause a distortion of the main field (*Fig.* 6), increasing the number of lines on one side of the conductor, and decreasing it on the other, tending to produce motion towards the weaker part of the field. If two conductors are placed close to one another and carry equal currents in opposite

directions, then the distortion of the magnetic field produced by one will be eliminated almost completely by the distortion produced by the other, and the whole magnetic

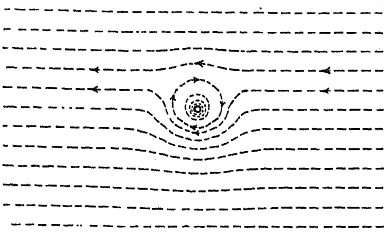

Fig. 6.

field will remain in its original position, but the conductors will tend to move, one in one direction and the second in the opposite (*Fig.* 7).

The case of a single conductor, situated in a magnetic field, experiencing a force and at the same time distorting the field, corresponds to the ordinary direct current generator or alternating current generator, and the case of two conductors, placed near one another and carrying equal and opposite currents, corresponds to the compensated direct current machine or the induction motor.

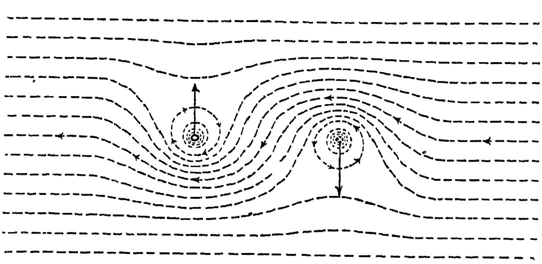

Fig. 7.

§ (3) Fundamental Principles.—A dynamo or motor consists, in its simplest form, of a conducting circuit, lying in one plane, which can rotate in a field of magnetic flux about an axis, also in the same plane, at right angles to the direction of the flux. In *Fig.* 8 the axis is represented by the line AB, and the flux is in the direction CD.

The ends of the conductor are attached to either (*a*) a split tube of copper which rotates with the coil, for a direct current machine, or (*b*) two concentric metal rings, for an alternator.[1] Conducting brushes rub on the tube or rings and convey the current to or from the circuit. In the direct current machine we may suppose the split tube to be so arranged that when the plane of the coil is at right angles to the flux the brushes pass from one half of the tube to the other. In an actual machine, for reasons which are specified later, the brushes do not occupy exactly this position.

If we imagine the conductor as in rotation, in such a manner that the upper part of the circuit is approaching the observer, an electromotive force will be produced in the direction indicated and a current will flow round the circuit. When the coil has made half a turn the direction of the flux will be reversed, and the current, therefore, will be reversed in the coil, so that the end which was positive will become negative.

Owing to the action of the split metal tube—the commutator—in the direct current machine, the connections between the brushes and the coil are reversed also, and the current continues to flow in the same direction through the external circuit; we have a direct current generator.

If two concentric rings are used instead of a commutator, the current in the external circuit reverses with that in the coil; the machine is an alternator.

Returning to the commutating machine, it will be seen that the action is reversible, and if, instead of moving the armature coil as before, an external source of current is applied, the coil will revolve so as to set itself in such a position as to embrace the maximum flux. By means of the commutator, which reverses the current in the coil at the right moment, the motion can be made continuous and a direct current motor is obtained.

To make an alternator act as a motor it is necessary that the current be made to reverse

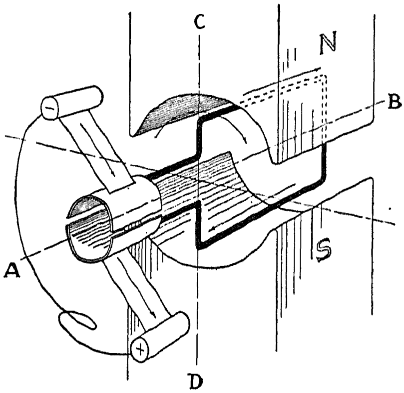

Fig. 8.

its direction at the instant when the revolving coil is at right angles to the direction of the flux. Such a motor must, usually, have means for starting, but if suitably started will run at a speed corresponding to the frequency of

[1] In some alternators the armature is fixed while the field of magnetic flux rotates.

the alternating current and exert considerable power.

The magnetic flux may be obtained by the use of permanent magnets, and under these circumstances the machine is known as a *Magneto Electric Machine* or a *Magneto.*[1] If electromagnets are used the machine is known as a *Dynamo.* The power produced by a magneto is very small in comparison to that obtainable from machines using electromagnets, and in this article it is intended only to deal with Dynamo Machinery.

The coils which carry the current required to produce the magnetic flux are called *Field Coils.* The coils in which the current is induced in a generator, or through which the external current passes in a motor, are built up into a form which is known as the *Armature.*

In most actual dynamos the armature coils like the field coils have an iron core.

§ (4) Designing a Dynamo.—We now proceed to discuss in an elementary way the

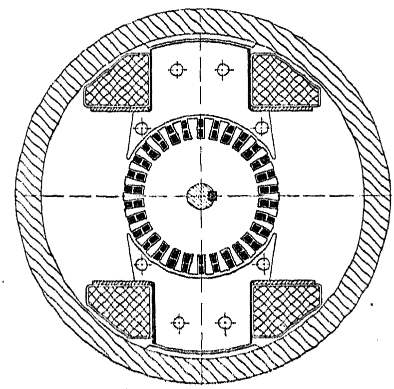

Fig. 9.

design of a small dynamo, and to show the application of some of the principles already discussed to an actual machine; by treating the matter in this way the various factors which affect the design can be most readily understood. The problem is to design a machine to convert electrical energy into mechanical energy, or mechanical into electrical; in the latter case the conditions of supply of electrical power are usually given—this may be 3-phase alternating current with a certain frequency and voltage, or direct current; there may be also some conditions as to the constancy of voltage, etc., and there are also usually conditions qualifying the mechanical power that the motor is required to give. These take the form of specifying the speed, horsepower, torque, speed variation, etc. In the example an armature of 7″ diameter is assumed to have sixty conductors arranged round the periphery, and a simple method of doing this is to arrange the conductors in 30 slots, two in each (*Fig.* 9). It is essential that the conductors should be joined together in such a manner as to form coils which embrace the armature, as shown in *Figs.* 10, 11. Each coil surrounds the armature twice and has its ends connected to adjacent sections of the commutator (*Figs.* 10 and 11). In addition it is necessary to arrange the coils in such a

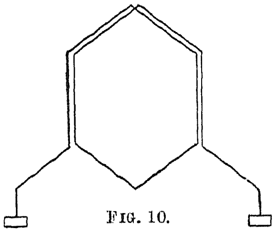

Fig. 10.

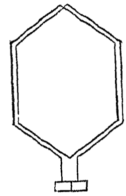

Fig. 11.

manner that they may be built up to form the armature, and for this purpose they should have uniformity of shape so that the coils may lie evenly on the armature.

(i.) *D.C. Machines.*—In a direct current machine this is secured by the arrangement

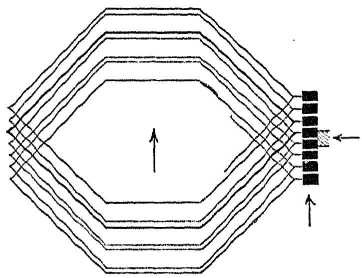

Fig. 12.

shown diagrammatically in *Figs.* 12 and 12A. In *Fig.* 12A each slot is supposed to contain only one conductor bar, and it will be seen that a bar such as 1, 1 in a slot at the top of the armature is connected at one end to the segment 1 of the commutator and at the

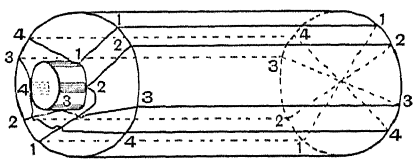

Fig. 12A.

other to the bar 1, 1 diametrically opposite to it. The left-hand end of this bar is connected to segment 2 of the commutator; thus a circuit is formed with its two ends connected to adjacent segments. Segment 2 is connected to 3 through the pair of bars 2, 2, and 2, 2 also diametrically opposite, and so on. The

[1] See article "Magneto, The High-tension."

armature coils thus form a continuous circuit of four complete turns, and from each turn tappings are taken off to two contiguous segments of the commutator. When the brushes are on segments 1 and 3 a current can pass from 1 to 3 either by the path 11111222223 or by the path 14444433333. In each case it circles the armature twice.

In the case of the machine illustrated in *Fig.* 9 in which we have 30 coils in series the connections may be also followed by means of the polar diagram (*Fig.* 13). Here it will be noticed that if the armature is rotated the coils will be connected to the commutator segments in such a manner as to give the combined electromotive force of two circuits, in parallel, each of 30 coils in series. *Fig.* 9 gives a sectional view of a machine such as that of

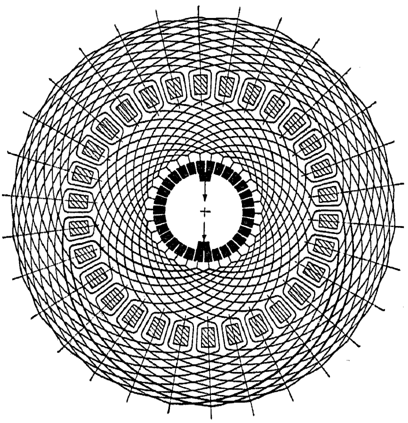

FIG. 13.

the example, designed to run at 1500 r.p.m., and is approximately to scale.

In considering this design it is first necessary to decide what amount of magnetism can be carried by the iron magnetic circuit. For the present it is assumed that such a calculation has been made, that the machine has two magnetic poles, and that it has been found that the amount of magnetism entering the armature on one side and leaving it on the other will be approximately $2{\cdot}3 \times 10^6$ lines of flux, or 2·3 megalines. This amount of flux will give a mean flux density over the surface of the armature of approximately 30,000 lines per square inch (4650 lines per square centimetre). With a rotational speed of 1500 r.p.m. the actual linear speed of the surface of the armature will be 2750 feet per minute, or 550 inches per second, or approximately 1400 centimetres per second. The average rate at which a conductor cuts the magnetic lines of force will be $30{,}000 \times 550$ — *i.e.* 16,500,000 lines per inch of conductor per second, that is to say, the average voltage in a conductor will be ·165 volt per inch, or 1·15 volts for the 7″ conductor assumed. If these conductors are joined up to form coils, and these connected in the manner specified above, there will be two paths in parallel, and each path will have 30 conductors in series, therefore the total voltage generated will be 34·5 volts.

If looked at from another aspect and it is desired to calculate the voltage which would occur due to lines of force entering and leaving a coil, we can assume that when a coil consisting of two conductors is in a plane at right angles to the axis between poles, that such a coil encloses 2·3 megalines. Half a revolution later, which will be accomplished in one 50th part of a second, the coil has turned completely round, and now has lines of force passing through it in exactly the opposite direction. The change of flux which has occurred is from $+2{\cdot}3$ megalines to $-2{\cdot}3$ megalines—that is, a total change of 4·6 megalines—and this has occurred in one 50th part of a second.

The average rate, therefore, is $4{\cdot}6 \times 50$, or 230,000,000 lines per second, which will give rise to an average voltage of 2·3 volts; and as there are 15 coils in each circuit of the armature, the total voltage will be 34·5 as previously determined.

We may write the expression just obtained $34{\cdot}5 \times 10^8 = 4 \times 2{\cdot}3 \times 10^6 \times 25 \times 15$. On the left-hand side we have the volts multiplied by 10^8; on the right $2{\cdot}3 \times 10^6$ is the change of flux per pole—the machine has two poles—25 is the frequency, and 15 the number of circuits. Thus we have

$$\text{Volts} = 4 \times \text{Flux per pole} \times \text{Frequency} \times \text{Number of circuits} \times 10^{-8}.$$

A little consideration shows that this formula is of general application.

Thus let the length of the armature be l centimetres and its radius a centimetres, let it make n revs. per second, let the flux be Φ, and the number of circuits N. The number of conductors will be 2N.

The surface of the armature through which the flux enters is πla cm.², and the average flux density is $\Phi/\pi la$. The speed of a conductor across the flux is $2\pi an$ cm./sec.

Thus the E.M.F. per cm. is $2\pi an\Phi/\pi la$ C.G.S. units, and the E.M.F. per conductor of length l is given by multiplying this by l. Hence

$$\text{Volts per conductor} = \frac{\Phi \times 2\pi anl}{\pi la} \times 10^{-8} = 2n\Phi \times 10^{-8},$$

and

$$\text{Total volts generated} = 2n\Phi \times 2\text{N} \times 10^{-8}$$
$$= 4 \times \Phi \times n \times \text{N} \times 10^{-8},$$

or

$$4 \times \text{Flux per pole} \times \text{Frequency} \times \text{Number of circuits} \times 10^{-8}.$$

(ii.) *Alternators.*—The method of calculation given above is applicable for direct current machines, as the voltage at any instant is the same as the instantaneous voltages of all the coils which are connected in series; that is to say, that if there are N coils, it will be N times the average voltage of each coil—in the present instance $15 \times 2{\cdot}3$, which is 34·5 volts. Machines,

however, are frequently made as alternating current generators or motors, and in such machines the coils, instead of being connected to a commutator which periodically reverses the direction of current, are connected to slip rings in the case of revolving armature machines, or simply brought to terminals in the case of fixed armature machines. In the present case we will assume that the machine has the armature conductors connected up so as to form a 3-phase alternating current machine. There are 60 conductors. They will be connected up in three symmetrical groups, each containing 20 conductors or ten coils, and spaced 120° apart. The form of the voltage supplied by an alternating current machine is usually designed to be very closely sinusoidal. Each conductor as it revolves and cuts the magnetic flux will have induced in it a voltage which will reproduce the shape of the magnetic field under each pole, for the reason that the armature is revolving uniformly. Thus if the curve giving the flux in terms of the time be sinusoidal, the curve connecting the voltage and the time will also be sinusoidal.

The voltage, therefore, of each conductor will have a form similar to that shown on the attached curve (*Fig.* 14). If now two conductors situated in adjacent slots are connected in series, each will have induced in it this same voltage form, but the resultant of the two voltages will be slightly different, in fact it can be obtained by adding together two such curves which have been displaced from one another by a distance corresponding to the pitch of a slot, which

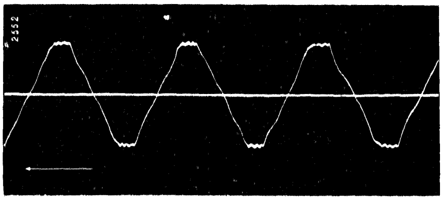

FIG. 14.

in the present instance is 12°. Similarly if three, four, or five conductors, situated in adjacent slots are connected in series, the resultant voltage of the five will be different from that of each individual one. The flux form shown on *Fig.* 14, due to a single slot, may be assumed to consist of a fundamental sine wave with superposed harmonics of various frequencies, and the process just described has the effect of cancelling the higher frequencies, leaving only the fundamental. In many machines not only are coils in adjacent slots connected in series, but these coils frequently have fractional pitch—*i.e.* they do not span the full distance from one pole to another. This fractional pitch winding tends to still further suppress any harmonics in the fundamental voltage wave, and a further refinement resorted to sometimes is the use of a number of slots not integral with the number of poles.

By all these various means the modern alternating current machine usually produces a wave of electromotive force which approximates exceedingly closely to the sine wave (*Fig.* 15). It will be noticed, therefore, in following through this description of the production of electromotive force in an alternator, the exact form of the flux distribution is not of importance as the whole process tends to eliminate any variations from a sinusoidal form, therefore machines built in this way will give a sine wave of

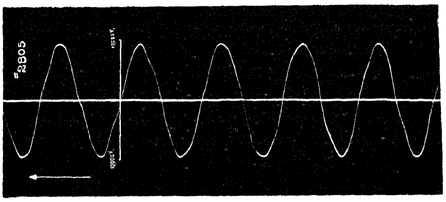

FIG. 15.

electromotive force even when the flux distribution is considerably distorted due to load.

The description given above is applicable perhaps more particularly to large turbo alternators, for in small machines with a small pole pitch, these methods cannot always be adopted, but in such cases it is usual to make the air-gap in the centre of the pole rather smaller than at the sides, and so give a flux distribution which is nearly sinusoidal, and has not many harmonics needing elimination.

If the form of the flux distribution under a pole need not have any particular shape, it will be simplest to assume that it is sinusoidal for the purposes of calculation. If, then, in the example already quoted, the flux distribution follows a sinusoidal form, the maximum value will be higher than the mean value previously assumed of 30,000 lines per sq. inch, in the ratio of $\pi/2$, for this is the ratio of the maximum to the mean value of a quantity which varies sinusoidally; hence the maximum density will be approximately 47,000 lines per sq. inch, and as the mechanical speed is the same as before, *i.e.* 550 inches per second, the maximum voltage per inch of conductor will be $47{,}000 \times 550 \times 10^{-8}$. This is equal to ·26 volt per inch, or 1·8 volts for a 7″ conductor, or 3·6 volts for a coil composed of two such conductors. This is the maximum value voltage, and as it follows a sinusoidal curve and has a frequency of 25 per second (corresponding to 1500 per minute) and two poles, this instantaneous value will be $3{\cdot}6 \sin 2\pi nt$, where n is 25. The effective value of an alternating current is measured by that of the direct current which produces the same heating effect, and this will be the square root of the mean square, or in the case of a current of sinusoidal wave form ·707 of the maximum value, so that the effective value of the voltage per coil will be $3{\cdot}6 \times {\cdot}707$, which is equal to 2·55 volts; and as there are ten

coils in each phase, the total voltage will be 25·5 volts. There is, however, a small factor to be taken into account which slightly reduces this value, and, where the coils, as in the present instance, are assumed to have a full pitch and are distributed in five adjacent slots, reduces the actual voltage by about 4 per cent, making the total effective voltage per phase 24·5 volts. When three phases are connected together in the form of a letter Y, it can be shown that the total voltage is $\sqrt{3}$ or 1·73 times the voltage per phase, so that in the particular case we are considering the voltage between terminals will be 42·5 volts. The same value for the voltage would be obtained by considering the change in flux in any coil, as in the direct current case, treating the flux as varying in a sinusoidal manner.

From the above considerations we have seen that the formula for obtaining the voltage for a direct current machine may be expressed as follows:

$$\text{Volts} = 4 \times \text{Flux per pole} \times \text{Frequency} \times \text{Number of coils in series} \times 10^{-8} \times \text{F}.$$

For an alternating current machine the factors are exactly the same, except that the constant, instead of being 4, is 4·44. This follows from the fact that we have to multiply the mean value of the flux by $\pi/2$ to obtain the maximum, and again by $1/\sqrt{2}$ to obtain the effective value. The product of these two factors is 1·11, thus the 4 of the original formula becomes 4·44.

The quantity F in this formula is the factor which allows for fractional pitch windings and other factors which tend to make the windings less efficient for producing voltage than it otherwise would be. It should not be much less than unity, and for most of the calculations below may be omitted.

(iii.) *The Magnetic Circuit of a Dynamo.*—This, unlike the simple anchor rings used in magnetic testing, is a composite one. In the simpler cases it may be considered as a series of portions formed by materials of different magnetic properties (such as air, soft iron, cast iron, etc.) composing a closed circuit. The component parts have different cross-sections and mean lengths. To a first approximation the total magnetic flux Φ produced by the ampere turns applied to one or more portions may be assumed to traverse the complete circuit without leakage. In that case we have

$$\text{Total flux } \Phi = \frac{\text{Magnetomotive force}}{\text{Total reluctance}}$$

$$= \frac{0{\cdot}4 \times \pi \times \text{ampere turns}}{\text{Sum of series reluctances}}$$

$$= \frac{0{\cdot}4 \times \pi \text{N}i}{\dfrac{l_1}{s_1} + \dfrac{l_2}{\mu_2 s_2} + \dfrac{l_3}{\mu_3 s_3} + \ldots},$$

where l_1, l_2, l_3 are the mean lengths (cm.),
s_1, s_2, s_3 cross-sections (sq. cm.),
$1, \mu_2, \mu_3$ permeabilities

of the air-gap ($\mu = 1$) and the various other parts of the circuit (field magneto cores, plate, armature core, etc.). It should be noted that the above equation

$$\text{Magnetic flux} = \frac{\text{M.M.F.}}{\text{Reluctance}}$$

for the magnetic circuit corresponds to Ohm's law for the electric circuit,

$$\text{Current} = \frac{\text{E.M.F.}}{\text{Resistance}}.$$

§ (5) Armature Reaction.—So far no account has been taken of the effect which may be produced when the armature bars are carrying current. Carrying current does not directly affect the voltage which would be induced in a conductor, but it has an indirect effect in that currents which flow in the armature bars produce a magnetising effect which may considerably distort the original distribution of magnetic flux in the machine. It is usual to calculate the total magnetomotive force of the armature conductors, and combine this with the original magnetomotive force of the field coils or exciting windings, in order to determine what the resultant magnetomotive force on the magnetic circuit will be, and so determine the amount of magnetisation that will occur under loaded conditions. In general the magnetising forces of the armature tend to neutralise the magnetising force of the field winding, so that in order to maintain the same amount of flux in a machine the field winding has to be considerably increased as the load on the machine increases. At any instant the various conductors in an armature will usually be carrying different currents, and they will occupy various positions relatively to the centre lines of the poles. The magnetomotive force due to each coil of the armature acts at right angles to the plane of the coil, and the number of ampere turns to which it is proportional is found by multiplying together the current in the coil and the number of turns. The resultant magnetomotive force may be regarded as due to the armature turns in a coil placed at right angles to the direction of this magnetomotive force; the number of ampere turns in such a coil is known usually as the armature reaction, and is determined in this way, as its principal purpose is for combination with the ampere turns on the field spools, in order to arrive at the resultant magnetising force of the machine.

(i.) *D.C. Machine.*—Consider now a D.C. machine. We require to find the direction and

magnitude of the magnetomotive force due to the armature current. In *Fig.* 16 let the brushes be so set that the current in a circuit AOB rotating in a clockwise direction is reversed each time the circuit is perpendicular to NS, the direction of the flux. The direction of the current in the circuit will be such that the lines of magnetic force due to it run as shown. The circuit in the position shown moves as though its right-hand face possessed south magnetic polarity and its left-hand face north polarity. The armature reaction is from right to left in a direction at right angles to the plane of the coil. The amount of the reaction in any direction making an angle θ with this plane is equal to

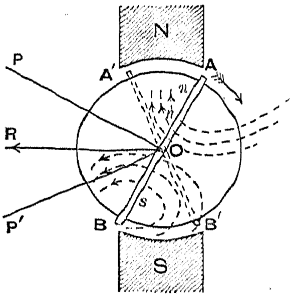

FIG. 16.

$$\text{Ampere turns} \times \sin\theta.$$

As the circuit passes the commutating position the right-hand face becomes the left hand and *vice versa*, but their polarities are also reversed through the change of current. The armature reaction is still from left to right, and of an amount given by the same expression. Now consider the complete armature. We shall have a second circuit A′B′ placed as shown, symmetrically with AB, but on the opposite side of NS. Let OR be perpendicular to NS and let θ be the angle between the plane of either coil and OR. The current is the same in each coil, and the resultant magnetomotive force of the two is clearly along OR, and we obtain

$$\text{Armature reaction} = 2 \text{ ampere turns per coil} \times \sin\theta.$$

This is for one pair of coils; the total number of such pairs with which we have to deal will be half the total number of circuits; these are arranged at various values of the angle θ. The resultant magnetomotive force due to the whole armature is therefore given by the expression 2 ampere turns per circuit $\times \frac{1}{2}$ number of circuits $\times$ average value of $\sin\theta$ between 0° and 90°. This average value, when the circuits are numerous, is $2/\pi$; while the ampere turns per circuit multiplied by the number of circuits is the total number of ampere turns. Now the armature reaction is measured per pole of the machine. Thus the result just found requires dividing by the number of poles of the machine and total ampere turns thus becomes ampere turns per pole.

We have finally for the D.C. machine the expression

$$\text{Armature reaction per pole} = \frac{2}{\pi} \times \text{Armature turns per pole.}$$

The direction in which the armature reaction acts will depend upon the position of the brushes. If, as above, the brushes are set so that commutation takes place in conductors situated midway between poles, then the direction of the armature reaction will be at right angles to that of the magnetising force of the field spools. Armature reaction acting in this direction does not demagnetise the field spools, but has a cross-magnetising effect tending to increase the density of flux at one side of the pole, and decrease it at the other. This distortion of the flux distribution is usually prejudicial in direct-current-machines, in that it causes bad commutation, as will be explained later. In small machines the usual remedy is to make the strength of the field spools high compared to the value of the armature reaction, and so keep the distortion to a value which is found by practice to be permissible.

In the actual machine which we have been considering it will be assumed that each of the armature bars carries 100 amperes (corresponding to 200 amperes total current from the machine as there are two circuits in parallel). There are 60 conductors in the machine, equal to 30 circuits, or 15 circuits per pole as it is a two-pole machine. Therefore the armature reaction expressed in ampere turns per pole will be $100 \times 15 \times 2/\pi = 960$ ampere turns. This armature reaction will be substantially constant in value and direction; as, due to the action of commutation under the brushes, the current is reversed in any coil during the time it passes under the brushes, and coils which occupy similar position and space will always carry the same current.

(ii.) *A.C. Machine.*—In a two or three phase alternating-current machine the currents are carried in two or three sets of windings, and are continually varying in value. In order to determine the value of the armature reaction it is necessary to consider the values of currents at some particular instant, and the position of the coils in which these currents flow. We shall assume that this machine is, as before, wound as a 3-phase machine, having three sets of circuits placed 120° apart, each set of circuits having ten turns or five turns per pole. Suppose that the instant be chosen when the current in one of the circuits is the maximum, and further that the direction in which the armature reaction acts is at right angles to this circuit, so that it has its full magnetising effect. The plane of the

circuit will be parallel to and the direction of the armature reaction perpendicular to the flux. It will further be assumed that each conductor carries 100 amperes (as measured by an ammeter so that 100 amperes is the effective value of the current). The armature reaction depends on the maximum current, and for this circuit containing five turns it will be $5 \times 100 \times 1{\cdot}414$.[1] The other two circuits will be displaced 120° from the first circuit, and they are carrying currents displaced 120° from the current in the first circuit. The value at the instant considered will be the maximum value multiplied by sin 120°, and due to the inclination of the coil, the component of its magnetising force in a direction at right angles to the first coil considered will be further reduced in proportion of sin 120° : 1. Thus the armature reaction due to this coil will be found by multiplying the maximum value by $\sin^2 120°$ or $\frac{3}{4}$. The total value of the armature reaction will therefore be $1{\cdot}414 \times 5 \times 100 \times (1 + \frac{3}{4} + \frac{3}{4})$, which is equal to $2{\cdot}12 \times 5 \times 100$, or 1060 ampere turns.

In this calculation no account has been taken of the small displacement which occurs in consequence of the conductors which form one coil occupying different slots, and as was shown in calculating the voltage, a correction factor amounting to about 4 per cent must be used; this will slightly reduce the armature reaction, and make the value in this particular instance taken 1020 ampere turns.

This armature reaction has been calculated for a comparatively simple position of the phases, but if any other instant were chosen, and the value of the currents corresponding to that instant and the displacement of the coils be taken into account, it would be shown that the armature reaction is substantially the same; in fact the armature reaction of a 3-phase machine remains practically constant in direction and in value relatively to the poles. A calculation for a 2-phase machine could be carried through in the same manner, and would give somewhat similar results.

The value per pole of the armature reaction for a D.C. machine can therefore be expressed as

$$\frac{2}{\pi} \times N_p \times i,$$

where N_p is the number of circuits per pole, and i the current in each armature conductor.

For the 3-phase[2] case this value becomes

$$2{\cdot}12 \times \frac{N_p}{3} \times i,$$

where i is the effective value of the current in each conductor.

The factor 2·12 is the product of 1·5 expressing the effect of the three circuits and 1·414 the ratio of the maximum to the effective current.

The calculation of the voltage from the flux of a machine and the calculation of the armature reaction have been gone into at some length, but these calculations are exceedingly important, and it will be shown presently that the flux and armature reaction of a machine are the two chief factors involved in a design.

§ (6) Output of the Machine.—The electrical output of a machine is the product of voltage multiplied by current, and in the particular example chosen, the direct-current output will be 34·5 volts × 200 amperes = 6900 watts. In the 3-phase case the output is three times the product of volts by amperes in each phase, that is, $24{\cdot}5 \times 100 \times 3 = 7300$ watts. It will be noticed, looking at these figures, that the same size of machine with the same amount of flux and the same value of current in each armature conductor, gives a slightly bigger output as a 3-phase machine than it does as a direct-current machine, but it will also be noticed that the calculated armature reaction for the 3-phase machine is also slightly larger than for the direct-current machine, and that these two figures have a direct proportionality—that is to say, the output is proportional to the armature reaction. The reason why in the two machines the outputs and armature reactions are not identical, is that, due to the disposition of the windings, the conductors are used a little more effectively in a 3-phase machine in this particular case than they are in a direct-current machine.

It is now proposed to show the relationship that the flux and armature reaction bear to the electrical and mechanical output of a motor or generator.

The electrical output of a machine in watts is the product of volts and amperes. From the previous calculations it has been shown that volts are proportional to the flux, frequency, and number of turns; and also that armature reaction is proportional to turns and current, consequently of course current will vary as armature reaction and inversely as number of turns. If, therefore, volts and amperes in the expression for output are expressed in terms of flux and armature reaction, and the equation simplified, it will be found that the output in watts can be reduced to the following expression:

$$\text{Watts} = 2\pi \times \text{Revs. per second} \times \text{Flux} \times \text{Total armature reaction} \times 10^{-8}.$$

Thus in a bipolar D.C. machine we have, omitting the factor F, and putting Armature reaction $= \Psi$, and Revs. per sec. = R,

$$\text{Volts} = 4\Phi \times n \times N \times 10^{-8},$$

$$\text{Amperes} = \frac{\Psi}{2} \times \frac{2}{N} \times \frac{\pi}{2},$$

$$n = \tfrac{1}{2}\,R \,.\, 2.$$

[1] The factor 1·414 measures the ratio of the maximum to the effective value of the current.

[2] See also § (6).

Hence

Watts = volt amperes

$= 2\pi R\Phi \times \Psi \times 10^{-8}$

$= 2\pi$ Revs. per sec. × Flux × Total armature reaction $\times 10^{-8}$.

The formula for an A.C. machine can be obtained similarly.

In the above expression the total armature reaction and the flux are used, being the armature reaction per pole multiplied by the number of poles in the machine and the flux issuing from either pole. Obviously, in this expression, 2π × revolutions per second is the angular velocity, and consequently since the Watts are equal to Torque × Angular velocity, the Torque will be represented by

$$\text{Flux} \times \text{Total armature reaction} \times 10^{-8},$$

which is equal to $(\Phi \,.\, \Psi)/10$ dyne cm.

Another method of deriving the output of a dynamo is as follows.

Each element, *e.g.* a square centimetre of surface of the armature, has a certain number of conductors carrying current; the force, in dynes, acting on the conductors in this element will be the product of the total current in these conductors and the magnetic flux density through the area. From this we can find the torque on the armature and hence the output. Let the radius of the armature in centimetres be a, its length l, the number of circuits each of one turn N, the number of poles 2, the total flux Φ, the current in amperes i, and the armature reaction Ψ.

(i.) *Direct Current.*—The number of conductors concerned is 2N which are connected so as to make N circuits or N/2 circuits per pole. The flux issuing from one pole is Φ, and the surface through which this flux passes is πal. Hence

$$\text{Mean flux density} = \frac{\Phi}{\pi a l}.$$

Current × Number of conductors per cm. of circumference

$$= \frac{2N}{2\pi a} \times \frac{i}{10} = \frac{Ni}{10\pi a}.$$

Hence

$$\text{Mean force per sq. cm.} = \frac{N\Phi i}{10\pi^2 a^2 l},$$

$$\text{Torque per sq. cm.} = \frac{N\Phi i}{10\pi^2 a l},$$

$$\text{Total torque} = \frac{N\Phi i}{5\pi} \text{ dyne cm.}$$

for there are $2\pi al$ sq. cm. on the armature.

But Ψ = Total armature reaction

$$= \frac{4}{\pi}\frac{Ni}{2} = \frac{2Ni}{\pi},$$

for there are two poles and N/2 circuits per pole.

Thus, $\quad \text{Total torque} = \dfrac{\Phi \,.\, \Psi}{10}$ dyne cm.

(ii.) *Alternating Current.*—We assume the positions of maximum current and maximum flux density to coincide and consider a current in a conductor when in a position making an angle θ with this maximum position. The armature has as many phases as there are circuits.

$$\text{The mean flux density} = \frac{\Phi}{\pi a l}.$$

Since the wave form is sinusoidal

$$\text{Maximum flux density} = \frac{\Phi}{\pi a l} \times \frac{\pi}{2}.$$

$$\text{Flux density when in position } \theta = \frac{\Phi}{2al}\sin\theta.$$

If the effective current be i amperes, its maximum value in C.G.S. units is $1{\cdot}414i/10$. Thus Current in position $\theta = (1{\cdot}414/10)i\sin\theta$. Number of conductors in an element $\delta\theta$ of the surface $= (2N/2\pi)d\theta$. Thus the force per unit length of this elementary strip

$$= \frac{1{\cdot}414 N\Phi i}{20\pi a l}\sin^2\theta\, d\theta.$$

Torque on armature of length l

$$= \frac{1{\cdot}414 N\Phi i}{20\pi}\int_0^{2\pi}\sin^2\theta\, d\theta,$$

$$= \frac{1{\cdot}414 N\Phi i}{20}.$$

Now consider one complete circuit made up of the conductors on two opposite elements $d\theta$ of the armature. The current is $1{\cdot}414i\sin\theta$ and the number of such circuits $2Nd\theta/2\pi$. Thus the ampere turns are $(1{\cdot}414Ni\sin\theta)/\pi$. The magnetomotive force due to this circuit acts in a direction perpendicular to it; to obtain the equivalent ampere turns which will produce the same effect in a direction perpendicular to the flux we must multiply the expression by $\sin\theta$, and to find the total armature reaction must sum this for all values of θ between θ and π. We thus find

$$\Psi = \frac{1{\cdot}414Ni}{\pi}\int_0^{\pi}\sin^2\theta\, d\theta,$$

$$= \frac{1{\cdot}414Ni}{2}.$$

Thus $1{\cdot}414Ni = 2\Psi$, and hence as for the D.C. case,

$$\text{Total torque} = \frac{\Phi\Psi}{10}\text{ dyne cm.}$$

If instead of supposing the conductors uniformly distributed over the armature we had supposed them concentrated into three sets of circuits each containing N/3 turns at angles of 120°, we should replace the $\dfrac{N}{\pi}\displaystyle\int_0^{2\pi}\sin^2\theta\, d\theta$ by $\dfrac{2N}{3}(1+\frac{1}{4}+\frac{1}{4})$ and the $\dfrac{N}{\pi}\displaystyle\int_0^{\pi}\sin^2\theta\, d\theta$ by one half this amount and arrive at the same result for the output. We should also

arrive at the result already obtained for the armature reaction.

Now

1 watt $=10^7$ ergs per sec.
$=10^7$ dyne cm. per sec.

Thus

1 dyne cm. $=10^{-7}$ watt sec.
$=10^{-7}$ joules.

And the Torque=
Flux × Total armature reaction $\times 10^{-8}$.

The output in watts is, we have seen, equal to 2π Revs. per sec. × Torque. Thus

Output $=2\pi\times$ Revs. per sec. × Flux
× Total armature reaction $\times 10^{-8}$ watts.

The flux Φ is measured by the number of lines of force issuing from one pole of the field. It is sometimes more convenient to work in terms of the total flux which, since there are two poles, is in this case equal to 2Φ, and then we have

Output $=2\pi\times$ Revs. per sec. $\times\frac{1}{2}$ Total flux
× Total armature reaction $\times 10^{-8}$ watts.

For practical engineering purposes it is sometimes preferable to have the torque expressed in inch-pounds rather than in dyne-centimetres; and if the total flux is expressed in megalines, and the total armature reaction in ampere turns then, changing the units of force and length, the expression for torque in inch-pounds then becomes

Torque in inch-pounds = Total flux × Total
armature reaction × ·0445.

§ (7) Electro-magnetic Induction.—A still further aspect of the conversion of mechanical into electrical energy can be obtained by considering the stored energy in an inductive circuit; by an inductive circuit is meant an electric circuit in a field of magnetic induction. Usually such a circuit consists of a number of turns surrounding an iron core.

When such a circuit carries a current it possesses energy, and the energy depends on the current and the total number of lines of force linked with the circuit. Let the number of turns of the circuit be N, the flux through each turn Φ, and the current i. The current itself will produce flux through the circuit, but we will consider first the case when Φ arises entirely from causes external to the circuit.

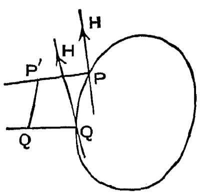

Fig. 17.

Consider a case when the lines of induction are perpendicular to the circuit. Take an element PQ of the circuit (*Fig.* 17) and imagine it displaced to P′Q′ in a direction perpendicular both to itself and to the flux; its ends must be supposed to rest on conducting rails PP′, QQ′. Let there be H lines of induction per cm. of the conductor in the neighbourhood of PQ, and let the current be i.

The force on PQ is $i\,.\,\mathrm{H}\times\mathrm{PQ}$, and the work done in the displacement is $i\,.\,\mathrm{H}\times\mathrm{PQ}\times\mathrm{PP'}$.

But $\mathrm{H}\times\mathrm{PQ}\times\mathrm{PP'}$ = increase of flux through the circuit.

Thus increase of energy $=i\times$ increase of total flux.

From this it follows that the total energy is equal to $i\times$ total flux.

Thus energy[1] $=i\times$ Total flux $=i\times\mathrm{N}\Phi$
= Ampere turns × Flux per turn.

Turn now to the case when the flux arises entirely from the current and denote by L the ratio of the total flux through the circuit to the current producing it.

Then $$\mathrm{L}=\frac{\text{Total flux}}{\text{Current}}=\frac{\mathrm{N}\Phi}{i}.$$

Hence $$\mathrm{L}i=\mathrm{N}\Phi.$$

The quantity L is known as the coefficient of self-induction of the circuit. It is measured in Henrys;[2] it depends on the shape and dimensions of the circuit and of the material with which it is surrounded. A circuit having a self-induction of 1 Henry is such that a change of current of 1 ampere per second produces an E.M.F. of 1 volt.

If the current is made to vary in any way, the flux through the circuit will alter and an electromotive force will be set up which, by Faraday's second law, is equal to the rate of decrease of the total flux, that is to $-d(\mathrm{N}\Phi)/dt$. Thus from the value of $\mathrm{N}\Phi$ already found we have

$$\text{E.M.F. of self-induction}=-\frac{d}{dt}(\mathrm{L}i).$$

To maintain the growth of the current an E.M.F. equal and opposite to this must be applied.

Work will be done and the energy of the circuit increased at a rate measured by

$$i\frac{d}{dt}(\mathrm{L}i),$$

and the product in the case in which L is constant becomes

$$\mathrm{L}i\frac{di}{dt}.$$

Thus the total amount of energy required to raise the current from zero to i is

$$\int_0^{C}\mathrm{L}i\frac{di}{dt}dt,\ \text{or}\ \tfrac{1}{2}\mathrm{L}i^2.$$

[1] If i is measured in C.G.S. units and the flux in lines per square centimetre, the energy will be in ergs. If the current be given in amperes and the flux in megalines, the energy will be in joules $\times 10^{-2}$.

[2] See "Electromagnetic Theory," §§ (4), (5).

This expression, if we substitute for Li its value $N\Phi$, becomes

$$\tfrac{1}{2}N\Phi i, \text{ or } \tfrac{1}{2} \text{ flux} \times \text{Ampere turns.}$$

In the cases we are concerned with we are dealing generally with coils carrying current moving in fields which, in the main, are not due to the current in the coil, and the energy stored in the coil is measured as above in the first case by the product of the flux per turn multiplied by the ampere turns.

In a dynamo, and for simplicity we will assume a D.C. case, although it applies equally well to any dynamo, a coil situated at right angles to the magnetic axis, so that it embraces the total flux of the machine, and carrying a current, will have stored magnetic energy in it. For instance, in the example we have considered already such a coil, consisting of one turn and carrying 100 amperes, embraces 2·3 megalines, and will have stored energy of $2{\cdot}3 \times 10^6 \times 100 \times 10^{-1}$ C.G.S. units or 2·3 watt seconds. Half a revolution later this coil will embrace flux in exactly the opposite direction, *i.e.* the direction of energy will be reversed, and the change in energy will be twice the above value, *i.e.* 4·6 watt seconds; the average rate of change, which, of course, represents power, will be this amount divided by the time during which the reversal occurs, which is 1/50th of a second. Therefore, the rate at which energy is being expended in order to cause this alternating magnetic energy is 230 watts in each coil; and as there are a total of 30 coils, the total of the machine will be $30 \times 230 = 6900$ watts, which was the output of the D.C. machine previously arrived at.

In considering the output of a D.C. machine, the direction in which the armature reaction operates is fixed by the brushes, and the magnetisation due to the armature is generally, for practical purposes, at right angles to the magnetic axis. In an alternating-current machine, however, the armature reaction does not act in this manner; in fact, only when running on a purely energy load does this occur. In a D.C. machine, due to the action of the commutator, the current delivered to the external circuit is a steady one, and though this machine may be, and frequently is, connected to a highly inductive circuit, the current is practically steady, and, therefore, no self-inductive voltage occurs. The voltage of the machine is the whole voltage of the circuit.

In an alternator the current is not commutated, but is applied to the line exactly in the form in which it is generated in the machine, *i.e.* as an alternating current; such an alternating current when put through an inductive circuit gives rise to a voltage induced in this circuit, and external to the alternator. It will thus be seen that the voltage generated in the alternator is only a portion of the whole voltage which is induced in the complete circuit and from which it differs in phase. If the matter is looked at in this way, and it is assumed that the current in the circuit is in phase with the total voltage in the circuit, this current will obviously be considerably out of phase with the voltage generated by the alternator alone. This is the usual case with alternating-current circuits. The current differs in phase very considerably from the voltage generated by the machine. In the more usual alternating-current circuits the effect of capacity can be neglected, and the effect of self-induction only considered. This causes the current to lag in time behind the voltage. In an alternator the effect of current lagging behind the voltage is to shift the direction of the armature reaction and cause it to oppose very largely the magnetising effect of the field spools, and thus to demagnetise the whole magnetic circuit. When considering the torque of an alternator it is necessary to take this factor into account, as it is only the energy component of the total armature reaction which gives rise to torque and requires the corresponding mechanical energy to rotate the machine.

If the value of the angle of lag be ϕ the output is given by the expression

$$\text{Volts} \times \text{Amperes} \times \cos \phi.$$

The above considerations show that in the design of a dynamo the two important factors are the amount of flux, which depends on the amount of iron in a machine, and the amount of armature reaction, which depends on the amount of copper; in designing a machine it may be made with a large amount of copper and a small amount of iron, or a large amount of iron and a small amount of copper; it is the skill and experience of the designer which determines the correct proportions of these two components. It is hardly feasible to discuss fully how a design should be arrived at in any particular machine as to the proportion of these two components, but an attempt will be made to show how each of them influences the design, so as to indicate how a proper relationship can be obtained.

§ (8) THE MAGNETIC CIRCUIT. DETAILS OF DESIGN.—In considering the magnetic circuit the most important feature is that iron becomes saturated at a flux density of about 100,000 lines per square inch, 15,000 to 16,000 lines per square centimetre (see *Fig.* 1). Up to this point the magnetic flux is roughly proportional to the magnetising force, the value of the permeability given by the ratio of B/H is nearly constant. Above this point the amount of flux is increased only slowly by increasing the magnetising force. The other feature is that where reversal of magnetism takes place, as it does in the

armature of dynamos, a loss is associated with this reversal.[1] This loss varies with different grades of iron, and it can be reduced by alloying a small amount of silicon, which increases the specific resistance and also to a small extent helps the permeability. In dynamo machinery also there is a loss due to eddy currents set up in the iron. This is a conductor, and currents are induced in it as it rotates in the field of the machine. These currents are greatly reduced by laminating the iron and separating the laminae by an insulating material. But metallic contact between the laminae cannot be entirely prevented; eddy currents and loss of energy are a necessary consequence resulting in the heating of the iron. In actual practice, and with ordinary frequencies, the losses that occur can be dealt with without excessive rise of temperature, and probably the chief limit in the magnetic circuit of modern machinery is the saturation limit. In a preliminary design of a machine it is necessary to make a sketch of the probable shape of the magnetic circuit. The section of iron can be reduced in the centre of the poles with the advantage that the length of turn of the magnetising coils can be made as small as possible. The section must be increased in the neighbourhood of the air gap so as to reduce the density of flux where it enters the armature, and where the iron is cut away in the form of slots to accommodate the windings.

A knowledge of the voltage, speed, and output of the machine and of the magnetic area and length of its armature and other parts enables us to calculate the total flux required in the armature to give the desired effect. The flux in the field coils and yoke must be greater in order to allow for leakage. By dividing the total flux in each part by the magnetic area of that part we get the corresponding flux density. The magnetisation curves for the various materials enable us to calculate the ampere turns per unit length to produce this flux density, and multiplying these by the length of the iron core in each case we find the total ampere turns.[2]

Allowance must be made for flux which leaks across the intervening space between poles and does not actually enter the armature, and a magnetic circuit has to be designed so as to keep this leakage as small as possible. Such magnetic leakage occurs when the machine is running on open circuit, but the amount is very much increased when currents are flowing in the armature windings which tend to demagnetise the field winding, and which consequently call for larger magnetising force on the field spools to produce the same amount of flux in the armature.

[1] See "Magnetic Measurements," § (1) (xii.); also "Magnetic Hysteresis." [2] See § (4) (iii.).

The next step in the design of a machine after a preliminary sketch of the magnetic circuit, and determination of the amount of flux which such a circuit would carry, is to calculate the number of turns on the armature for the voltage required. Such a calculation will probably involve a modification in the amount of flux in the magnetic circuit in order that a convenient and symmetrical form of winding may be used. For instance, in a three-phase machine the slots must obviously be some multiple of three, and it is also necessary that an integral number of turns should be used in each slot. Having made the necessary modifications, the armature reaction can be calculated from the number of turns used and the amount of current which the machine is to carry. This armature reaction will enable us to determine the amount of leakage which will occur, and also to determine how much of the magnetic circuit will have to be sacrificed in the form of slots to accommodate the winding. These considerations may further modify the design of the magnetic circuit. Having done this it will be necessary to consider the winding itself, whether space can be found for the conductors to carry the currents allowed for, with a reasonable current density in the copper, whether losses in the copper will cause too high a temperature, whether room can be provided for the necessary insulation, and whether in the case of large alternating-current machines excessive eddy currents are likely to occur in the large copper conductors. The value of the armature reaction arrived at will also determine the number of ampere turns which must be put on the field windings, as these ampere turns must not only supply the magnetism, but must be able to overcome the neutralising effect of the armature reaction, and the necessary space must be available on the magnetic structure for field spools of sufficient size. These considerations may lead to modification in the winding, that is to say, possibly a smaller number of turns may be necessary, with a corresponding smaller armature reaction, and consequently a larger flux must be used.

Another important feature in the design is that a machine must conform with patterns, dies, and other parts which may exist in a manufacturing organisation, and also the machine must be capable of being modified for various voltages.

From all these considerations it will be realised that the design of a dynamo is a very complex matter, and very many considerations influence the final design which is chosen, but the two broad features stand out which influence the output obtained from a machine; first, the amount of magnetic flux which can be carried in the iron circuit,

and secondly, the amount of current which can be carried in the copper circuit. If a quality of iron were available which would allow, say, 10 per cent more flux to be carried, then the output could be increased by this amount, but it also could probably be increased still further, as the leakage flux would now be a smaller percentage, and consequently the armature reaction could be increased since the consequent increase in leakage could now be permitted. By this means it is probable that, provided the copper heating is not a limit on a machine, a 10 per cent increase in the permeability in the steel would allow about 20 per cent more output to be obtained from a given size of machine. Researches are being made in alloyed steels, and it is possible that some result of this type may be eventually obtained.

With regard to the other limits, it is improbable that a better conducting material at a reasonable price will be obtained than copper, but continual improvements are being made in means for getting rid of the heat generated in the copper conductors, and also great improvements are taking place in the methods of insulating coils, and economising the space occupied by the insulated conductors. In the preliminary design of dynamos, it is convenient to express armature reaction in the form of ampere turns per unit of circumference, and flux in the form of mean flux density per square inch of circumference of the armature. Permissible values may be assigned to these two quantities, depending on the type and size of machine to be designed, and from them a first approximation can be quickly obtained to the general dimensions.

§ (9) Induction Machines.—Most of the considerations given above apply to machines where the initial magnetisation is supplied by means of direct current. A rather different form of machine is an induction machine, of which the chief example is the induction motor. The machine consists of two parts, the stator, or fixed part, and the rotor which, in a motor, rotates in the field due to the stator. In this case the excitation necessary to maintain the flux in the machine is supplied by alternating current, and, as already mentioned, when alternating current and flux are used, alternating electromotive forces are introduced into the circuit. It is necessary, therefore, in an induction motor, in order that the power factor may be reasonably high, that the magnetising current should be kept small. The same considerations apply in induction motors as in all other dynamo machines, leading to the result that the output is the product of the active armature reaction and active flux. In this type of machine it is not necessary to use a component of the magnetising current to neutralise the rotor or working armature reaction, as this, as we shall see, is automatically done by means of a current differing in phase by a right angle from the magnetising current which is induced by the reaction of the stator windings. It is also very desirable that the amount of leakage flux should be kept a minimum, as obviously if a large leakage flux occurs, the actual working flux in the armature will be reduced, and the output of the machine will fall in consequence.

Another feature in an induction motor which influences its ultimate output is that a slip must occur in order to induce the necessary currents in the rotor bars. Slip is the difference between the speed of rotation of the rotor and the speed of rotation of the magnetic field on the stator, as will be described later. If the rotor current is large, requiring a large slip, the frequency of the rotor currents increase, and a phase displacement of the rotor currents relatively to the working flux will take place which reduces the effective torque of the motor.

Most induction motors are made as 3-phase machines, but it is a little simpler to understand the theory of a 2-phase motor, and therefore this will be discussed. In a 2-phase motor the stator has two sets of coils arranged at right angles to one another and connected respectively to the two phases of the supply circuit. The rotor is assumed to have a large number of phases. If the stator is connected to the supply circuit, currents will flow and flux will be produced. This flux will be just sufficient to induce a voltage in the stator equal to the supply voltage, and the current will be just enough to produce this amount of flux. Current and flux are always in phase with one another, *i.e.* attain their maxima at the same instant. Voltage is, however, greatest when the flux change is greatest, and as sinusoidal values of current, flux, and voltage are assumed voltage will be directly out of phase with current. Voltage will also be induced in the rotor windings due to the alternating flux produced by the stator currents.

Referring to *Fig.* 18, assume for the moment that, due to magnetising currents flowing in the stator winding AA, flux oscillates in the direction BB. This flux induces voltage in the coil AA and also in the rotor coils *aa*. If the rotor coils are connected up so that current can flow through them due to the voltage induced by the flux along BB, and if such currents are in phase with the voltage so induced, then the currents will be at a maximum in the region *aa*, since the coils in this position embrace the largest amount of flux. The magnetising force causing flux to oscillate along axis BB will be the resultant of the currents in AA and *aa*, and this resultant

will not be equal to the original magnetising force of AA until an additional current flows in AA which is equal and opposite to the currents in *aa*. All this is just what happens in an ordinary static transformer, and the

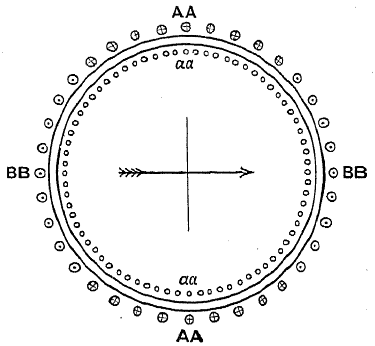

FIG. 18.

net result is that there are two components of current in AA, one an impressed magnetising current in phase with the magnetism along BB and at right angles to the voltage across AA, and the other equal and opposite to the current in *aa*. These two latter currents are at a maximum value when the flux is at a minimum and are in phase with the voltage across AA. Further, they are carried by conductors placed close to one another and they therefore neutralise one another, and as there is no flux when they are at a maximum they do not exert any force on one another tending to cause rotation of the rotor. So far, the effect of the currents in the phase BB has been ignored, and the conditions discussed are those that would occur in a single-phase motor or static transformer. However, the windings BB have the same relationship to the phase B of the supply as windings AA to phase A. Whilst, therefore, the flux along BB is a minimum and the currents in *aa* and their counterpart in AA are a maximum, the flux due to phase B will have a maximum value in the direction AA. The two conductors *aa* and AA carrying equal currents in opposite directions are in a magnetic field at right angles to the direction BB, parallel, that is, to the line joining the two conductors A and *a*. Thus the case illustrated in *Fig.* 7 arises. A strong circumferential force acts on the conductors at *aa* tending to cause rotation in the rotor.

There is another and rather simpler way of regarding an induction motor, which is based on the fact[1] that the currents in the two sets of coils AA and BB give rise to a rotating magnetomotive force which produces a continuously revolving flux. The rotating flux cuts the rotor bars and gives rise to voltages and currents in them. The voltage will be greatest where the rate of cutting is greatest, *i.e.* where the flux is densest, and if the currents in the rotor bars are in phase with the voltages induced these currents will be greatest where the flux is greatest, and consequently mechanical forces will occur as in *Fig.* 6. When the motor is running, its rotational speed will be slightly slower than the rotational speed of the flux, and only the difference in speed will cause cutting of the flux by the rotor bars. The rotor windings have a low resistance, and the slip or speed of cutting will be just sufficient to produce the voltage necessary to force the current required in the rotor windings through the resistance of the windings. The rotor windings consist of bars or wires carried in slots, and are therefore inherently highly inductive, but when the motor is running the frequency of the rotor currents is so low that inductive voltage is very small and the currents in the windings are practically in phase with the voltage induced in the bars, and the phase relations discussed above hold. When starting the rotor is at a standstill, the frequency is the same as in the stator, and the currents tend to become displaced and no longer occur in the bars situated in the densest portion of the flux; further, the low resistance rotor winding tends to prevent flux penetrating into the rotor. The conditions at starting are not, therefore, favourable for high starting torque, but in small motors sufficient initial torque can usually be obtained at the expense of a large initial rush of current. In larger motors resistance is inserted in the rotor windings and cut out after the motor has attained speed.

§ (10) COMMUTATION. — Direct - current machines are usually made with a closed armature winding from which connections are made at regular intervals to the commutator bars. Diagrams, *Figs.* 10 and 11, show portions of two forms of such winding, the first being suitable for high - voltage machines, and the second for low - voltage machines. In each case, the span between the two sides of the coil is practically one pole-pitch on the armature. *Fig.* 12 shows a portion of a winding connected to the commutator, and with a brush in position. This brush is arranged so that the coils make contact with it when they are in the neutral position between poles, that is to say, when there is no voltage induced in them; the coil being connected to the commutator bars which are in contact with the brush, and short-circuited by the brush. Commutation consists in

[1] The magnetic fields due to the two currents may be represented by expressions H sin nt and H cos nt. These are at right angles, and their resultant is H inclined at an angle nt to the direction of the second field. The direction, therefore, rotates, the period being $2\pi/n$.

reversing the current in the coils during the time that they are short-circuited by the brush.

Carbon or graphite brushes are used, as these ensure lubrication of the commutator, and also have a considerable amount of resistance. The resistance between the brush and the commutator segments is practically proportional to the area of segment in contact with the brush. If reversal were considered to take place very slowly, it could be seen that

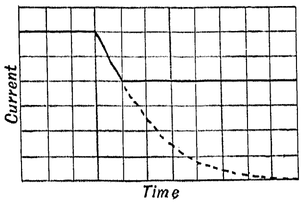

FIG. 19.

the current flowing from a brush into the winding through the commutator bars will divide up amongst the coils with which the brush is in contact in proportion to the contact resistance between the bars and the brush, and consequently the amount of current will gradually change as the coil moves past the brush.

In actual practice commutation has to be effected in a very short interval of time (usually ·001 to ·002 second), and the reversal of a large current in a coil which is embedded in slots in the iron of the armature in a very short interval of time would give rise to a considerable voltage, which tends, as shown earlier, to prevent reversal of the current. It is therefore necessary to use force to cause this reversal of the current in the time allowed, and this is done by causing the coil, during the period of reversal, to rotate in a magnetic field, which will give a voltage equal and opposite to the self-inductive voltage of the coil. Immediately the coil is short-circuited by the brush, the current will tend to change to an ultimate value equal to the voltage induced in the coil divided by the resistance of the coil, and such a curve of current charge is shown on *Fig.* 19.

The initial part of this curve is to a large extent independent of the resistance of the coil and brush, and depends upon the rotational voltage and the self-induction of the coil, and in order that the current may be reversed properly, the rotational voltage must be made proportional to the current which the machine is carrying. The usual means for doing this

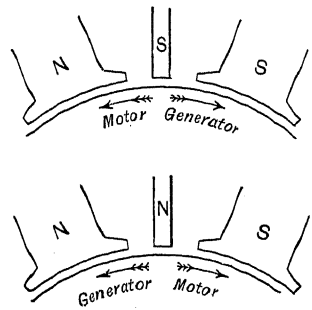

FIG. 20.

is to provide the machine with small auxiliary poles called Commutating Poles, situated midway between the main poles. *Fig.* 20 shows such an arrangement of poles.

These poles are provided with coils which are traversed by the main armature current, so that the commutating flux produced is proportional to the current which the machine is carrying. *Fig.* 21 shows the distribution of flux and armature reaction for the commutating pole machine at no load and when carrying full load. This diagram shows clearly the distortional effect produced by the commutating poles which enables commutation to be effected. *Fig.* 22 shows a similar curve for a machine which has a com-

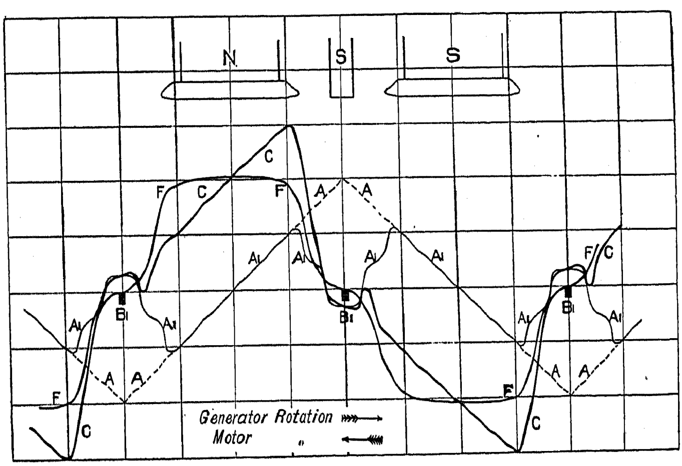

FIG. 21.

pensating winding on the main poles in addition to the commutating poles.

In these figures the letters F and A refer to the flux and armature reaction, while C is the current.

Suppose that the machine is carrying 100 amperes, then the current in the coil would have to change from plus 100 amperes to minus 100 amperes during the commutation period, or during the time that it is short-circuited by the brush. If this has not happened, the coil will be carrying more or less current than should be, and the current will have to change suddenly when it breaks contact with the brush. This sudden change in current at the end of the commutating period gives rise to sparking, and if bad sparking takes place the commutator rapidly deteriorates and the machine becomes inoperative. The important object to be obtained in the proper designing of a machine is that commutation shall take place without appreciable sparking. The means for accomplishing this result have been discussed, but in practice they are not always attainable, and it is therefore undesirable to build machines in which the current per coil exceeds a certain safe value. If a large current machine has to be built, it is necessary to build it with many poles, and a corresponding number of parallel circuits, so that the current in each individual coil is kept to a safe value. In addition to limiting the amount of current in the coil, it is desirable to make the self-induction as low as possible.

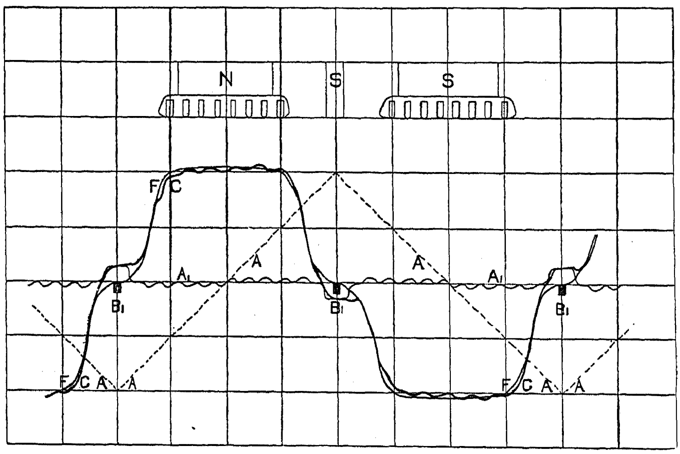

FIG. 22.

In the diagram, *Fig.* 12, is shown a means frequently used in D.C. machines, in which it will be noticed that there are two coils per slot, and that the pitch of the end windings is an integral number plus a half.

The induction of a coil undergoing commutation is not the self-induction of the coil by itself, but its induction relatively to the next coil which is still short-circuited by the brushes. In the arrangement shown on *Fig.* 12 one side of the coil is in the same slot with the coil next to it, and therefore its self-induction is very low, and mutual induction relatively to the next coil high; on the other side the coils occupy adjacent slots, and therefore the self-induction is represented by the flux that can pass through the tooth between them. The energy available for causing sparking and burning of the commutator and brushes is represented by the product of the surplus or deficit current that the coil carries at the moment it leaves the brushes, and the flux associated with this current that can pass through the tooth or teeth between coils. Expressed in other words, it is proportional to the square of the current in a coil multiplied by the coefficient of self-induction. As it is not possible to neutralise the flux of self-induction exactly by means of commutating poles under all conditions of operation, it is desirable to keep the self-inductive energy low. This can be done by means described above and other similar devices, and also by keeping the core length short and by keeping the current in each coil as low as possible. An actual oscillograph of the current in a coil of a comparatively large generator when running heavily overloaded is shown on *Fig.* 23. If

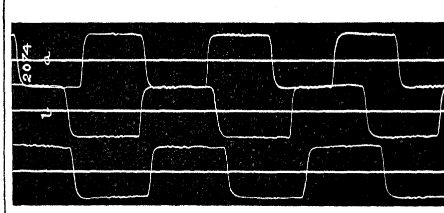

FIG. 23.

commutation is taking place correctly, the current flowing from brushes to commutator will be evenly distributed over the surface of the brush, and consequently the potential difference between brush and commutator will be uniform. Therefore a convenient

means of testing proper commutation is to measure the difference of potential from front to back of the brushes; if this is low, commutation is correct.

§ (11) Direct-current Generators and Motors.—The great advantage of direct-current machines is that:

(i.) They can be made self-exciting.

(ii.) They can be used in conjunction with storage batteries.

(iii.) The speed can be readily varied.

So far as generators are concerned, the tendency at present is to confine these to small machines, though in certain cases large machines are used, especially in connection with electrolytic plants; but, in consequence of the possibility of varying the speed, there is a big field for both large and small direct-current motors.

The magnet frame of a large machine is shown on *Fig.* 24.

The number of poles on a direct-current machine depends on the size, speed, and the voltage. Generally, the larger the output, the greater the number of poles; the higher the speed, the fewer the poles, and the higher the voltage, the fewer the poles. The factors which determine the design and permissible flux density at the air-gap and in other parts of the magnet are: armature reaction; the leakage between the poles, and more particularly between main and commutating poles; the permissible size of armature conductors and slots, and the current in the conductors both from the point of view of heating and the possibility of satisfactory commutation.

Some consideration has been given to these features in the early part of this article. The actual design of the machine cannot be made subject to any definite rules, as the final choice depends on factors, many of which are purely of a manufacturing nature, but in practice it has been found that a number of poles which correspond to a frequency of 20 to 30 cycles give a satisfactory design of machine. The length of the core varies between p and $\frac{1}{2}p$, where p is the pole pitch at the circumference of the armature.

In most D.C. machines the mechanical stresses due to centrifugal force do not form a limit in the design, as limits due to commutating difficulties occur earlier. The armature punchings on small machines are made in a complete circle, and for large machines are made in segments, the segments overlapping one another by a half. For a

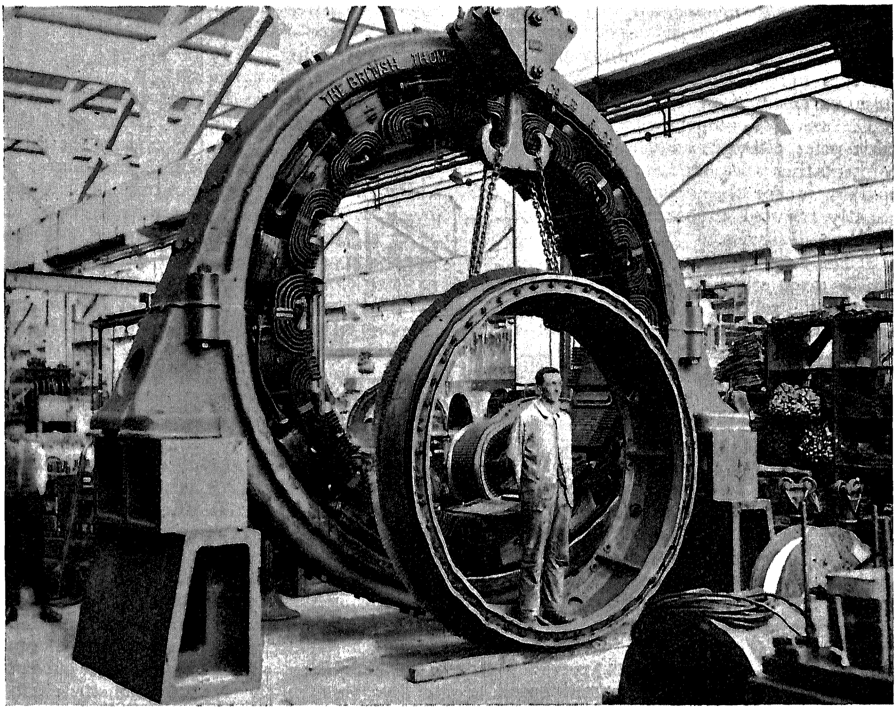

Fig. 24.

given diameter of armature the amount of material will be reduced somewhat by increasing the number of poles, though this gain is most marked when changing from two to four or six poles, but if too great a number of poles are used, there may be excessive magnetic leakage between the poles. The commutator consists of copper bars in width about $\frac{1}{4}$ in. to $\frac{3}{8}$ in. insulated from one another by plates of mica about ·03 to ·04 inch thick. It is undesirable to allow more than 25 to 50 volts per inch of circumference of the commutator, as in case of a very severe or sudden overload excessive sparking may momentarily occur at the brushes, and the copper vapour and carbon particles may form a conducting path round the commutator, thus a flash over may occur from one brush to another.

The use of a compensating winding on the main poles, either in addition to or instead of commutating poles, tends to prevent excessive sparking under these conditions, and is frequently resorted to on machines subject to very severe service.

It has been mentioned that D.C. machines can be made self-exciting; they may also be separately excited. When self-excited there are two ways of arranging the exciting circuit. These are known as shunt and series excitation respectively. In the first case the exciting windings are connected across the terminals of the machine, and in the other case the exciting windings are arranged in series between the armature and the external circuit. In some cases a combination of both these methods of excitation is used. *Fig.* 25 shows the two arrangements.

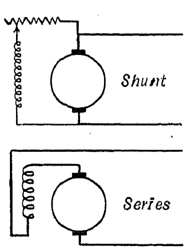

FIG. 25.

(i.) *Shunt Dynamo.*—With the shunt method a dynamo will tend to keep constant voltage with constant speed of rotation, and this is usually the desired condition for a generator, as the line is most conveniently carried at a constant voltage. Actually, the voltage of a shunt machine drops slightly with increase of load, due to the demagnetising effect of the armature in reducing the flux, and also to ohmic drop in the windings of the machine. This drop in the armature voltage of course decreases the excitation current, and the effect is therefore accumulative. In order that a shunt machine may maintain its voltage reasonably steady, it is necessary that the magnetic circuit should be saturated to a certain extent; in other words, the flux is not directly proportional to the exciting current.

In the curve, *Fig.* 26, are shown two so-called saturation curves from a typical machine, *i.e.* curves which show the relationship between the generator voltage and exciting current. These two curves correspond to normal speed and half speed of the machine. On the same diagram are shown also three other curves—the straight lines A, B, C—which correspond to different values of resistance of the exciting circuit. The slope of the lines gives in each case the value of the ratio voltage/exciting current, *i.e.* the resistance.

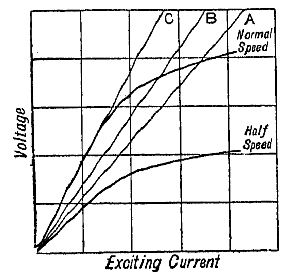

FIG. 26.

If the machine is operating at normal speed, it will be seen that definite voltages occur at the intersections of A and B with the upper curve, but when the resistance of the exciting circuit is increased to correspond to C, no definite voltage is obtained, and the machine becomes unstable. The angle of intersection of these lines is a measure of the stability of the machine. There is nearly always a small amount of residual magnetism in the iron circuit, which gives initial tendency for the machine to excite itself. The connections between the brushes and exciting winding must be such that this initial tendency becomes accumulative and the machine excites itself. It is also necessary that the winding should have a sufficiently low resistance, otherwise self-excitation will not occur. In the curve, which corresponds to the low speed of the machine, it will be noticed that the voltage produced by the machine is not enough to cause sufficient excitation current to flow through the resistance of the exciting windings. At this speed, therefore, the machine will not self-excite. The shunt current of a dynamo may be as low as $\frac{1}{2}$ per cent of the main current on large machines, and 5 to 10 per cent on small machines. In any case it is a small proportion of the total current of the machine, and it is therefore an easy matter to arrange variable resistance in the exciting circuits, whereby the voltage of the machine can be controlled.

(ii.) *Series Dynamo.*—The series method of excitation is unsuitable for generators, except under a few special conditions of operation, but in many cases a few series turns are added to a shunt machine to correct for the inherent drop in voltage that occurs with increased load.

(iii.) *Shunt Motor.*—For motors both forms of excitation are used. The shunt method of

excitation gives a tendency to constant speed for a constant voltage on the supply circuit and varying load, and the series method gives a variable speed—low speeds with heavy loads, and high speed with light loads.

When a machine is running as a motor coupled to a source of supply, the voltage generated in the armature will be approximately equal to the voltage on the line. When this voltage is constant, the excitation of a shunt motor will be constant, and independent of the load; therefore flux will be constant, and as voltage depends on flux and speed, the speed will be constant also independently of the load in the armature.

(iv.) *Series Motor.*—In the series motor, however, if the load increases, the current in the armature increases, so also does the excitation and flux; therefore the speed will decrease, as a lower speed will be sufficient to generate the necessary voltage with increased flux. The torque depends on the flux and armature current, and consequently a series motor is capable of exerting a very large torque at low speeds. This makes it particularly suitable for such duties as operating trains, etc. A series motor must never be entirely without load, otherwise it may run away and attain a dangerous speed. On the other hand, a shunt motor may be operated entirely without load, and will run at a definite speed. All motors, whether series or shunt type, must have a resistance inserted in series with the armature during starting period until the armature can attain sufficient speed to generate the voltage equal to the supply voltage. This resistance is cut out after the motor has attained its speed.

The mechanical construction of an armature is illustrated in *Fig.* 27. This shows the punchings carried on a cast-iron hub or spider, and the means adopted for firmly securing them in place. Ventilating ducts are left at intervals in the punchings. A complete armature is shown on *Fig.* 28.

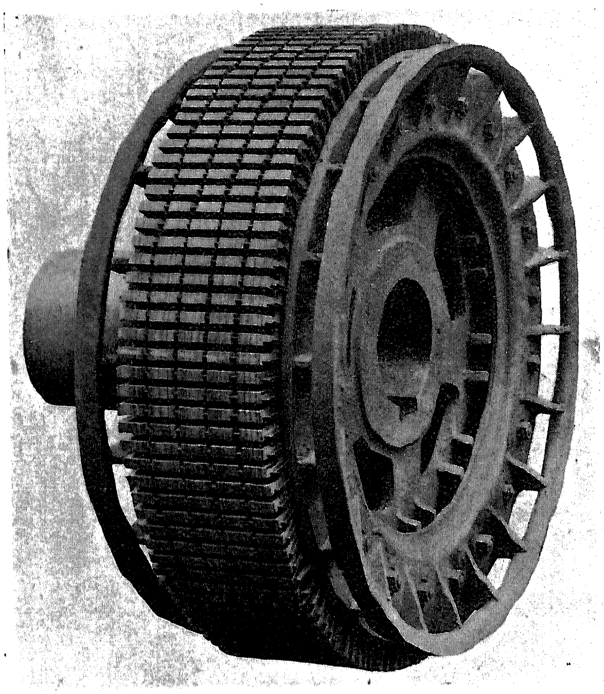

Fig. 27.

Typical views of complete machines are figured in *Figs.* 29 and 30.

§ (12) Alternators.—In the alternator the commutator is eliminated, the ends of the windings being brought direct to the terminals of the machine. The elimination of the commutator also allows the machines to be made much more readily in large sizes. At the present day the alternator is the most usual form of generator which is used. It is coupled to steam turbines, water wheels, steam engines, and gas or oil engines; the total capacity of the machines installed being in the order given.

The steam turbine has a very high rotational speed (necessary owing to the high velocity

which steam attains when issuing from a nozzle), and alternators have been built which can be directly coupled to steam turbines. In this country the usual frequency is 50 cycles, which gives rotational speeds of 3000 r.p.m. for 2-pole machines or 1500 for 4-pole machines, and most of the alternators now built run at either of these speeds.

Alternators are made in almost all cases with the armature stationary, and the field revolving ; the two chief reasons for this being that with a revolving field it is only necessary to carry through the slip-rings the small amount of energy required for exciting the field, and further that it is much easier to put high voltage armature coils on the stator than on the rotor, especially if the rotor runs at a very high speed.

The largest machines which are being built at present have capacities of 10,000-15,000 kw. at 3000 r.p.m., and 30,000-40,000 kw. at 1500 r.p.m. Such machines are usually designed to operate with a power factor of 80 per cent. The usual voltage for such machines is between 6000 and 12,000 volts. It has not been found desirable to build machines on a much higher voltage than 15,000, and if higher voltages are required for transmission purposes, this is easily obtained by means of step-up transformers.

The principal difficulties in connection with the designing of alternators for coupling to steam turbines are mechanical. In order to get the output mentioned above, it is necessary to go to a very high peripheral speed, which would attain in some cases 25,000 feet per minute. The rotor is usually built in the form of a cylinder with slots, which carry the exciting windings. The end portions of the winding are retained in place by stout steel rings. The exciting winding consists of coils formed from a flat copper strip, both the individual turns and the complete coil being insulated with mica.

Great care has to be used in designing these machines and in choosing the right material to deal with the very high centrifugal forces associated with the high speed of rotation. It is necessary to give special attention to the proper balancing of rotors, otherwise serious vibration will occur, as machines very often have to pass through what is called the "critical speeds." This is the speed at which the rotor would naturally vibrate, and depends on its weight and the elasticity on the shaft. Means have to be provided on all machines which have to pass through this critical speed to prevent the vibration becoming dangerous at this point.

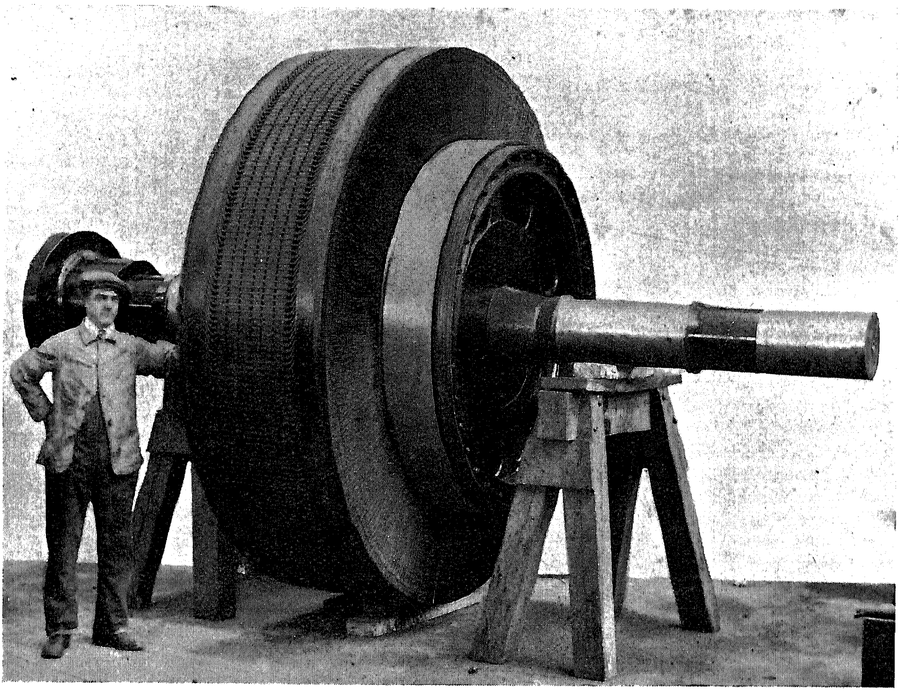

FIG. 28.

The heat generated by the losses in the machine is carried off by means of air which is forced through the machine by means of fans on the end of the rotor, ducts being provided both in the rotor and stator to ensure that the air comes in contact with all parts.

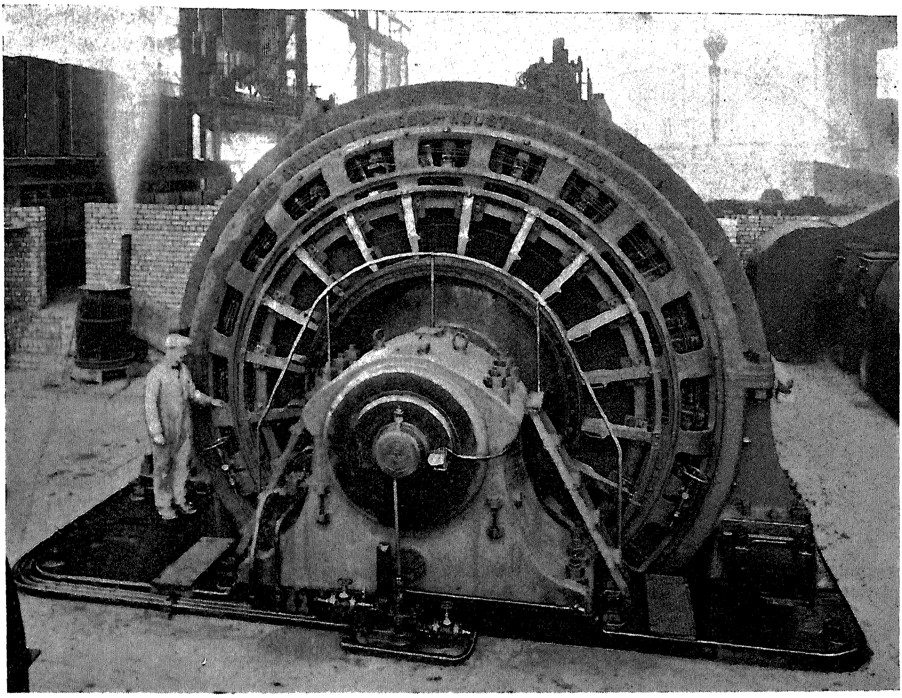

FIG. 29.

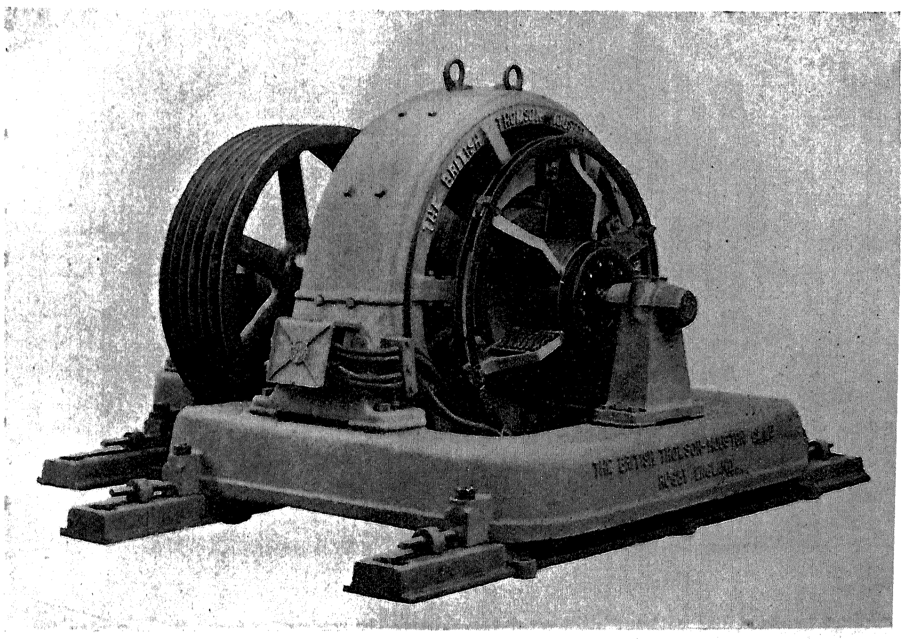

FIG. 30.

Sectional views of typical turbo-alternators are shown on *Figs.* 31 and 32.

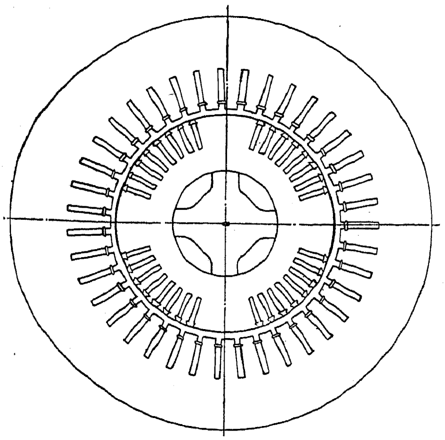

FIG. 31.

Fig. 33 shows a stator frame without the windings, and *Fig.* 34 a similar machine completely wound. A 2-pole rotor with the exciting ring is put in place on *Fig.* 36. The excitation is usually supplied by means of a small direct-coupled direct-current generator, a view of which is shown on *Fig.* 37. Another view of

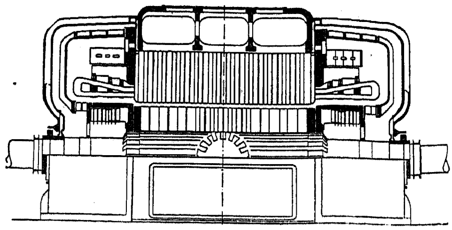

FIG. 32.

a high-speed alternator coupled to a steam turbine is shown on *Fig.* 38.

Alternators which have to be coupled to steam engines rotate at a much lower speed, and therefore have to have more poles. A typical machine is shown on *Fig.* 39, the rotor for such a machine being shown on *Fig.* 40. A partially wound stator is shown on *Fig.* 41.

Machines for coupling to waterwheels are intermediate in speed from those which are

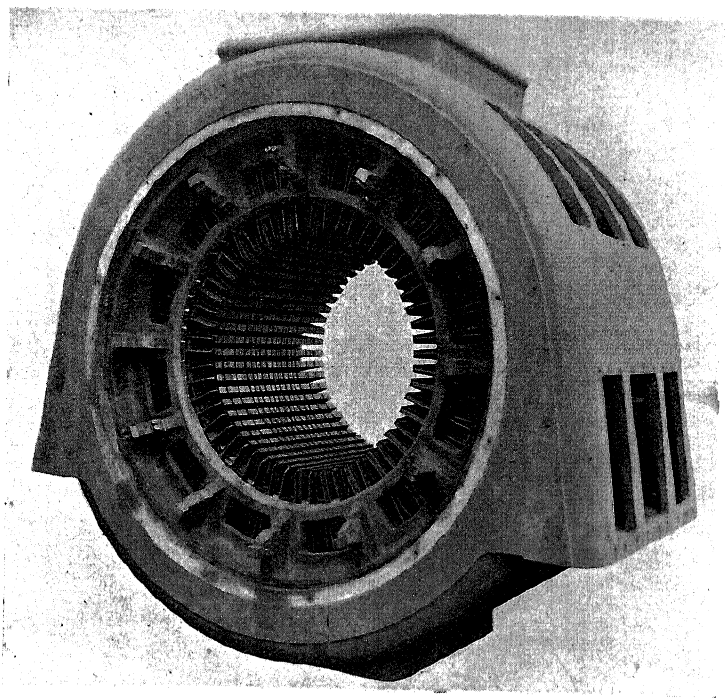

FIG. 33.

windings in place, but without steel retaining rings, is shown on *Fig.* 35, and the retaining driven by steam-engines and steam-turbines. Such machines are built with definite poles,

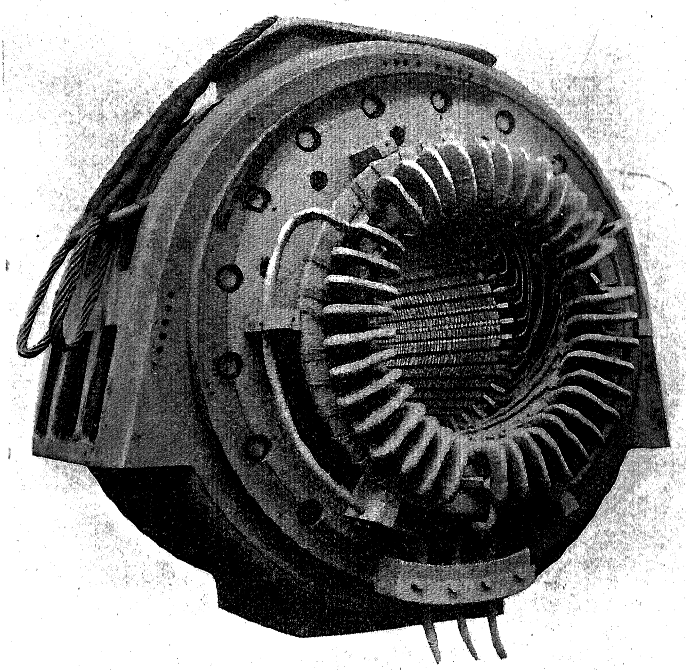

FIG. 34.

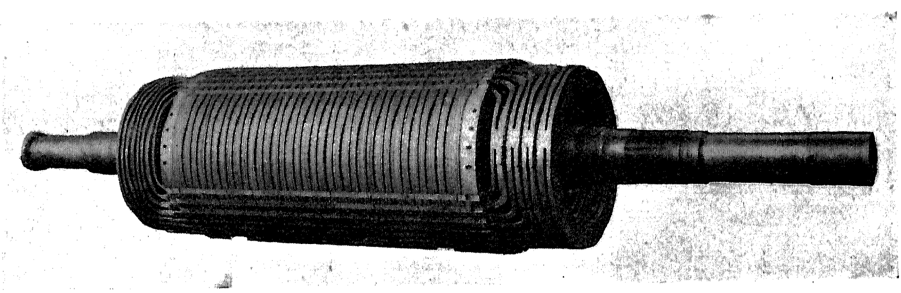

FIG. 35.

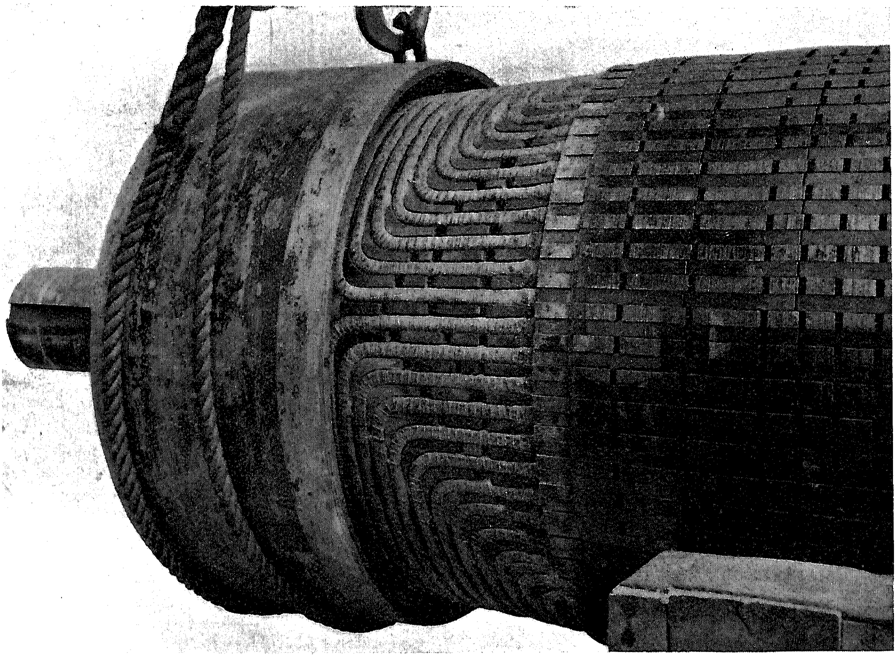

FIG. 36.

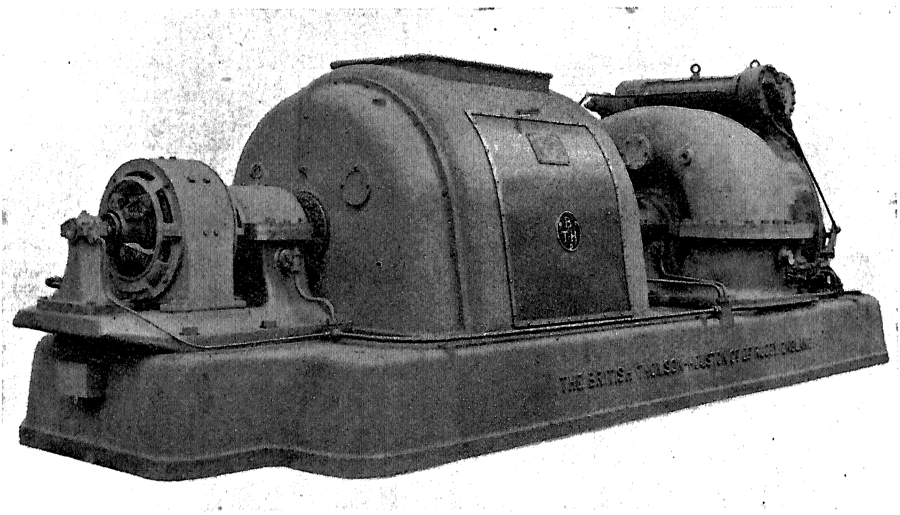

FIG. 37.

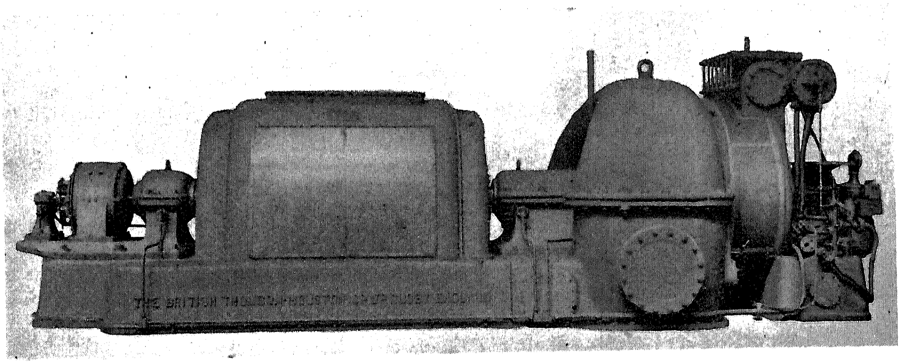

Fig. 38.

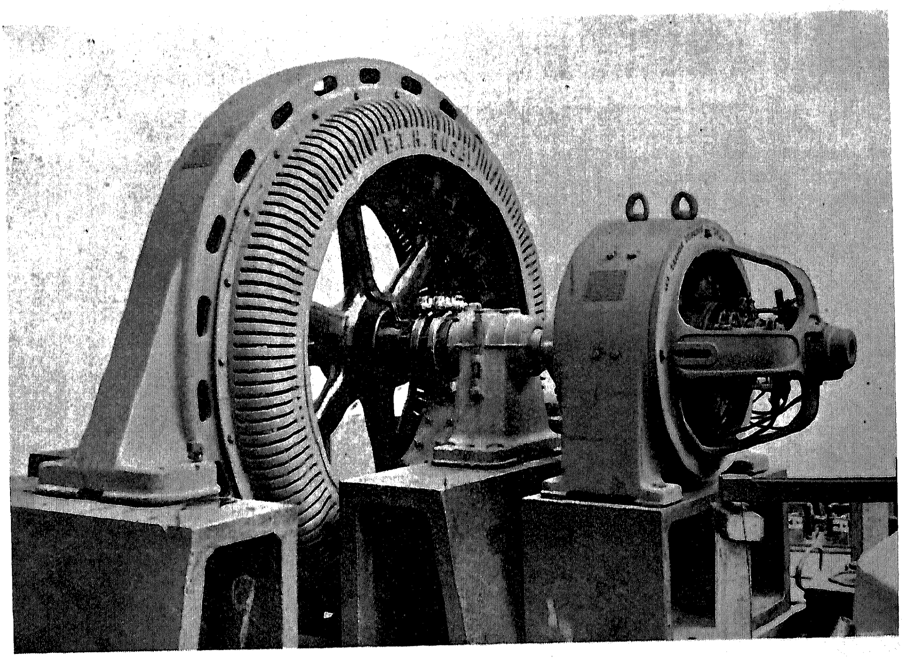

Fig. 39.

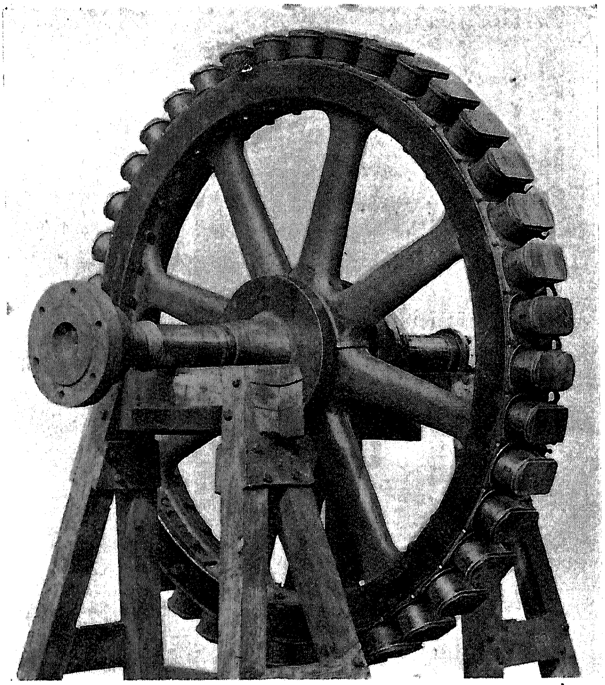

FIG. 40.

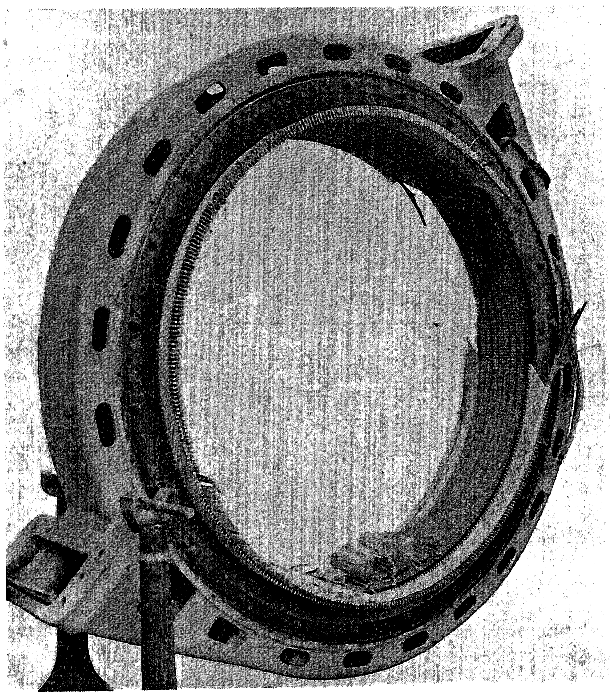

FIG. 41.

which have to be very strongly constructed as the waterwheel is liable to run away if the load is suddenly removed, and construction has to be sufficiently robust so that the machine

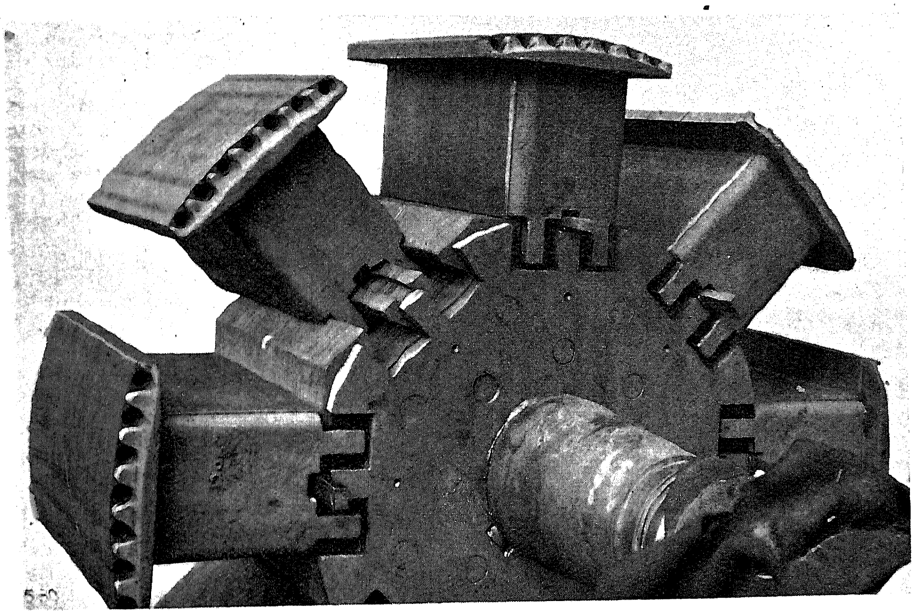

FIG. 42.

will hold together even at speeds twice the usual speed. The construction of rotor used on such machines is shown on *Figs.* 42 and 43.

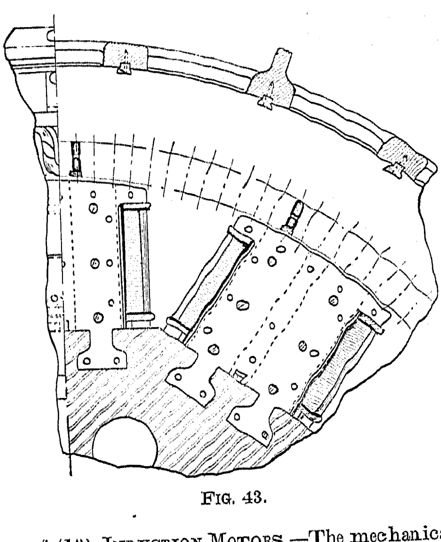

FIG. 43.

§ (13) INDUCTION MOTORS.—The mechanical construction of a typical induction motor is shown on the attached sectional drawing (*Fig.* 44).

The stator consists of a ring of laminations slotted on the inside and carrying the primary windings. The windings are arranged in groups corresponding to the number of phases and number of poles. The form of windings

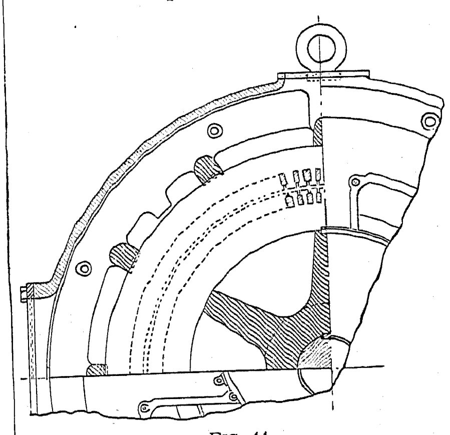

FIG. 44.

depends on the size of the motor and voltage of supply. For small machines, and some high-voltage machines, the conductors consist of round wires formed into coils, and for larger machines the conductors consist of rectangular

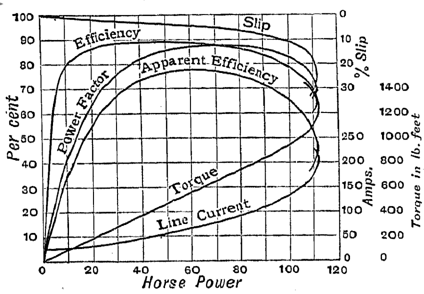

FIG. 45.

bars. The rotor consists also of a ring of punchings of a lesser radial depth than the stator, as higher flux densities can be allowed in the rotor. The rotor winding is usually arranged for low voltage, and consists either of a set of bars short-circuited at their ends by rings, or of rectangular bars connected up to form groups corresponding to the number of poles and phases.

The speed at which the magnetic field of an induction motor revolves, expressed in revolutions per minute, is obtained by multiplying the frequency in periods per second by 120, and dividing by the number of poles; for example: an 8-pole, 50-cycle motor will have

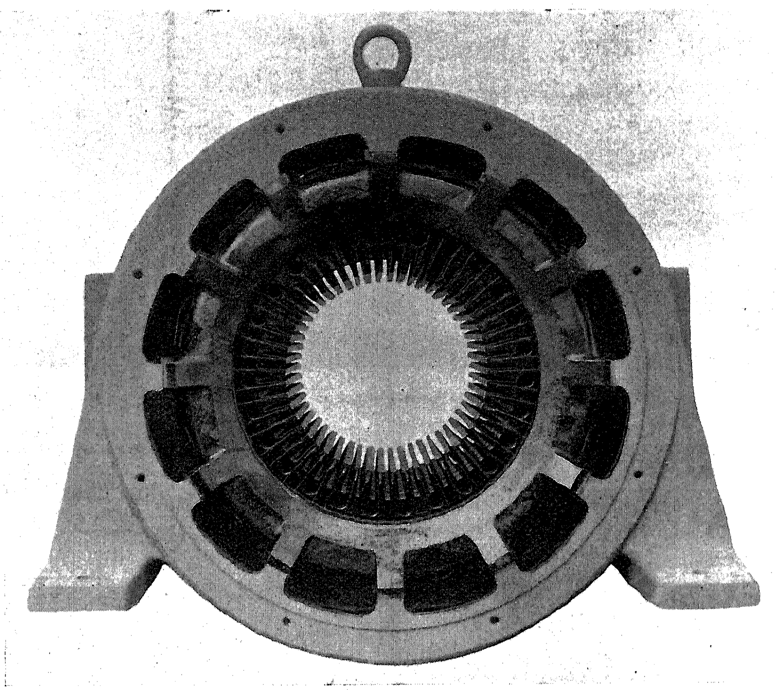

FIG. 46.

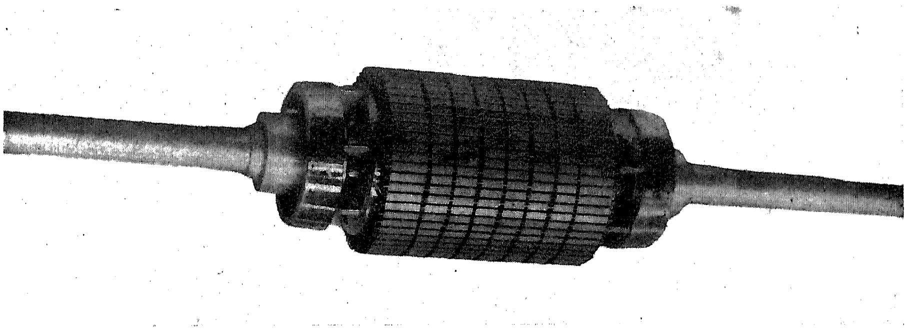

FIG. 47.

a speed of 750 revolutions per minute. The rotor will revolve at approximately this speed when the motor is unloaded, and will have a slower speed when fully loaded. The difference of speed or slip amounts to 2 or 3 per cent in large motors, and about double this amount in small motors.

A curve sheet showing the performance of an induction motor is shown on *Fig.* 45.

An unwound stator is shown on *Fig.* 46, and an unwound rotor in *Fig.* 47. The stator consists of a cast-iron frame with feet. The laminations are carried in this frame and firmly held in place by heavy cast-iron end flanges. The completely wound stator is shown in *Fig.* 48. The coils in this machine are all of the same shape and nest into one another at the ends, forming a basket-like construction. The terminals of the three phase are seen on the near side of the stator frame.

A completely wound rotor is shown on *Fig.* 49.

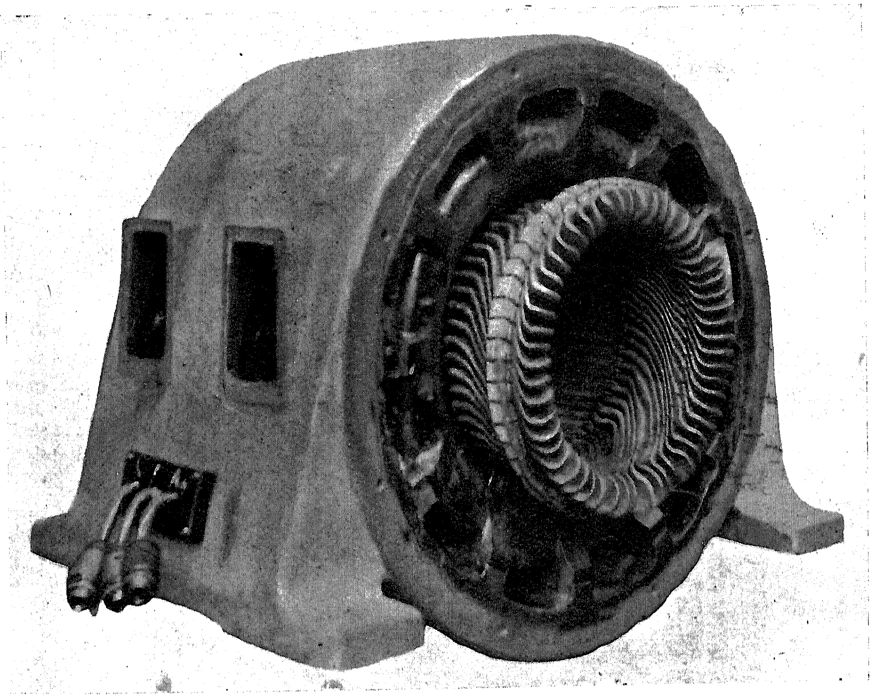

FIG. 48.

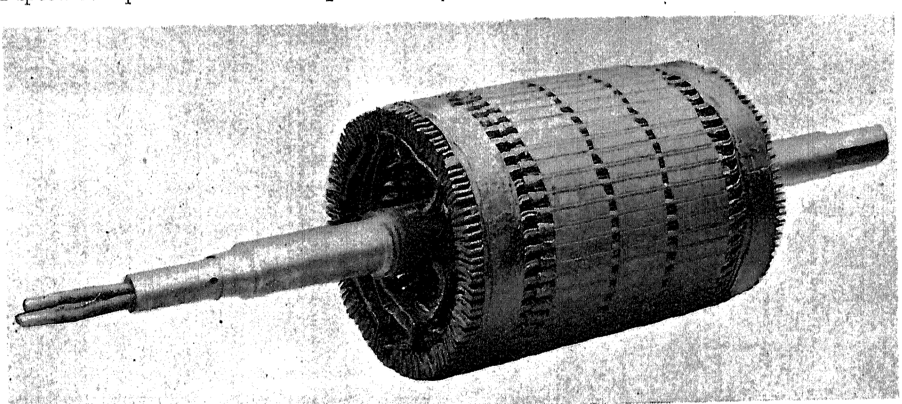

FIG. 49.

A short-circuited or " Squirrel Cage " type of rotor is shown on *Fig.* 50. In this particular rotor the bars are electrically welded to the end short-circuiting ring, so that the whole structure is practically a jointless piece of copper. It has been mentioned already that a squirrel cage induction motor will give a reasonable starting torque at the expense of a large starting current. A motor of normal size and construction will take about five to six times normal current when connected to the mains, provided the supply voltage remains normal. This large current will cause heavy losses in the windings—six times normal current will cause thirty-six times normal losses. Provided this initial rush of current is not detrimental to the voltage regulation of the supply system, the limit of ability to withstand such a current lies in the motor itself, and usually in the rotor winding, as the current density is usually higher in the rotor bars than in the stator winding. Joints in the winding are a source of trouble, as obviously soldered joints are not always suitable if the winding is liable to be overheated, and bolted joints are likely to become loose. The welded rotor illustrated is

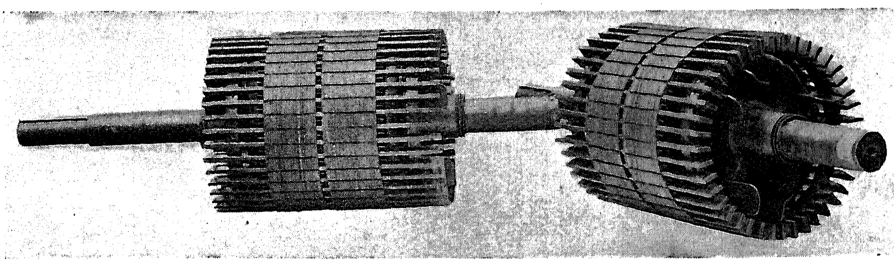

FIG. 50.

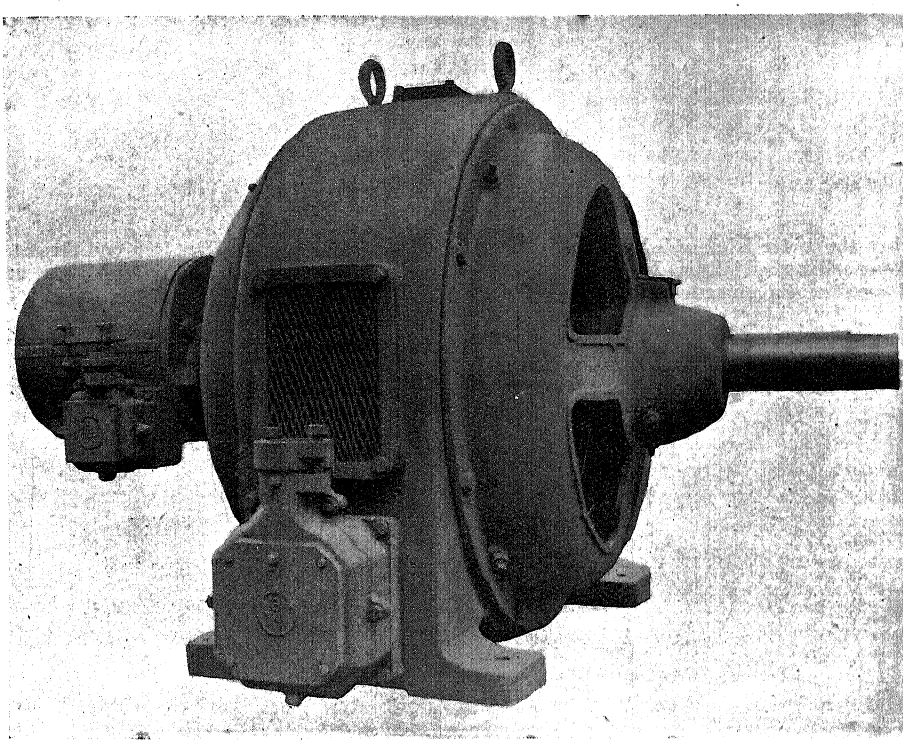

FIG. 51.

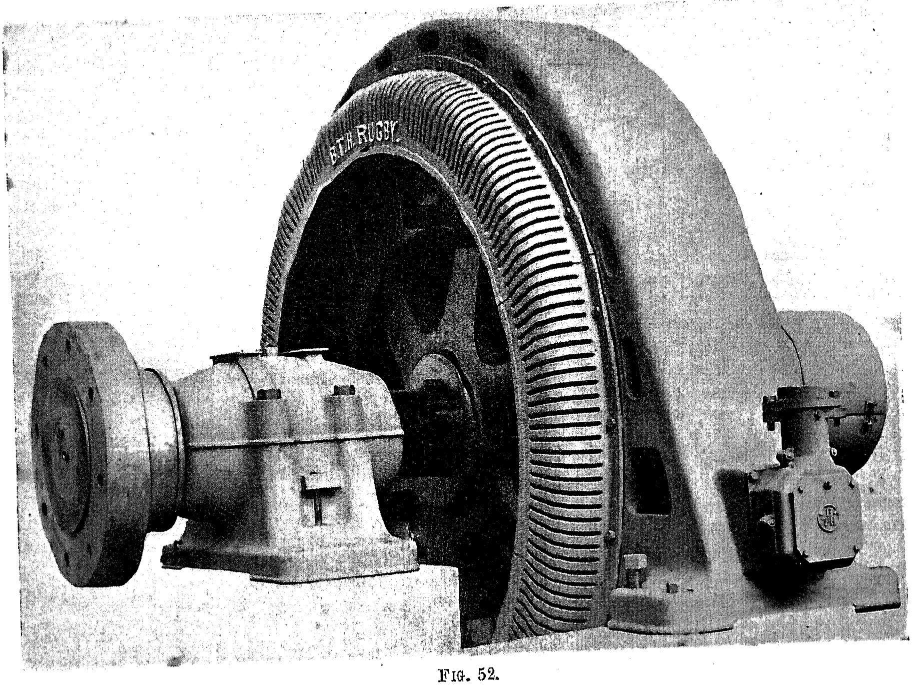

FIG. 52.

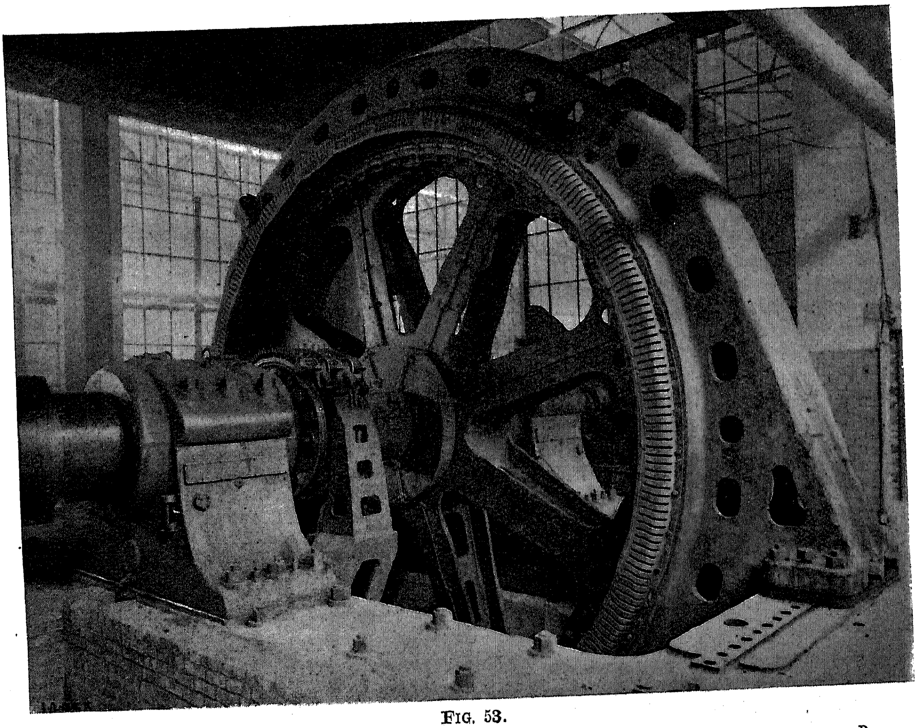

FIG. 53.

most suitable for withstanding the momentary overheating which may occur at starting. It can be shown that the amount of energy dissipated in a rotor winding is equal to the amount of mechanical work done in accelerating a machine up to full speed, but if the motor has to start against a load torque, the amount of loss in the rotor will be more.

Where a motor is only required to start against a comparatively small load, the voltage at the terminals is sometimes reduced at starting and raised again when the motor has attained full speed. A convenient way to do this is to use a small transformer and a throw-over switch, or the windings can be connected $\curlywedge$ when starting, and changed to Δ for running. This arrangement reduces the starting voltage to 58 per cent, and the initial rush of current to one-third of what it would be if started at full voltage.

Where it is necessary to keep the starting current low, and where large starting torques are required, a phase-wound rotor is used. Such a motor is illustrated in *Fig.* 49. The ends of the phase are connected to slip-rings on which carbon or graphite brushes make contact, and resistance is introduced during the starting.

The rings are sometimes short circuited when the motor has attained full speed in order to avoid the contact losses in the brushes and rings. Illustrations of typical induction motors are given in the figures on pp. 208, 209: *Fig.* 51 shows a small motor used for general industrial purposes; *Fig.* 52 is a large motor with separate bearings; and *Fig.* 53 is a motor for driving a continuous steel-rolling mill. This motor is rated at 5000 H.P. at a synchronous speed of 92 revolutions per minute and a maximum output of 12,000 H.P. at about 90 r.p.m. The corresponding torques are $3 \cdot 45 \times 10^6$ inch-lbs. and $8 \cdot 45 \times 10^6$ inch-lbs.

Effective Value. The effective value of any quantity is the square root of the mean square of that quantity. If the quantity vary harmonically and be given by an equation such as $i = \mathrm{I} \sin \omega t$, then the effective value $\bar{\mathrm{I}}$ is given by the equation

$$\bar{\mathrm{I}} = \frac{\mathrm{I}}{\sqrt{2}} = 0 \cdot 7071 \times \mathrm{I}.$$

For $\quad i^2 = \mathrm{I}^2 \sin^2 \omega t = \dfrac{\mathrm{I}^2}{2}(1 - \cos 2\omega t),$

and the mean value of $\cos 2\omega t$ is zero. Hence

$$\bar{\mathrm{I}} = \sqrt{(\text{mean value of } i^2)} = \frac{\mathrm{I}}{\sqrt{2}}.$$

Electric Charge. See "Units of Electrical Measurement," §§ (2), (3).

Electric Discharge through Gases, at low pressures. See "Electrons and Discharge Tube," § (1).

Electric Displacement: the value of the quantity $KR/4\pi$ where R is the electric intensity and K the inductive capacity at any point of an electrical field. See "Units of Electrical Measurement," § (13).

Electric Field: the portion of space in the neighbourhood of a charged body or current throughout which the electric forces to which it gives rise to are sensible.

Electric Force or Intensity. The force in dynes experienced by a unit charge of positive electricity concentrated at any point in an electric field measures the electric force or intensity of the field at that point. The assumption is made that the presence of the charge does not disturb the field. See "Units of Electrical Measurement," § (2).

Electric Oscillations, damping of, due to radiation and resistance. See "Wireless Telegraphy," § (7).

Electric Potential at a Point. The work necessary to bring a unit of positive electricity from beyond the boundary of the field to the point, without disturbing the existing electrical distribution, measures the potential at the point. See "Potential."

Electric Stress as a limitation to the use of dielectrics. See "Dielectrics," § (9).

Dynamics of. See *ibid.* § (2).

Electric Waves, detectors of, for use in wireless telegraphy. See "Wireless Telegraphy," § (18).

Production of, by the acceleration of a moving charge. See *ibid.* § (1).

Production of, on engineering scale. See *ibid.* § (11).

Electrical Extraction and Refining of Metals. See "Electrolysis, Technical Applications of," VI. §§ (15)-(23).

Electrical Intensity, definition of. See "Electrostatic Field, Properties of," § (7); "Units of Electrical Measurement," § (12).

Distribution of, in discharge tube. See "Electrons and Discharge Tube," § (3).

ELECTRICAL MEASUREMENTS, SYSTEMS OF

§ (1) Fundamental Units.—All electrical measurements are founded on one of two systems, and each of these, when complete, requires four fundamental units. The fundamental units in each of the two systems are those of length, mass, time, and a property of the electromagnetic medium. In the first, or electromagnetic system, the property of the medium utilised is magnetic permeability, and in the second, or electrostatic system, the dielectric constant is used. Frequently, for convenience, these properties are assumed to be of zero dimensions, but really the dimensions are not known.[1]

In mechanics there are only three fundamental units, those of length, mass, and time, and these three would probably serve for a system of electrical measurements if the identity of electrical and mechanical phenomena could be established. This, however, is not possible without knowing the dimensions of "magnetic permeability" and "dielectric constant." The electromagnetic and electrostatic systems of measurement, in common with all others in which length, mass, and time are fundamental units, are called "absolute" systems, and because the units of length, mass, and time generally chosen are the centimetre, the gram, and the second respectively, the systems are also referred to as "Centimetre Gram Second" systems, or more briefly "C.G.S." systems.

§ (2) Definitions.—In the electromagnetic system, unit electric current is defined as that of which the unit length at a unit distance from the unit magnetic pole exerts on the latter a unit of force, the unit magnetic pole being defined as that which exerts unit force on a similar pole at unit distance; the medium

[1] See "Units of Electrical Measurement," § (3).

is supposed to be a vacuum. In the electrostatic system unit current is that which conveys the unit quantity of electricity in unit time, unit quantity being defined as that which exerts unit force on an equal quantity at unit distance. Again the medium is supposed to be a vacuum.

Starting from these two definitions Weber first framed two distinct systems of electrical measurements. Subsequently, Professor W. Thomson (later Lord Kelvin) defined a unit of work on Weber's system and thus allowed all physical measurements to be connected together. Of the two systems of electrical measurements, the electromagnetic one is more convenient than the other for general purposes and is the one used in electrical engineering.

The value of such systems for quantitative measurements cannot be over-estimated. If, instead, units had been arbitrarily chosen, the relations between them would still exist, and by the use of coefficients it would be possible to pass from one kind of measurement to another, but the number and complexity of these coefficients would make such a choice inexcusable.

§ (3) Electrical Units. — The electrical phenomena susceptible of direct measurement are Quantity, Current, Resistance, and Electromotive Force. With respect to Quantity, it has been found by experiment that two equal and similar quantities of electricity concentrated in two points repel one another with a force (F) directly proportional to the quantity (Q), inversely proportional to the square of the distance (d) between the points, and inversely proportional to a quantity called the dielectric constant (K) which varies with the medium. The equation representing the facts is

$$F=\frac{Q^2}{Kd^2}. \quad . \quad . \quad . \quad . \quad (1)$$

(i.) *Electrostatic.*—In the electrostatic system K is usually taken as of unit value in a vacuum, and in such a case the unit of quantity is that which exerts a force of one dyne upon an equal quantity, the two being collected at points one centimetre apart in a vacuum.

With regard to Current, it has been experimentally proved (first by Faraday) that the quantity (Q) of electricity conveyed by any given current (I) is simply proportional to the strength of the current and to the time (t) during which it flows. Hence we have the equation

$$Q=It. \quad . \quad . \quad . \quad . \quad (2)$$

The mechanical effects observed in connection with electricity give the connection between electrical and mechanical units. Whenever a current flows through any circuit it performs work, or produces heat or chemical action equivalent to work, and it has been experimentally proved that the work (W) done is directly proportional to the square of the current (I), to the time (t) during which it acts, and to a quantity known as the resistance (R) of the circuit, which can be proved to be constant so long as the physical conditions are unaltered. This is expressed by the equation

$$W=I^2Rt. \quad . \quad . \quad . \quad (3)$$

It follows that the unit current flowing for a unit of time will perform a unit of work (1 erg) in a circuit of unit resistance.

By experiment, Ohm's law connecting current (I), electromotive force (E), and resistance (R) has been verified, the equation being

$$I=\frac{E}{R}. \quad . \quad . \quad . \quad . \quad (4)$$

From this it follows that the unit electromotive force is that which produces the unit current in a circuit of unit resistance.

If the dielectric constant K of air be assumed to be equal to unity, equations (1) to (4) suffice to measure all electric phenomena by reference to length, mass, and time. Otherwise expressed, it is possible to determine Quantity, Current, Resistance, and Electromotive Force, by reference to Mechanical Units only. Equation (1) determines Quantity in terms of a Force and a distance, and since Force is measured in terms of a mass, length, and time, Electric Quantity can be expressed in a Length-Mass-Time system. Equation (2) determines Current in terms of Quantity and Time. Equation (3) gives Resistance in terms of Current, Time, and Work, and since the last is measured in terms of a Force and a Length it follows that Electric Resistance can also be measured by reference to mechanical units. Lastly, (4) gives Electromotive Force in terms of Current and Resistance. It is clear, therefore, that the system is a coherent one enabling measurements of Quantity, Current, Resistance, and Electromotive Force to be measured in terms of Length, Mass, and Time.

The units based on these four equations are called electrostatic units and are little used, except in electrostatics. The system is founded on a statical phenomenon, the force between two electric charges, and this is not the most convenient scheme for dealing with the many dynamical applications of electricity.

(ii.) *Electromagnetic.*—Now the force exerted by a current on the pole of a magnet in its vicinity is a purely mechanical effect. This force (F) has been experimentally proved to be proportional to the strength of the current (I) and to the strength of the magnetic pole

(m). Further, if the current be at all points at the same distance from the magnetic pole, that is, if the conductor conveying the current is bent in a circle of radius r round the pole, the force is proportional to the length (L) of the conductor and inversely proportional to the square of the distance (r). This relation is expressed by the equation

$$F=\frac{ILm}{r^2}. \qquad (5)$$

From which it follows that in this the Electromagnetic System the unit current is that of which the unit length everywhere at a unit distance from a unit magnetic pole exerts on the latter the unit force (1 dyne).

In a manner similar to that for the electrostatic unit of quantity the magnetic pole strength (m) is defined as that which exerts unit force upon an equal magnetic pole, the two being at points 1 cm. apart *in vacuo* which is assumed to be of unit magnetic permeability. If the medium be of magnetic permeability μ, we have the general equation

$$F=\frac{m^2}{\mu d^2}. \qquad (6)$$

If μ is supposed to have no dimensions and the equations (2), (3), (4), (5), and (6) are adopted as fundamental, they give a distinct system of units called the Electromagnetic System. The Electromagnetic System and the Electrostatic System are both absolute inasmuch as all measurements in them can ultimately be referred to the fundamental units of Length, Mass, and Time. As previously stated, the electromagnetic units are found much the more convenient when dealing with electromagnetic phenomena, and it is this system which is most generally used.

§ (4) Practical Electromagnetic Units.—The units of resistance, of electromotive force, and others in the electromagnetic system are either too large or too small to be convenient in practice. Definite multiples or sub-multiples of these units are therefore used. Some of these practical units and their relation to the C.G.S. units are given below:

	Name of Practical Unit.	Value of Practical Unit.
Resistance	Ohm	10^9 C.G.S. units
Current	Ampere	10^{-1} ,,
Electromotive Force	Volt	10^8 ,,
Quantity	Coulomb	10^{-1} ,,
Capacity	Farad	10^{-9} ,,
Inductance	Henry	10^9 ,,

These practical units are consistent with the four fundamental units, 10^9 centimetres, 10^{-11} gram, one second, and unit magnetic permeability of a vacuum. In this system the Ohm, Ampere, and Volt are of convenient size, but such units as the Farad are inconvenient; the microfarad is generally used instead of the Farad as the unit of capacity. The unit of dielectric constant in this system is 10^{18} C.G.S. unit and is never used; the dielectric constant is always given in electrostatic units.

§ (5) Dimensions of the Electrical Units.—Every quantity which is measured is given a name consisting of two parts or factors. The first is a number and the second is the name of an agreed unit of measurement. Thus we have 14 grams, 50 centimetres, 20 seconds, etc. The gram, centimetre, and second are the names of the units or standards of mass, length, and time, and the numbers 14, 50, and 20 denote the number of such units in the quantity measured. The units of length, mass, and time are usually designated by [L], [M], and [T] respectively, and are independent and fundamental. The electrical units we have seen can be expressed in terms of these, but as they are derived units it is necessary to know at what power each of the fundamental measurements enters into a derived measure. Thus velocity is measured in units of length divided by units of time and the powers of the fundamental measures of length and time in the derived unit of velocity are 1 and -1 respectively. Put otherwise, the dimensions of velocity are $[L/T]$ or $[L^1T^{-1}]$. Acceleration is the rate of change of velocity and the dimensions of the unit of acceleration are $[LT^{-1}T^{-1}]$ or $[LT^{-2}]$.

The product of a mass into an acceleration gives the number of units of Force required to produce the given acceleration in the given mass. The dimensions of the latter are therefore $[MLT^{-2}]$. From equations (1) to (6) the dimensions of the electrical units in the electromagnetic system may readily be obtained. Thus from equation (6) $[MLT^{-2}]=[m^2L^{-2}\mu^{-1}]$. Hence, the dimensions of m, the unit Magnetic Pole, are $[L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-1}\mu^{\frac{1}{2}}]$. From equation (5) we have $[MLT^{-2}]=[ILL^{\frac{3}{2}}M^{\frac{1}{2}}T^{-1}\mu^{\frac{1}{2}}L^{-2}]$. Hence the dimensions of I, the unit of Current, are $[L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\mu^{\frac{1}{2}}]$. Similarly, from equations (3), (4), and (5) it is easy to find that the dimensions of the unit of Resistance are $[LT^{-1}\mu]$; the dimensions of the unit of Electromotive Force are $[L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}\mu^{\frac{1}{2}}]$; and the dimensions of the unit of Quantity are $[L^{\frac{1}{2}}M^{\frac{1}{2}}\mu^{-\frac{1}{2}}]$. They all involve μ. Similarly, dimensions of the units in the electrostatic system may be written down. These dimensions are indeed given in Table I. and it will be observed that all include K.

TABLE I

DIMENSIONS OF ELECTRICAL UNITS IN THE ELECTROSTATIC AND ELECTROMAGNETIC SYSTEMS

L = Length. M = Mass. T = Time.
μ = Magnetic Permeability. K = Dielectric Constant.

Unit.	Symbol.	Dimensional Formulae.	
		Electrostatic.	Electromagnetic.
Quantity	Q	$\left[\frac{L^{\frac{3}{2}} M^{\frac{1}{2}} K^{\frac{1}{2}}}{T}\right]$	$\left[\frac{L^{\frac{1}{2}} M^{\frac{1}{2}}}{\mu^{\frac{1}{2}}}\right]$
Dielectric Constant	K	$[K]$	$\left[\frac{T^2}{L^2 \mu}\right]$
Current	I	$\left[\frac{L^{\frac{3}{2}} M^{\frac{1}{2}} K^{\frac{1}{2}}}{T^2}\right]$	$\left[\frac{L^{\frac{1}{2}} M^{\frac{1}{2}}}{T\mu^{\frac{1}{2}}}\right]$
Resistance	R	$\left[\frac{T}{LK}\right]$	$\left[\frac{L\mu}{T}\right]$
Electromotive Force	E	$\left[\frac{L^{\frac{1}{2}} M^{\frac{1}{2}}}{TK^{\frac{1}{2}}}\right]$	$\left[\frac{L^{\frac{3}{2}} M^{\frac{1}{2}} \mu^{\frac{1}{2}}}{T^2}\right]$
Magnetic Pole Strength	m	$\left[\frac{L^{\frac{1}{2}} M^{\frac{1}{2}}}{K^{\frac{1}{2}}}\right]$	$\left[\frac{L^{\frac{3}{2}} M^{\frac{1}{2}} \mu^{\frac{1}{2}}}{T}\right]$
Magnetic Permeability	μ	$\left[\frac{T^2}{L^2 K}\right]$	$[\mu]$
Capacity	C	$[KL]$	$\left[\frac{T^2}{L\mu}\right]$
Self Inductance / Mutual Inductance	L / M	$\left[\frac{T^2}{LK}\right]$	$[L\mu]$

§ (6) RATIO OF UNITS.—According to the definition of the unit magnetic pole the magnetic permeability μ of vacuous space is unity, and according to the definition of the unit charge the dielectric constant K of vacuous space is also unity. Now, although we have every right to make these assumptions separately, they cannot be made simultaneously since μ and K are really related. Hence unless μ and K are always inserted in formulae and equations the two systems of units are distinct the one from the other. It is clear from Table I. that the unit of quantity in the electromagnetic system is $1/\sqrt{K\mu}$ times greater than the unit of quantity in the electrostatic system. Further, since the dimensions of electric quantity must be the same however measured, the dimensional expressions for electric quantity in the two systems must be equal. Hence

$$\left[\frac{1}{\sqrt{K\mu}}\right] = \left[\frac{L}{T}\right].$$

The same relation may be obtained by equating the dimensional expressions in the two systems for any electric quantity. The equations do not enable us to find the dimensions of K or of μ, but it follows that $1/\sqrt{K\mu}$ has the dimensions of a velocity. This velocity is usually denoted by v; as already shown,[1] it is the ratio of the Electromagnetic Unit of Quantity to the Electrostatic Unit of Quantity. Its value is 3×10^{10} cm. per sec.

Maxwell proved theoretically that $1/\sqrt{K\mu}$ is the velocity of an electromagnetic wave in air, and when such waves were produced by experiment and their velocities measured, the prediction was verified. Further, it has been experimentally proved that $1/\sqrt{K\mu}$ is also the velocity of light, and that light is an electromagnetic phenomenon.

§ (7) VALUES ADOPTED FOR THE UNITS.—The Absolute or C.G.S. system of units, while being ideal inasmuch as they are independent of the physical properties of any material, was, almost from the time it was suggested until the last few years, deemed by many to be impracticable, owing to the necessarily limited accuracy of absolute measurements.

At the first meeting in 1862 of the Electrical Standards Committee of the British Association the question was very carefully considered, and it was recognised as desirable to refer results to concrete standards, made to represent as nearly as possible the C.G.S. units or multiples of them. The unit of measurement and the standard of reference thus became distinct things, and the general policy for the past sixty years has been to have reference standards, but to adjust them from time to time so as to more nearly approach the C.G.S. units or multiples of the units. In recent years, however, absolute measurements of electrical resistance and current have been made with an accuracy in excess of all commercial requirements, and in the opinion of many scientific workers it is no longer necessary or desirable to state values in terms of such concrete standards as are in use. The precision required in practice being less than that it is possible to obtain in absolute measurements, it is satisfactory in every way to give values in terms of the C.G.S. units or multiples of the units.

§ (8) ABSOLUTE MEASUREMENTS.—The three fundamental electric units are the Ohm, Ampere, and Volt, and since these are related by Ohm's Law the accurate measurement of any two of them fixes the third.

I. ABSOLUTE MEASUREMENT OF RESISTANCE.

§ (9) THE OHM (10^9 C.G.S. UNITS).—Various methods for the absolute measurement of resistances have been used, and experiments based on these have been carried out with

[1] See "'v,' the Ratio of the Units."

very great care. It is difficult to compare accurately the results obtained owing to the variety of concrete standards in terms of which the results are expressed. In some cases mercury columns of known dimensions and temperature were used, but in the majority of cases coils of wire were employed as reference standards.

In the electromagnetic system, taking μ as unity, resistance has the dimensions of a velocity, and any method devised for the absolute measurement of a resistance must therefore involve measurements of length and time, or measurements of other quantities having length and time in their dimensional formulae.

Referring to Table I., when $\mu=1$, Inductance has the dimension [L], and it is largely by the use of inductances combined with measurements of time that all absolute measurements of resistance have been made.

§ (10) KIRCHOFF'S METHOD.—Two coils a and b (Fig. 1), between which there is a mutual inductance M, are connected to a battery B, a

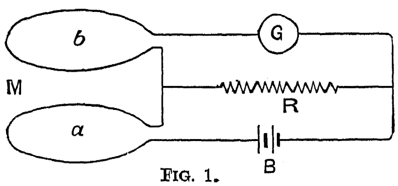

FIG. 1.

galvanometer G, and a resistance R, the value of which is desired. With the circuit closed the *steady* deflection of G is first measured. The mutual inductance M is then reduced to zero by a change in position of one of the coils and the galvanometer kick observed together with the logarithmic decrement.

Kirchoff's first measurement, which was made in 1849, has only historical value. Rowland (*American Journal*, 1878, xv.) improved the method by reversing the current through the coil a instead of removing the coil b; in this case the quantity of electricity passing through the ballistic galvanometer is twice that given above. Glazebrook, Sargant, and Dodds also reversed the current through the coil a and further modified the method by using the same galvanometer for measurement of the steady and induced currents. A shunt was employed for the measurement of the steady current.

In the last case let M be the coefficient of mutual inductance between the coils, T the period of the galvanometer needle, α the deflection due to the primary current, β the throw due to the induced current, and h the factor by which the deflection α must be multiplied in order to correct for the shunting of the galvanometer. Then, if i be the current and G the galvanometer constant,

$$\frac{Mi}{R}=\frac{GT}{\pi}\sin\tfrac{1}{2}\beta, \quad \text{and } i=hG\tan\alpha.$$

Hence the resistance of the secondary circuit in absolute measure is given by

$$R=\frac{Mh\pi}{T}\cdot\frac{\tan\alpha}{\sin\frac{1}{2}\beta}.$$

M/T is of the dimensions of a velocity and $h\pi\tan\alpha/\sin\frac{1}{2}\beta$ is merely a ratio.

The original difficulty lay in the calculation of M with the necessary precision, but, as Glazebrook pointed out in 1890, it should be possible to determine M within 1 or 2 parts in 10,000. Lord Rayleigh showed (*Phil. Mag.*, 1882) that the attainable precision largely depends on the ratio of the diameters of the coils to their distance apart. If the mutual inductance were of the Campbell form (*Roy. Soc. Proc.* A, 1907, lxxix.), the measurements of the diameter and distance apart of the coils could be made with sufficient accuracy to enable M to be calculated within 1 or 2 parts in 100,000. The method is subject to whatever uncertainty attaches to the use of a ballistic galvanometer (*Roy. Soc. Phil. Trans.*, 1882, p. 669), and this probably is where improvement is most desirable. For educational purposes the method is simple.

(i.) *Experiments.*—The induction coils used in Rowland's experiments were wound on brass bobbins. Three coils were used, the mean radii being respectively 13·710 cm., 13·690 cm., and 13·720 cm. These were used two at a time, the bobbins having carefully ground ends so that they could be fitted end to end with their axes in line. The constant of the ballistic galvanometer was determined first by calculation from its dimensions and afterwards by comparison with that of a large double coil of an electrodynamometer constructed on the Helmholtz-Gaugain plan. After a comparison the instruments were interchanged in position so as to eliminate any difference between the values of H at the two places. The probable error in determining this constant appears to have been about 1 part in 10,000. A tangent galvanometer with a circle 50 cm. in diameter was used for measuring the direct current and its constant was compared with that of a single circle of wire about 83 cm. in diameter.

In Glazebrook's experiments (*Roy. Soc. Phil. Trans.*, 1883) no separate measurements for eliminating variations in H were necessary owing to the use of one galvanometer. The coils used by Glazebrook had a mean radius of about 26 cm. and all dimensions were carefully measured. The positions of the mean planes were estimated from the axial breadth of a coil, and any doubt as to the

exact positions was removed by reversal of the bobbins relative to the gauge pieces between them. Each experiment included 8 observations of induced current and 2 of steady current deflection, and these observations were made for each of the four positions in which the coils could be placed by reversing them without changing the distance between their centres.

Further measurements were made by Rowland (*La Lumière Électrique*, 1887, xxvi.) in 1884.

(ii.) *Results.*—In 1878 Rowland made comparisons with certain resistance coils the values of which had been given in B.A. units and concluded that 1 B.A. unit $=0{\cdot}9911 \times 10^9$ C.G.S. units.

Glazebrook made comparisons with standard coils known in B.A. units and gave as the mean of all his results (B.A. Report, 1890) 1 B.A. unit $=0{\cdot}98665 \times 10^9$ C.G.S. units.

In 1884 Rowland found 1 B.A. unit to be equal to $(0{\cdot}98627 \pm 40)\ 10^9$ C.G.S. units.

§ (11) Roiti and Himstedt's Method.—Himstedt (*Wied. Ann.*, 1886, xxviii.) modified Kirchoff's method so that it was not the first deflection produced by the induced current that was measured. The primary and galvanometer circuits (Fig. 2) were separate and were made and

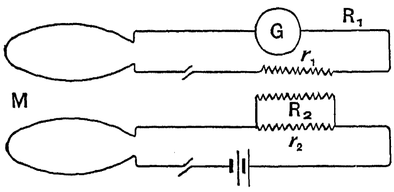

Fig. 2.

broken in rapid succession by circuit breakers. The frequencies of make and break were the same, but the times were so adjusted that the current passing through the galvanometer was either the induced current at make or that at break. A stationary deflection α_1 of the galvanometer was thus obtained, the relation being very approximately

$$G \tan \alpha_1 = \frac{niM}{R_1 + r_1},$$

n being the frequency of the interruptions, i the primary current, M the mutual inductance between the circuits, and $R_1 + r_1$ the resistance of the secondary circuit.

The resistances r_2 and R_2, which are equal respectively to r_1 and R_1, are now removed and r_1 and R_1 substituted. The value of the current is undisturbed and the deflection α_2 of the galvanometer is such that

$$G \tan \alpha_2 = \frac{r_1 i}{R_1 + r_1}.$$

Combining this with the previous equation we have

$$r_1 = nM\frac{\tan \alpha_2}{\tan \alpha_1}.$$

The principal difficulty is that connected with the galvanometer when used to measure an interrupted current.

(i.) *Experiments and Results.*—Roiti in 1884 used an interrupted current method and found 10^9 C.G.S. units of resistance to be equal to that of a column of mercury 105·896 cm. long and 1 sq. mm. in cross-section, all at 0° C.

Himstedt (1886) found that a column of mercury 106·08 cm. long and 1 sq. mm. cross-section at 0° C. had a resistance of 10^9 C.G.S. units.

§ (12) Weber's Method of Transient Currents.—A large coil of effective area A (the sum of the areas enclosed by the turns) is mounted with its plane in the magnetic meridian and is capable of being rotated about a vertical axis. Included in the circuit of the coil is a ballistic galvanometer of known constant. To measure the total resistance of the circuit the coil is rapidly turned about its vertical axis through half a revolution. If H is the horizontal magnetic intensity in the position of the coil, the total change of induction is 2AH and the total quantity of electricity which flows through the circuit is 2AH/R. If N is the number of turns on the galvanometer, a the radius, T the period of the needle, and θ the deflection (corrected for damping) produced by the flow of the quantity of electricity 2AH/R, then

$$R = \frac{A}{aT}\frac{4\pi^2 N}{\sin \frac{1}{2}\theta} \cdot \frac{H'}{H},$$

where H is the horizontal magnetic intensity in the position of the galvanometer.

If $H' = H$, the formula is correspondingly simplified. The part A/aT is of the dimensions of a velocity, the remaining portion being merely a ratio.

There is a difficulty in ensuring that the axis of rotation is vertical, and Lord Rayleigh pointed out that it was a decided advantage to carry out measurements near to the magnetic equator. Glazebrook (*Electrician*, 1890) showed that the effect of the time of duration of the induced current was important. He showed that if the effect of the induced current was prolonged for one second, the period of the galvanometer needle being twenty-three seconds, the deflections are reduced by 0·1 per cent.

For absolute measurements of resistance the method is not recommended, but an adaptation is of interest to students and teachers for measuring the horizontal and vertical intensities of the earth's magnetic field.

(i.) *Experiments.*—Measurements were made by Weber himself, and later by Weber and

F. Zöllner. These latter used in their experiments coils as large as one metre in diameter. The method of recoil was used. Turning the coil first through 180° from the initial position, the first deflection (positive, say) was observed. The needle then swings through its zero position to the negative side and back again to zero. At the instant the needle arrives at zero the second time the coil is turned back to its original position, thus reversing the motion of the needle, which swings to a maximum deflection on the negative side, then back again to the positive side, and as it passes again through zero the coil is again turned through 180°, and so on.

In the experiments made by Weber and Zöllner galvanometer magnets 20 cm. and 10 cm. long were used and the results obtained in the two cases differed by 2 per cent. It is obvious that the needles were far too long. However, the measurements were largely intended as a test of the apparatus.

Later with the same coils Wiedemann (Wiedemann's *Elektricität*, Band 4, p. 913) made a careful determination at Leipzig. The needle was small and carried beneath it an arrangement on which weights could be placed to alter the moment of inertia of the suspended system. Instead of the method of recoil being used, the method of multiplication was employed. (Maxwell, *Elec. and Mag. Art.* § 747 and § 751.) An arrangement of stops was provided enabling the coil to be turned quickly through 180° and back again. The coil was turned suddenly a number of times in succession through this angle, always when the needle had returned to its zero position, so that the deflections were multiplied as far as the limits of the scale would allow. To express the unit of resistance in terms of the resistance of a mercury column, observations were made with and without ten Siemens mercury units in circuit with the coils.

Mascart, De Nerville and Benoit (*Ann. de Chemie et de Phys.*, 1885) have also employed the method, using two coils about 15 cm. in diameter and three coils about 30 cm. in diameter. Both the smaller and larger coils were mounted to admit of being turned through exactly 180°, and at the centre of the larger coil was suspended a small magnetometer needle. By turning the coil round a vertical axis through 90° from its position when arranged for inductive use, it could be used as a galvanometer coil and its constant compared with that of the galvanometer used in the experiments. Thus H/H′ was accurately determined.

(ii.) *Results.*—Wiedemann found that 106·162 cm. mercury 1 sq. mm. in cross-section at a temperature of 0° C. had a resistance of 10^9 C.G.S. units.

Mascart, De Nerville and Benoit found 10^9 C.G.S. units $=1{\cdot}0142$ B.A. unit, or 106·37 cm. mercury of cross-section, etc., as above had a resistance of 10^9 C.G.S. units.

§ (13) Weber's Method of Damping.—A magnet of considerable magnetic moment is oscillated at the centre of a coil, first when the circuit of the coil is open, and again when the circuit is closed. The period of vibration and the logarithmic decrement of the oscillations are observed. In the case when the circuit of the coil is closed the motion of the magnet sets up currents in the coil which react on the magnet and damp its motion. The resistance R of the coil circuit is deduced from the effect which the currents induced in it by the motion of the magnet have in resisting that motion. R is given by the expression (see Gray's *Absolute Measurements*, vol. ii. part ii.)

$$\mathrm{R}=\frac{\mathrm{M}^2\mathrm{G}^2}{2\mathrm{I}(k'-k)}+\frac{\mathrm{L}}{2}\left(3k'-k+\frac{n^2-k^2-a^2}{k'-k}\right),$$

where M is the moment of the magnet, I the moment of inertia of the suspended apparatus, G the principal galvanometer constant of the coil, and L the self inductance of the coil. k and k' are equal respectively to $2\lambda/\mathrm{T}$ and $2\lambda'/\mathrm{T}'$, where λ and λ' are the logarithmic decrements in the two cases and T and T′ the respective periods of the magnet. $a=2\pi/\mathrm{T}'$ and $n=\mathrm{MH}/\mathrm{I}$.

The measurement of the magnetic moment M and of the horizontal magnetic intensity H are of first importance, and at the present time (1920) neither magnetic moment nor magnetic intensity has been measured in C.G.S. units with the accuracy that resistance has been measured by other methods. It will further be observed that R is proportional to the square of M so that a very accurate determination of M is necessary. Again the moment of inertia I is not easy to determine for small magnets, and if a large magnet is employed there is uncertainty as to the distribution of its magnetism. Corrections are required for the arc of oscillation and for temporary induced magnetisation due to the action of the current. Further, the value of R is directly proportional to the difference between the logarithmic decrements.

In the opinion of Lord Rayleigh, Rowland, and Glazebrook, the formula is sufficient to show that the method cannot compete with most of the other methods used for absolute measurements.

(i.) *Experiments.*—The method was used by W. Weber (*Pogg. Ann.* Bd. 82, S. 337), first in 1851, but Weber was interested more in the development of the method than in the accuracy of the measurements.

With modifications the method has been employed by H. F. Weber, Dorn (*Wied. Ann.*,

1882, xvii., and 1889, xxxvi.), Wild (*Mém. de l'Ac. des Sc. St-Pétersbourg*, 1884, tome 32, Nro. 2), and Kohlrausch (*Phil. Mag.* xlvii.). The most important modification is that used by Kohlrausch, which practically amounts to a combination of Weber's Method of Transient Currents with the Method of Damping. Weber had previously used this method. The constant of the galvanometer with which the earth-inductor was connected was eliminated by determining the logarithmic decrement of the motion of the galvanometer needle, first when the circuit of the galvanometer was closed, and again when it was open. Calling these decrements γ and γ_0, and putting a, β for the arcs of vibration in the method of recoil (Maxwell's *Electricity and Magnetism*, § 750), and T the period of the needle when the circuit was open, Kohlrausch's formula is, to a first approximation,

$$R=\frac{32a^4H^2T(\gamma-\gamma_0)}{I}\cdot\frac{a\beta}{(a^2+\beta^2)^2},$$

where R is the resistance of the circuit composed of the inductor and galvanometer, I is the moment of inertia of the magnet and the suspended system, and a is the radius of the galvanometer. A defect pointed out by Lord Rayleigh and by Rowland (*American Journ. of Science*, 1878) is the great number of quantities difficult to observe, which enter the equation as squares and fourth powers. In Kohlrausch's experiments the diameter of the wire occupied 2 per cent of the radius of the coil, making it uncertain to what point the radius should be measured. Three other quantities than the radius, viz. H, γ, and I, are very difficult to determine, and H enters as the square. Rowland sums up a criticism of this method with the remark, "The method is defective because, although absolute resistance has the dimensions of Space/Time, yet in this method the fourth power of space and the square of time enter, besides other quantities which are difficult to determine."

(ii.) *Results*.—Dorn used a Siemens resistance unit verified by Strecker, and found that 106·243 cm. of mercury of 1 sq. mm. cross-section at 0° C. has a resistance equal to 10^9 C.G.S. units.

Wild employed coils by Siemens and Halske as reference units and found that 106·027 cm. of mercury of 1 sq. mm. cross-section at 0° C. has a resistance equal to 10^9 C.G.S. units.

Kohlrausch used a mercury resistance unit. The mean result was that 10^9 C.G.S. units of resistance was equal to that of 106·34 cm. of mercury of 1 sq. mm. cross-section, all at 0° C.

§ (14) METHOD OF ROTATING COIL (British Association Method). —This it appears was originally suggested by Weber, but it was also independently put forward in 1863 by Lord Kelvin (then Sir William Thomson) to the Electrical Standards Committee of the British Association. The method is very fully described in the Reports of the British Association covering the period 1862–1867, and by Lord Rayleigh and Sir Arthur Schuster in *Roy. Soc. Proc.*, 1881.

The method consists in spinning with uniform velocity about a vertical axis, a circular coil at the centre of which is suspended a small magnetic needle. The circuit of the coil is complete, and although the current in the coil alternates as it is rotated in the earth's magnetic field, the reversal of the coil relatively to the needle causes all the impulses to have a unidirectional effect on the needle. Apart from self induction, the current is of maximum value when the plane of the coil is in the magnetic meridian.

Let H = horizontal intensity of earth's magnetic field,
A = effective area enclosed by all the turns of the coil,
θ = angle of inclination of coil with the magnetic meridian,
ω = angular velocity which must be uniform.

Then we may put $\theta=\omega t$.

The rate of cutting of the magnetic lines is $AH\omega\cos\omega t$. If L is the self inductance of the coil, R its resistance, and i the current in it, then

$$L\frac{di}{dt}+Ri=AH\omega\cos\omega t,$$

from which we have

$$i=\frac{AH\omega}{R^2+L^2\omega^2}\{R\cos\omega t+L\omega\sin\omega t\}.$$

If unit current through the coil produces a magnetic intensity G at the centre, and the magnetic intensity due to i is resolved in two directions, (1) at right angles to the meridian and (2) in the meridian, these components are

$$\frac{AHG\omega}{2(R^2+L^2\omega^2)}\{R+(R\cos 2\omega t+L\omega\sin 2\omega t)\}$$

and

$$\frac{AHG\omega}{2(R^2+L^2\omega^2)}\{L\omega+(R\sin 2\omega t-L\omega\cos 2\omega t)\}.$$

It will be observed that the magnetic intensities consist of two parts, one constant and one periodic. If the moment of inertia of the needle at the centre of the coil is chosen sufficiently great the effect of the periodic terms becomes negligible. When such is the case the two components of the magnetic intensity due to the currents in the coil are seen to be $AHG\omega R/2(R^2+L^2\omega^2)$ and $AHGL\omega^2/2(R^2+L^2\omega)$.

The latter magnetic intensity is opposed to that of the earth's field so that the total

magnetic intensity along the magnetic meridian is

$$H-\frac{AHGL\omega^2}{2(R^2+L^2\omega^2)}.$$

Hence, if α is the deflection of the needle,

$$\tan\alpha=\frac{AHG\omega R/2(R^2+L^2\omega^2)}{H-(AHGL\omega^2)/2(R^2+L^2\omega^2)},$$

which reduces to

$$\tan\alpha=\frac{AG\omega R}{2(R^2+L^2\omega^2)-AGL\omega^2},$$

from which R can be determined.

This equation is not quite exact since the effect of the magnetic field due to the magnet at the centre of the coil and also the torsion of the fibre supporting the magnet have been neglected. These corrections are contained in the equation employed by the 1863 British Association Committee, which in the notation hitherto used is

$$R=\frac{AG\omega}{2\tan\alpha(1+T)}\left\{1+\frac{GM}{AH}\sec\phi-\frac{2L}{AG}\left(\frac{2L}{AG}-1\right)\tan^2\alpha\right\}.$$

MHT is the torsion of the fibre per unit of angular rotation.

Maxwell (*Elec. and Mag.* § 763) gives the more complete expression

$$R=\frac{AG\omega}{2\tan\alpha\left(1+T\dfrac{\alpha-\beta}{\sin\alpha}\right)}\left\{1+\frac{GM}{AH}\sec\alpha-\frac{2L}{AG}\left(\frac{2L}{AG}-1\right)\tan^2\alpha-\left(\frac{2L}{AG}\right)^2\left(\frac{2L}{AG}-1\right)^2\tan^4\alpha\right\},$$

where β is the azimuth of the magnet when there is no torsion. Although the equation given in the *B.A. Report* does not include the term involving $\tan^4\alpha$, it is understood that this term was used in reducing the results.

If at first L be assumed to be negligibly small and the correction due to torsion of the fibre be zero, the equation for R may be written

$$R=\frac{AG\omega}{2\tan\alpha}=a\omega\pi^2n^2\cot\alpha,$$

where a denotes the effective radius of the coil, since $A=n\pi a^2$ and $G=2n\pi/a$. From this it is seen that the resistance R is given in terms of the radius of the coil, the angular velocity, the number of turns, and the angular deflection. Only one linear quantity is concerned and on the accurate evaluation of this much depends. Indeed it appears that the accuracy of the method is limited only by errors of measurement of the effective radius of the coil and of the deflection. The speed of rotation can be made very uniform and small slow variations allowed for. With regard to the coil, the radius of a coil of many turns cannot be measured with such accuracy as a single-layered coil. It is probable that the diameter of a many-layered coil cannot be measured with a probable error less than 0·05 mm. amounting in a coil of 500 mm. diameter to 1 part in 10,000.

Lord Rayleigh has pointed out that if the metal ring on which the wire is wound be on a large scale, currents may be developed in it even although it is divided into two parts by insulation, and suggests that the ring should be made of a badly conducting material. A serious error, unless great care is taken, is in a false estimate of L (see complete equation for R). Since the effect of L increases with the square of the speed the effect of self inductance may be eliminated by varying the speed, and this method was used by Lord Rayleigh and Professor Schuster. Lord Rayleigh further suggests the introduction of a second coil in a plane perpendicular to that of a first (*Roy. Soc. Proc.*, 1881, p. 123). By this means the relative correction for self inductance would be reduced to one-quarter, while the deflection would remain unaltered. Rowland (*American Journal*, 1878) studied the method with care, and in addition to the above possible sources of error pointed out that owing to currents being induced in the suspended metallic parts the needle is dragged with the coil. This effect is no doubt minute but cannot be estimated.

(i.) *Experiments.*—In the famous experiment of the British Association Committee the radius of the coil was 15·7 cm. and the coil had 307 turns. The self inductance L, or as it was then called, the electromagnetic capacity, was stated in the *B.A. Report* to be 397,750 metres, but Maxwell in his paper on the "Electro-magnetic Field" gives a corrected value of 430,165.

Lord Rayleigh and Professor Schuster in 1881 again used the B.A. apparatus. Various improvements were introduced and modifications in procedure adopted as checks. In preliminary experiments very consistent results were obtained at constant speeds whether the rotation was in one direction or the other; but when deflections at various speeds were compared, the larger deflections were found to fall very considerably short of proportionality to the speeds. It was proved that this was due to a wrong correction for self inductance.

In Lord Rayleigh and Dr. Schuster's experiments the value of L which best satisfied the observations was 456,748 metres and the result of direct measurement was about 450,000 metres. The value of L was recalculated to be 451,448 metres. When all

the evidence is taken into consideration there can remain little doubt that the reductions of the B.A. Committee are affected by a serious underestimate of L. In 1863 the B.A. Committee employed a governor to regulate the speed, which latter was measured by taking the times at which a bell sounded, the bell receiving a stroke every 100 revolutions. Lord Rayleigh and Dr. Schuster used the stroboscopic method, the vibrating tuning-fork being compared from time to time with a standard fork of Koenig's construction.

In 1882 Lord Rayleigh (*Roy. Soc. Phil. Trans.*, 1882) used an improved rotating coil apparatus, the principal difference being an enlargement of the linear dimensions in the ratio of about 3 to 2, and a general strengthening of all parts. H. Weber (*Der Rotationsinduktor*, 1882) also made measurements in 1882, using an inductor with a horizontal axis of rotation.

(ii.) *Results*.—Until about 1850 all units of resistance were based on the more or less arbitrary size and weight of some conductor in the form of a wire. Weber had made a measurement previous to 1863 in terms of the metre and second, but this differed from the B.A. measurement by about $8\frac{1}{2}$ per cent. Although it was subsequently proved that the measurement of the B.A. Committee was in error by about 1·8 per cent, the advance towards obtaining a coherent system of units was marked and the work has been highly appreciated throughout the scientific world.

Lord Rayleigh and Dr. Schuster in their first experiments found 1 B.A. unit $=0{\cdot}9893 \times 10^9$ C.G.S. units, or 10^9 C.G.S. units $=1{\cdot}0108$ B.A. units.

In 1882, with the improved apparatus Lord Rayleigh concluded that 1 B.A. unit $=0{\cdot}98651 \times 10^9$ C.G.S. units, or 10^9 C.G.S. units $=1{\cdot}01367$ B.A. units.

The result of H. Weber's measurements was 1 B.A. unit $=0{\cdot}9877 \times 10^9$ C.G.S. units.

§ (15) Method of Lorenz.—In this a resistance is compared with a mutual inductance and a time, the latter being the period of rotation of a portion of a conducting circuit in a magnetic field.

The method was proposed and first employed by Lorenz of Copenhagen in 1873 (*Pogg. Ann.*, 1873, cxlix. 251). In the original apparatus (*Fig.* 3) a circular disc of metal was rotated at a uniform rate about an axis through its centre in the magnetic field due to a coaxial coil carrying a current. The disc was touched near its centre and at its circumference by two metal brushes and the circuit completed through a sensitive galvanometer G and a resistance R, the latter being included in the main current circuit.

Let M denote the mutual inductance between the coil and the disc, and n the number of revolutions per second made by the disc. The induced voltage between the centre and edge of the disc is Mni, where i

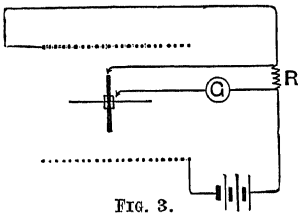

Fig. 3.

is the current through the coil. This induced voltage is balanced against the potential difference Ri at the extremities of the resistance R. Hence when there is no current through the galvanometer

$$Ri = Mni,$$

i.e. $$R = Mn.$$

M is calculated from the dimensions of the coil and disc and n is measured directly.

In no practical case can Mn be very large and therefore R must be small. In the days when experiments were first made by this method there were no low resistance standards and a difficulty presented itself which was likely to lead to serious errors. Because of this Lord Rayleigh in his experiments adopted a method of shunting as shown in *Fig.* 4. The main current from the

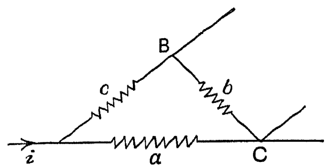

Fig. 4.

battery was divided into two parts, the larger of which passed through a and the smaller part through c and b. If i is the main current, the current through c and b is $ia/(a+b+c)$, and hence the difference of potential between B and C is $iab/(a+b+c)$. It is convenient to think of $ab/(a+b+c)$ as R.

Methods based on this principle have been used by Lorenz (*Wied. Ann.*, 1885, xxv.), Lord Rayleigh and Mrs. Sidgwick (*Roy. Soc. Phil. Trans.*, 1883, clxxiv. 295), Rowland and Kimball (*La Lumière électrique*, 1887, xxvi.), Duncan, Wilkes, and Hutchinson (*Phil. Mag.*, 1889), Jones (*Electrician*, 1890, p. 552), Ayrton and Jones (*B.A. Reports*, 1897), and Smith (*Roy. Soc. Phil. Trans.*, 1913, ccxiv.)

The influence of terrestrial magnetism is not really disturbing if the intensity of the earth's field does not fluctuate rapidly. If the field

is reasonably constant any effect is eliminated by reversing the current. At the brush contacts near the centre of the disc and at the edge there are very appreciable thermoelectric forces which fluctuate rapidly, and can only partially be eliminated by reversing the current unless a very large number of observations are taken. These thermoelectric forces may produce great practical difficulties. The measurement and control of speed is common to most methods, and no serious difficulty presents itself. The main constant error is associated with the linear measurements involved in the calculation of M. This received very careful consideration by Lord Rayleigh (*Phil. Mag.*, Nov. 1882), who investigated the best dimensions of the coil, or coils, and the disc. Smith (*Roy. Soc. Phil. Trans.* A, ccxiv. 37) calculated the rates of variation of the mutual inductance with changes in the radii of coil and disc, and found that in the apparatus experimented with by Ayrton and Jones, errors of 0·01 mm. in the measurements of the radii of coil and disc introduced respective errors of 14 parts and 5 parts in 100,000 in the calculation of M.

(i.) *Experiments.*—In the measurements made by Lord Rayleigh and Mrs. Sidgwick the coils employed were those previously used by Glazebrook in his measurements by the Method of Transient Currents. The two coils were first placed close together with the disc between them so as to give the maximum inductive effect. The axle was mounted vertically in the frame used for the rotating coil determinations, and the arrangements used for driving and measuring the speed were the same as for the rotating coil. The diameter of the disc was about 0·6 of that of the coils. This size was chosen in order that dM/da should not be too large. The edge of the disc was made cylindrical, and contact with the edge was made by a brush of fine copper wires placed tangentially to the edge and amalgamated with mercury. An additional potentiometer circuit was introduced to approximately balance the thermoelectric effects at the brush contacts and the inductive effect of the earth's magnetic field in which the disc rotated. Two series of measurements were made with the coils close together, and a third series with the coils separated to such an extent, with the disc midway between them, that dM/da was very small indeed.

In the measurements made by Jones in 1891 the coil consisted of a single layer of double silk-covered wire wound on a cylinder of brass about 53·5 cm. in diameter, in a screw thread of about 0·6 mm. pitch. Very great care was taken in the machining of the cylinder, and the mean plane of the coil was carefully marked. The disc was 33 cm. in diameter; it was insulated from the axle and was driven by an electric motor coupled direct and was ground true by an emery wheel; its diameter was measured by a Whitworth measuring machine. The stroboscopic method for measuring and controlling the speed was employed, the tuning-fork being bowed and not electrically maintained. The brush finally adopted was a single wire perforated by a channel through which a small stream of mercury flowed. The central brush was fed also with mercury. The resistance directly measured was that of a column of mercury, so that the experiment gave the resistivity of mercury directly. In order to avoid any appreciable reduced voltage due to the earth's magnetic field the axis of rotation of the disc was placed at right angles to the magnetic meridian; practically perfect compensation was obtained by the slight movement of a magnet some distance away from the disc.

In 1897 Ayrton and Jones tested the Lorenz apparatus made for Professor Callendar, who was then at the McGill University (*B.A. Report*, 1897). It was very similar to that previously used by Jones except that the coil was wound on a marble cylinder. Three brushes 120° apart were employed at the circumference of the disc in order to eliminate small errors due to imperfect centring with the coil.

In 1913 F. E. Smith designed and used the apparatus now at the National Physical Laboratory. In his apparatus there are two pairs of coils and two discs. The current is taken off by brushes rubbing on the edges of the discs instead of by one brush at the edge and another on the axis. Thermoelectric effects are thus much reduced. The dimensions of the coils and discs were chosen with full regard to the following considerations.

If A is the radius of coil, a the radius of a coaxial disc, and x the length of the coil, then for small changes dA, da, and dx, in these dimensions the change dM in the mutual inductance can be obtained from the increment formula

$$\frac{dM}{M} = q\frac{dA}{A} + r\frac{da}{a} + s\frac{dx}{x}.$$

The sum $q+r+s$ is always equal to unity, and all three quantities cannot be of the same algebraical sign. For a coil on marble, wound with bare copper wire, the radius and axial length of the coil can be measured with great precision. As the disc must rotate and has brushes in contact, its dimensions when spinning are not likely to be determinable with equal accuracy. Since by properly choosing the diameter and length of coil and size of disc either q, r, or s can be made exceedingly

small, it appears good policy, conditionally that the apparatus is not cumbersome, to make r very small. This condition is fulfilled in the Lorenz Apparatus at the National Physical Laboratory. Changes of 0·1 mm. in A and a produce changes in M of 30·0 and 0·07 cm.

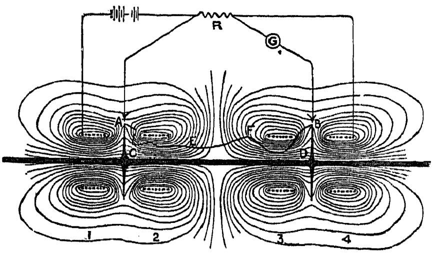

FIG. 5.

respectively, the value of M being about 29,000. Actually a change in the diameter a of the disc of 0·5 mm. is necessary to produce a change in M of 1 part in 100,000.

The Smith Lorenz Apparatus (*Figs.* 5A and 5B) consists of two metallic discs which support ten ends of a single wire, or that between five wires suitably arranged in series, is balanced against the difference of potential between two points on a standard resistance, the current through which is the same as that flowing through the four coils. A diagrammatic sketch of the magnetic field is shown in *Fig.* 5.

The current in the coils 1 and 2 is in the opposite direction to that in the coils 3 and 4, and the resulting magnetic fields are therefore opposite in direction. Each pair of coils and the disc between them is similar in disposition to that of a Campbell standard[1] form of mutual inductance, but the mutual inductance can be changed by varying the distance apart of the two coils. The intensity of the magnetic field at points in the neighbourhood of the edge of a disc is zero, or very nearly so, and it will thus be realised that the measurement of the radii or that of a radial arm is not one of first importance. The discs themselves are used merely as supports of the insulated wires and segments. On the edge of each disc ten segments of stabilite are secured, and to these phosphor-bronze segments of square

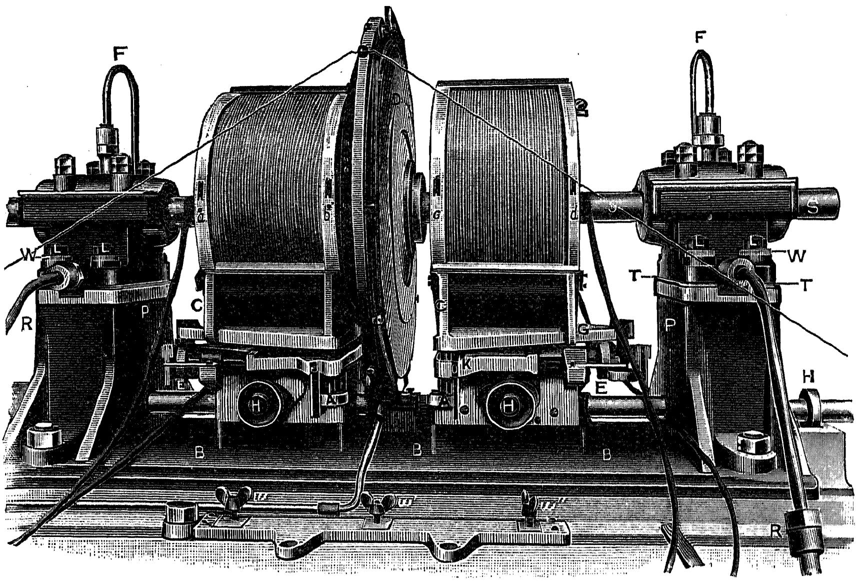

FIG. 5A.

conducting wires insulated from the disc and which rotate in a magnetic field produced by a current in four coils. An electric motor is used as a source of power. Phosphor-bronze wire brushes make contact with segments made of the same alloy attached to the ends of the rotating wires, and the difference of potential between the brush contacts at the section are screwed. The ten phosphor-bronze segments thus form a rim, except that small insulating air gaps separate the segments. Insulated wires pass from the segments on one disc to the segments on the other disc, the wires passing through channels milled in the discs and through central holes drilled in

[1] See "Inductance, Measurement of," § (54).

the shaft. A difference of potential is produced between the ends of a rotating conductor, and its value depends only on the position of the ends of the conductor (in this case the phosphor-bronze segments) and not upon its position, conditionally that the conductor passes through the coils carrying the current. Thus the potential difference at the extremities of a rotating conductor ACDB is not altered if its shape is changed to AEFB (see *Fig.* 5).

The brushes consist of phosphor-bronze wire 0·12 mm. diameter, and to obtain as small thermo-electric effects at the contacts as possible the wire was drawn from other wire of square section similar to that employed for the segments on the disc. The fine wires forming a brush are stretched by two spiral springs and resemble violin bows. The wires meet and leave the segments tangentially. The overall length of a brush is 20 cm., and contact is made with one or two segments over a length varying from 5 to 6 cm. Petrol is fed by means of a wick to the edge of a disc and acts as a cleanser and a lubricant. The rapid variations in the thermo-electric voltage rarely exceeded 0·1 microvolt over intervals as long as 20 minutes.

There are two principal ways of using the apparatus. In the first, the ten brushes (5 on each disc) are included in a circuit so as to be in series. When each brush is in contact with a single segment the differences of potential due to five rotating conductors are added together, the remaining five conductors being ineffective. When each brush connects two neighbouring segments the ten rotating conductors are arranged in five sets of two in parallel, and the total potential difference is the same as before. By having a comparatively large arc of contact between each brush and a segment (or segments), and twice as many segments as brushes, the circuit made through the brush contacts is never broken.

In the second method the brushes are divided into two sets of five in parallel, and the total potential difference is the same as that of a single rotating conductor.

The discs are about 53 cm. in diameter and are of phosphor-bronze. They are mounted on a shaft of copper-aluminium alloy. The bearings, the pedestals, and all metallic parts were tested for magnetic quality to ensure freedom of magnetic material. One disc, two coils, and a part of the supporting framework are shown in *Fig.* 5A.

The coils are wound with bare copper wire on hollow marble cylinders, having double-threaded screw grooves cut on the surface. The two wires on any one cylinder form two adjacent helices which may be connected in series or in parallel. In the general use of the instrument they are connected in series, but they may at any time be disconnected from one another and an insulation test made. Carrara marble was chosen as the material of the cylinders, and No. 24 hard-drawn copper wire for the coils. The mean diameter of a coil is about 35·9 cm. and the axial length is about 16 cm. The dimensions were very accurately determined.

Each cylinder (see *Fig.* 5A) is mounted on a strong metal support, and its position with regard to a disc may be altered by screw adjustments. Engraved platinum plugs are fixed in the cylinders, and by means of observations on these the distance between the mid-planes of two coils is determined.

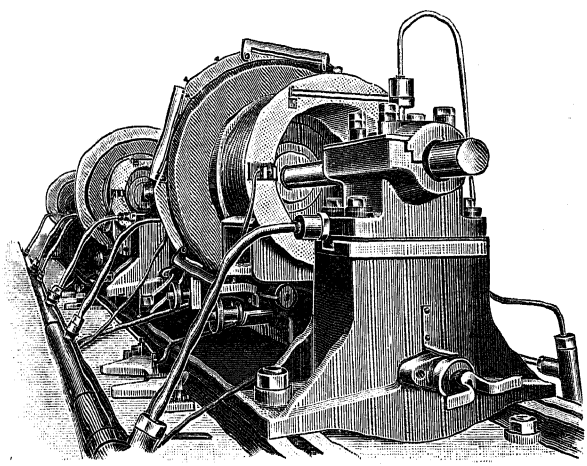

FIG. 5B.

The electric motor used for driving is situated at a considerable distance from any one of the coils, and its influence on the result was calculated and also experimentally proved to be negligibly small. A commutator is fixed to the axle of the motor, and this serves to charge and discharge a condenser placed in one arm of a Wheatstone bridge; by keeping the bridge permanently balanced, the speed of the apparatus is maintained constant and a directly driven chronograph enables the speed to be calculated. A fly-wheel of phosphor-bronze is added to reduce the effect of small sudden disturbances. The magnitude of the observed sudden fluctuations was of the order of 5 parts in 100,000.

The calculation of the mutual inductances between a coil and disc was made by the formula given by Viriamu Jones,[1] viz.

$$M = \Theta(A+a)ck\left\{\frac{K-E}{k^2}+\frac{1-c^2}{c^2}(K-\pi)\right\},$$

where Θ is the angular length of the helix, A its radius, a the radius of the disc or contact circle, and d the axial length of the helix.

$$c^2 = 4Aa/(A+a)^2,$$
$$k^2 = 4Aa/\{(A+a)^2+d^2\}.$$

K, E, and π are complete elliptic integrals.

The changes of mutual inductance, (1) when the axis of a coil is not normal to a disc and (2) when the axes of coil and disc are parallel but coincident, are difficult to calculate but easy to measure electrically, and by such measurements the axes of coils and discs were made to coincide.

(ii.) *Results.*—Lord Rayleigh found as a result of his measurements that

1 B.A. unit $=0{\cdot}98677\times10^9$ C.G.S. units,
or 10^9 C.G.S. units $=1{\cdot}01341$ B.A. unit.

In 1884 Rowland, Kimball, and Duncan found ($0{\cdot}98642\pm18$) B.A. unit equal to 1 ohm, and Duncan, Wilkes, and Hutchinson in 1889 found the ohm equal to 0·9863 B.A. unit.

The final results of five sets of measurements made by Jones in 1891 gave the resistivity of mercury at 0° C. as 94067 C.G.S. units. According to this result a column of mercury 106·307 cm. long and 1 sq. mm. cross-section all at 0° C. has a resistance of 10^9 C.G.S. units.

In 1897 Ayrton and Jones made comparisons with coils of wire, and the general result was that the resistance at 0° of 106 cm. of mercury 1 sq. mm. in area is equal to $1{\cdot}00026\times10^9$ C.G.S. units.

Smith gave the results of 56 measurements made under various conditions, during a period slightly over three months. The mutual inductance, the speed of rotation, the temperature of the coils, and the resistance were all varied. The maximum difference of any result from the mean was 5 parts in 100,000, and the average difference from the mean was ± 1·5 parts in 100,000. The probable observational error was 3 parts in a million. The probable error of the absolute measurements is believed to be not more than 2 parts in 100,000. The result may be stated in the following way:

The ohm, 10^9 cm./sec. is represented by the resistance at 0° C. of a column of mercury $14{\cdot}4446\pm0{\cdot}0006$ grams in mass, of a constant cross-sectional area (the same as for the international ohm),[2] and having a length of $106{\cdot}245\pm0{\cdot}004$ cm.

[1] See "Inductance, Calculation of," § (3).

§ (16) Campbell's Alternating Current Method (*Roy. Soc. Proc.*, 1908, lxxxi., and *Roy. Soc. Proc.*, 1912, lxxxvii.).—This is a direct comparison of a resistance with a combination of mutual inductance and the period of an alternating current in which two-phase alternating currents are used.

In *Fig.* 6, M is a mutual inductometer the value of which must be known with great

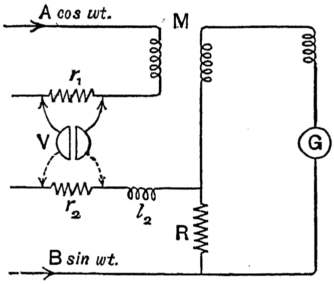

Fig. 6.

accuracy, and R is a resistance the value of which is desired. If A cos ωt and B sin ωt be the instantaneous values of currents in quadrature obtained from a two-phase alternator or phase-splitting device, then when the galvanometer shows no deflection the electromotive force introduced into its circuit is zero at every instant, and hence

$$\frac{d}{dt}(\text{MA}\cos\omega t)+\text{RB}\sin\omega t=0,$$

so that $R=(A/B)\omega M$.

The galvanometer G is a vibration galvanometer tuned to a frequency n where $p=2\pi n$. R is not perfectly non-inductive. Let its self inductance be l causing circuit A to be out of quadrature with B by a small angle x. Then when $A=B$ there will be a balance when

$$\omega M\cos(\omega t+x)-R\cos\omega t-l\omega\sin\omega t=0,$$

and since l is small compared with M

$$\omega M\cos\omega t-\omega Mx\sin\omega t-R\cos\omega t+l\omega\sin\omega t=0.$$

Thus $\qquad R=\omega M$ and $x=\div l/M$.

The inductometer used by Campbell was calibrated against a Campbell standard, and the errors of calibration being only a few parts in a million the error of the standard only is involved. This (*Proc. Roy. Soc.*, 1907, lxxix.) can be made as small as that of any other standard, and when the primary is of bare wire on marble, as was the case in Campbell's experiments, the value is determinable within 1 part in 100,000. The compari-

[2] See § (38), the area of the column assuming the mercury to be of normal density, 13·596 grams per c.c., will be 1 sq. millimetre.

sons were made with alternating current, but there seems no reason to suspect the material on which the coils were wound. The frequency determination could be improved, but the close agreement between the 3 results obtained (greatest difference $=3$ parts in 100,000) indicates that the error due to this cause was also small. Errors may arise due to the wave forms being not exact sine curves, and Campbell has examined this case. When there is a departure from the sine form the instantaneous values of the currents may be written

$$\Sigma A_s \cos(s\omega t+\phi s) \text{ and } \Sigma B_s \sin(s\omega t+\phi s)$$

respectively, where $s=1.\ 3.\ 5.\ .\ .\ .$

In this case the ratio of the effective values will be

$$(A_1^2+A_3^2+A_5^2+\ .\ .\ .)^{\frac{1}{2}}/(B_1^2+B_3^2+B_5^2+\ .\ .\ .)^{\frac{1}{2}},$$

$$i.e.\ A_1(1+a_3^2+a_5^2+\ .\ .\ .)^{\frac{1}{2}}/B_1(1+b_3^2+b_5^2+\ .\ .\ .)^{\frac{1}{2}}.$$

Campbell showed that in his experiments $(a_3+a_5+\ .\ .\ .)$ and $(b_3+b_5+\ .\ .\ .)$ were neither of them of an order greater than 1/100; hence the last written expression will not differ from A/B by more than 1 part in 20,000. The error, if any, can be eliminated by repeating the experiment with the coils of the alternator interchanged.

Campbell thought the probable error of his measurements to be about 1 part in 10,000.

(i.) *Experiments.*—Campbell only has made measurements by this method. His standard of mutual inductance was of the Campbell type but was not suitable for direct comparison with resistance coils. A secondary standard was therefore constructed in the form of a mutual inductometer of range from 11,000 microhenries to 0·01 microhenry, and for permanence the bobbins were made of white marble.

When making measurements the ratio of A to B was found by observing the effective values of the two currents by the respective potential differences produced in the nearly equal resistances r_1 and r_2, these voltages being read alternately on a very sensitive electrostatic voltmeter V. The alternator was run at as steady a speed as possible, the galvanometer tuned, and at every half-minute a balance was obtained by slight adjustment of M and of the phase of the B circuit. The adjustment of phase was made by a small variable self inductance l_2 (*Fig.* 6). A second observer simultaneously switched the voltmeter alternately from r_1 to r_2. As A/B differed from unity by only about 0·5 per cent and the scale of the voltmeter enabled readings to be taken with an error less than 1 part in 50,000 the ratio could be determined with great accuracy. A set of readings extended over about 15 minutes and the average frequency over this interval was taken, the maximum variation being from 2 to 3 parts in 1000. The vibration galvanometer was of the moving coil type and was amply sensitive for the purpose.

In making measurements the connections of the leads to the voltmeters, and also those to the variable inductance l_2, were systematically interchanged in order to eliminate as far as possible the slight inequality in capacity and leakage of the leads and any effect of stray field from the coil l_2. In some of the experiments the connections to the alternator coils were altered so as to interchange the positions of the coils relative to R and M.

(ii.) *Results.*—Campbell found

$$\text{One Ohm} = 10^9 \text{ C.G.S. units}$$
$$= 1{\cdot}0002_5 \text{ International Ohms.}$$

§ (17) Foster's Method.—In 1880 Professor G. Carey Foster made some measurements by a method suggested by him, the principle of which is essentially the same as that of the B.A. Rotating Coil. In the B.A. method the rotating coil forms part of the galvanometer; in Foster's method the current is measured by an independent galvanometer, and the conductor, whose resistance is given by the experiments, is entirely distinct from the rotating coil. So far as this method possesses any particular advantages they arise from the circumstance last mentioned, inasmuch as the resistance to be measured may be a coil of wire of any material, or it may be a conductor of any shape immersed in a bath of oil to keep it at a constant temperature.

The nature and arrangement of the essential parts of the apparatus are shown in *Fig.* 7. In this R is the wire of which the resistance is desired, B a battery, and G a tangent galvanometer. C is a rotating coil, and the ends of the wire of the coil are connected through a commutator K upon the axle, with the extremities of R, a sensitive galvanometer g being inserted in the circuit.

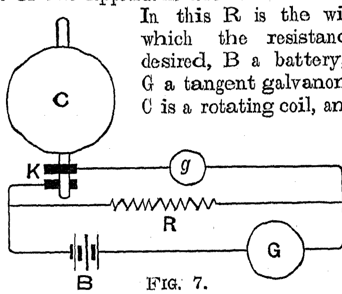

Fig. 7.

The circuit is only completed through K for a portion of the time. The commutator was of ivory with two pieces of platinum on opposite sides. Contact with the external

circuit was made through two platinum-faced gun-metal wheels each about 15 cm. diameter, which revolved in contact with the ivory cylinder. This arrangement was adopted in order to avoid the heating, and consequent thermo-electric action, which would probably have resulted from the use of rubbing contacts.

The platinum contact pieces had an angular breadth of about 20 degrees so that the coil was in connection with the rest of the circuit during about $\frac{1}{9}$th of each revolution, and the middle of the period of contact was made to coincide with the instant of maximum induced E.M.F. in the coil. The extreme variation of induced E.M.F. during contact was 1·83 per cent.

The results may be expressed in terms of the experimental data as follows:

Let A be the total area included by all the turns of the rotating coil, H the horizontal magnetic intensity, ω the angular velocity of the coil, and $2a$ the arc of contact made by the commutator. Then E the effective E.M.F. produced by the coil is given by the equation

$$E = HA\omega \frac{\sin a}{a}.$$

If G is the galvanometer constant (*i.e.* the intensity of the magnetic field in the centre of the galvanometer system produced by unit current in the galvanometer coils) and θ the deflection of the galvanometer, then

$$I = \frac{H}{G} \tan \theta$$

and

$$R = \frac{E}{I} = \frac{HA\omega G(\sin a/a)}{H \tan \theta},$$

or

$$R = \frac{AG}{T} \frac{2(\sin a/a)}{\tan \theta},$$

where T is the period of one revolution of the coil. The expression assumes that the experiment is made in a region of uniform magnetic intensity; failing this, a correction is necessary.

The coil used was somewhat similar to that of the B.A. Committee, but stouter in construction. Foster made only preliminary experiments and attached no great importance to his results.

The main advantage of the method lies in the elimination of self inductance, but against this there is a possibility of disturbance from mutual inductance between different parts of the circuit. The thermo-electric effects at the points of contact might also be troublesome. The method is probably inapplicable for precise measurements owing to uncertainty of the arc of contact, but the simple theory should render it useful to teachers. If bow-wire brushes (see Lorenz method) were employed, the thermo-electric effects would be small.

§ (18) ROSA'S METHOD.—Rosa (*Bureau of Standards Bull.*, 1909, v. No. 4) has made preliminary measurements with an apparatus in which two revolving coils at right angles to one another rotate in a strong magnetic field produced by two stationary coils, set somewhat farther apart, relatively, than the coils of a Helmholtz-Gaugain galvanometer, the whole constituting a kind of two-phase alternator without iron (*Fig.* 8). The wave

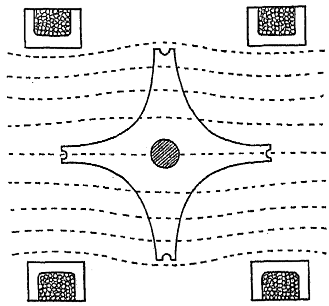

FIG. 8.

form of the induced electromotive force is not a sine; instead of varying at a maximum rate as it passes through zero, the electromotive force varies at a minimum rate. A revolving coil moves parallel or nearly parallel to the magnetic lines for an appreciable distance at the region of minimum electromotive force, thus giving a very small induced voltage for a considerable angle. This permits the electromotive force to be commuted without sensible loss. In making an absolute

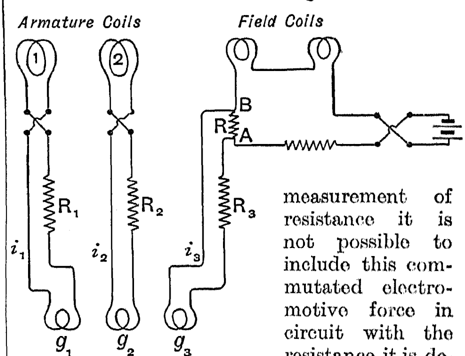

FIG. 9.

measurement of resistance it is not possible to include this commutated electromotive force in circuit with the resistance it is desired to measure; instead, a differential galvanometer with 3 windings stranded together is used. One of these, g_3 (*Fig.* 9), carries a constant current from the terminals AB of the resistance R, through which flows the current passing through the field coils. The other windings, g_1 and g_2, carry the respective currents from the armature coils 1 and 2. The field coils are so disposed as to make the

electromotive force at 45° of either side of the maximum equal to one-half the maximum, and under these circumstances the sum of the two currents through g_1 and g_2 is constant within about 3 per cent, and the fluctuation has a frequency four times that of either of the main induced currents. The effect on the differential galvanometer needle is the same as though the two currents i_1 and i_2 were combined in a single winding. Each circuit has its two-part commutator, and each has the same resistance as the circuit carrying the constant current. These resistances do not, however, have to be known. When the galvanometer is balanced, the sum of the average induced voltage generated by the two coils is equal to the voltage at the extremities of the resistance R which is the resistance to be determined absolutely.

If M_1 and M_2 be the respective mutual inductances of the revolving coils with the fixed coils, when each is in the position of maximum inductance, n the number of revolutions per second, and I the field current, the average value of the induced currents will be

$$i_1=\frac{4nM_1I}{R}$$

and

$$i_2=\frac{4nM_2I}{R},$$

if the effect of self inductance is negligible. The third current i_3 is RI/R_3, where R_3 is the total resistance of the circuit, including R.

Hence, when the constant current i_3 is balanced against the pulsating currents,

$$R=4n(M_1+M_2).$$

With appropriate interchanges any want of balance in the galvanometer windings may be eliminated.

No results have yet been published and some experimental difficulties cannot therefore be anticipated. It should be possible to measure directly by this method resistances as great as 10 ohms, and in consequence the thermo-electric effects at the commutators should be nearly or wholly negligible. The resistances R_1, R_2, and R_3 might also be as great as 1000 ohms, and in such case the variation of contact resistance at the brushes might be negligible. There will be temperature changes of resistance which could be appreciably reduced by making the circuits largely of manganin. There should be no trouble in keeping the speed constant. To determine M, Rosa suggests a comparison with a standard of mutual inductance such as that of Campbell's, or a mutual of two coaxial coils in the same plane.

§ (19) Grüneisen and Giebe's Method.—In this a self inductance L consisting of a single-layered coil on marble has its value in C.G.S. measure calculated from its dimensions, and its value in international units determined by measuring it in terms of a resistance and a frequency. The dimensions are inductance [L], resistance [LT^{-1}], and frequency [T^{-1}]. For the measurement of L in international units its value is first determined in terms of a capacity and two resistances, the capacity is subsequently measured in terms of a frequency and three resistances.

Grüneisen and Giebe (*Ann. d. Physik,* Sept. 1920, lxiii.), working at the Physikalisch Technischen Reichsanstalt, employed three coils A, B, and C, each of which was 35·5 cm. in diameter. The coils are of bare copper wire 0·5 mm. in diameter and each consists of one layer wound on marble. The pitch of coil A is 1 mm. and B and C are of $\frac{3}{4}$ mm. pitch. Coil A has 162 turns and a self inductance of about 0·01 henry; B and C each have 447 turns and a self inductance of about 0·05 henry; each of the latter can be subdivided by applying leads to $\frac{1}{3}$ and $\frac{2}{3}$ of their lengths, and by appropriate connections 13 different self inductances can be built up, all the coils of which are, however, of approximately the same diameter.

To calculate the self inductance of a coil it is necessary to know the radius R, the pitch p, the diameter of the wire d, and the number of turns N. The self inductance L can then be calculated by the Lorenz equation as modified by Rosa (*Bureau of Standards Bull.*, 1911, viii.):

$$L=\frac{8\pi}{3}RN^2Q\left(\frac{R}{Np}\right)-4\pi RN\left\{A\left(\frac{d}{p}\right)+B(N)\right\}.$$

Here Q is a function of R/Np, A a function of d/p, and B a function of N. Q contains elliptic integrals of the first and second order, which can be obtained from Legendre's tables.

The effects of errors in the measurement of R, p, and d can be obtained from the equation

$$\frac{\Delta L}{L}=\alpha\frac{\Delta R}{R}+\beta\frac{\Delta p}{p}+\gamma\frac{\Delta d}{d},$$

the coefficients α, β, and γ depending somewhat on the shape of the coil. For coil B they are

	α.	β.	γ.
Coil B . .	+1·672	−0·670	−0·002
$\frac{1}{3}$ B . .	+1·456	−0·4526	−0·0032.

If the error in the calculated value of L has to be within 1 part in 100,000, then R must be determined within about 6 parts in a million, p within 15 parts in a million, and d within about 3 parts in 1000.

The cross-section of the wire used was determined partly from its weight, length, and density, and partly from its electrical resistance, length, and resistivity. The pitch was measured directly by means of microscopes, and numerous measurements of diameters were made by special contact methods. Irregularities in diameters were allowed for when computing L. A measurement of the

mean diameter was also made by measuring the length of wire and number of turns.

To measure the self inductance in international electrical units the following procedure was adopted. A coil of self inductance L and resistance r_3 was first evaluated in terms of a capacity C and two resistances r_1

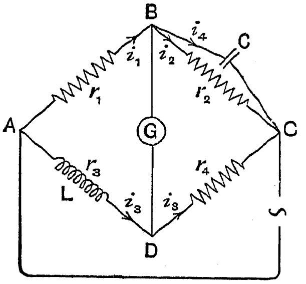

FIG. 9A.

and r_4 by a modified Maxwell bridge method (*Fig.* 9A).

Neglecting small distributed capacities, we have, when no current passes through the galvanometer,

$$L\frac{di_3}{dt}+r_3i_3=v_A-v_D=v_A-v_B$$
$$=r_1i_1.$$

Now $$v_B-v_C=r_2i_2=r_4i_3$$

and $$i_4=C\frac{d}{dt}(v_B-v_C)=Cr_4\frac{di_3}{dt}.$$

After substitution we have

$$Li_4=Cr_4(r_1i_1-r_3i_3)=Cr_1r_4i_1-Cr_2r_3i_2$$
$$=Cr_1r_4(i_1-i_2),$$

and since $i_4=i_1-i_2$ we have

$$L=Cr_1r_4.$$

If K_1, K_2, etc., represent the small capacities in the various parts of the bridge and C be increased by a small adjustable rotary condenser C_a, then the complete expression is

$$L=r_1r_4(C+C_a)-\frac{r_1r_4}{r_2}(r_1K_1+r_4K_4-r_2K_2).$$

To eliminate K_1, K_2, etc., the coil of self inductance L was replaced by a bifilar wire of equal resistance and of small calculable self inductance l. C was removed and the bridge balanced by adjustment of the rotary condenser. Then

$$l=r_1r_4C_1-\frac{r_1r_4}{r_2}(r_1k_1+r_4k_4-r_2k_2).$$

Combining this with the previous equation we have

$$L-l=r_1r_4(C+\Delta c),$$

where Δc is the change made in the capacity of the rotary condenser.

r_1, r_2, and r_4 were special resistances of small capacity and small self inductance. Alternating current was used, the frequencies employed being 332, 500, and 720 per second. G is a tuned vibration galvanometer and was capable of detecting 10^{-8} ampere at a frequency of 300 per second. All leads to the bridge arms were arranged in a bifilar fashion as shown in *Fig.* 9B.

The capacity C consisted of a number of air condensers built up of circular discs of an

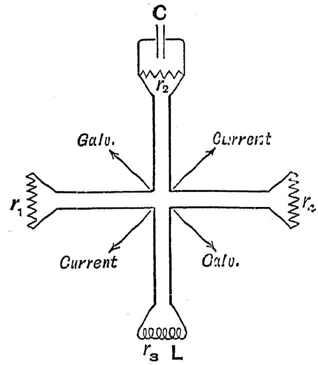

FIG. 9B.

aluminium alloy. The value of C was determined by the Maxwell interrupter method, the relation being

$$C=\frac{1}{nr},$$

where n is the number of discharges per second and r a resistance in international ohms. r is not, however, a single resistance.

From the two equations

$$L=Cr_1r_4 \text{ [farads ohms}^2\text{]}$$

and $$C=1/nr \text{ [seconds/ohms]}$$

we have

$$L=\frac{r_1r_4}{nr} \text{ int. henries [int. ohms seconds].}$$

The values obtained on various dates for the self inductance of a coil of approximately 0·05 henry are as follows :

Date.	$L=0{\cdot}05\times$	Differences from Mean. Parts in 1,000,000.
20.4.1914	$1+66\cdot10^{-6}$	− 7
28.4. ,,	1+82 ,,	+ 9
29.4. ,,	1+72 ,,	− 1
1.5. ,,	1+87 ,,	+14
2.5. ,,	1+91 ,,	+18
4.5. ,,	1+67 ,,	− 6
5.5. ,,	1+78 ,,	+ 5
7.5. ,,	1+69 ,,	− 4
8.5. ,,	1+73 ,,	± 0
12.5. ,,	1+67 ,,	− 6
13.5. ,,	1+65 ,,	− 8
14.5. ,,	1+66 ,,	− 7
23.5. ,,	1+70 ,,	− 3
25.5. ,,	1+74 ,,	+ 1

The ratio of the value of the self inductance L in 10^9 centimetres to its value in international measure is the ratio of the ohm (10^9 C.G.S. units) to the international ohm.

Grüneisen and Giebe give the following summary of their results:

Coil.	L in 10^9 cm.	L in Int. Henry.	$\frac{\text{L abs.}}{\text{L int.}}$	Mean Ratio for each Combination.
Section A	0·010 138 20_1	0·010 133 06	1·000 50_7	1·000 50_7
B	0·050 029 66	0·050 004 0	1·000 51_3	1·000 51_3
B	28 681 96_3	28 667 24_9	51_3	1·000 51_3
B	28 684 07_6	28 669 39_0	51_2	
B	10 261 05_5	10 255 89_4	50_3	
B	10 261 09_0	10 255 80_0	51_6	1·000 50_5
B	10 262 03_0	10 256 95_3	49_5	
C	0·050 009 65	0·049 983 1	1·000 53_1	1·000 53_1
Section C	28 672 28_4	28 656 77_7	54_1	1·000 52_0
C	28 672 63_3	28 658 32_7	49_0	
C	10 257 73_2	10 251 98_6	56_1	
C	10 258 06_9	10 252 88_0	50_8	1·000 52_1
C	10 257 60_7	10 252 50_3	49_8	

The mean ratio is $1{\cdot}00051_6$.

After comparing the mean effective diameters of the coils and sections of same by an electrical method, Grüneisen and Giebe conclude that

1 international ohm

$$=1{\cdot}00051 \text{ ohm } (10^9 \text{ C.G.S. units}),$$

and estimate the probable error to be ± 3 parts in 100,000. The corresponding length of the mercury column is 106·246 cm.

This value is almost identical with that found by Smith, but there is reason to believe that the units obtained from the mercury standards of resistance of the National Physical Laboratory and the Reichsanstalt differ by 3 parts in 100,000. If this is so the difference between the results of the two absolute measurements may be 4 parts in 100,000.

§ (20) Summary of Results.—A summary of the results of the principal measurements by all methods are given in the table on following page.

§ (21) The B.A. Unit.—It will be seen from the table that nearly half of the results are given in terms of the B.A. unit, and it may be useful to state clearly what is meant by that unit. Originally the B.A. unit was supposed to be equal to the ohm (10^9 C.G.S. units) within about 1 part in 1000, and the original B.A. unit was the result of absolute measurements made by Maxwell, Jenkin, and Balfour in 1863. In 1864 Matthiessen and Hockin constructed a number of coils of various materials to represent the B.A. unit. The resistance of these coils did not keep absolutely constant, and in after years the B.A. unit was taken as the mean of the values of six of these coils. The B.A. unit of one period is not therefore necessarily the same as that of another period. Every precaution was taken to ensure constancy, but with wire standards of resistance great difficulty is experienced. In 1908 (*British Association Report of Elec. Stands. Committee*, 1908) it proved possible to trace the changes in these coils with a fair measure of success, and the corrections to results of absolute measurements due to changes in the coils can in a number of cases be calculated. This has been done by Smith (*Roy. Soc. Phil. Trans.*, 1913, ccxiv. 32), in the case of the coils used by Lord Rayleigh, Glazebrook, and Jones.

§ (22) Final Results.—The corrected results of the absolute measurements expressed in terms of centimetres of mercury are:

Observer.	Ohm in Centimetres of Mercury.
1882. Rayleigh . . .	106·26 cm.
1882. Glazebrook . . .	106·25 ,,
1883. Rayleigh and Sidgwick .	106·24 ,,
1891. V. Jones . . .	106·31 ,,

Unfortunately it is not possible to deal in the same way with the standards of other investigators as the particulars available are insufficient for the purpose. It is, however, of particular interest to note that these corrected values are in very good agreement with the results of recent measurements made by Smith, by A. Campbell, and by Grüneisen and Giebe. These are tabulated below, together with the values obtained by Wiedemann in 1885 and by Dorn in 1889.

Observer.	Ohm in Centimetres of Mercury.
1882. Rayleigh . . .	106·26 cm.
1882. Glazebrook . . .	106·25 ,,
1883. Rayleigh and Sidgwick .	106·24 ,,
1885. Wiedemann . . .	$106{\cdot}16_2$,,
1889. Dorn	$106{\cdot}24_3$,,
1891. V. Jones . . .	106·31 ,,
1912. Campbell . . .	$106{\cdot}27_3$,,
1913. Smith	$106{\cdot}24_5$,,
1920. Grüneisen and Giebe .	$106{\cdot}24_6$,,

The mean of all these values is $106{\cdot}24_8$, and it appears that within 1 part in 10,000 the ohm (10^9 C.G.S. units) can be represented by the resistance at 0° C. of a column of mercury of the same cross-section as the international ohm and having a length of

$106{\cdot}24_5$ centimetres.

II. ABSOLUTE MEASUREMENT OF CURRENT

§ (23) DIMENSIONS. — The dimensions of current in the electromagnetic system are $[L^{\frac{1}{2}} M^{\frac{1}{2}}/T\mu^{\frac{1}{2}}]$. If, as is customary, μ be assumed to have no dimensions, the dimensions of current are $[L^{\frac{1}{2}}M^{\frac{1}{2}}/T]$. The square of these dimensions is $[LM/T^2]$, which is that of a force. Hence to measure a current it may suffice to measure a force only. If instead other quantities are measured these must, together, include the dimensions of a force. Thus the product of the dimensions of magnetic intensity (commonly called magnetic force) $[M^{\frac{1}{2}}/L^{\frac{1}{2}}T\mu^{\frac{1}{2}}]$ and magnetic pole $[L^{\frac{3}{2}}M^{\frac{1}{2}}\mu^{\frac{1}{2}}/T]$ is of the dimensions of a force $[ML/T^2]$, and this suggests that current may be measured in C.G.S. units in two ways: (i.) By galvanometer methods in which the intensity of the magnetic field produced by an electric current is compared with the intensity of the earth's horizontal field (independently determined) by the action of the field on a magnet; and (ii.) by a current weigher in which the mutual action between a current and a magnet is measured by comparing it with the force exerted by gravity on a known mass.

It is also possible to measure current by measuring the force due to one portion of a circuit on another portion of the same circuit. Such measurements include (iii.) those in which the mutual action between the currents in two or more coils takes the form of a torque, which may be measured by the torsion of a wire or with a bifilar suspension; and (iv.) current weighers in which the mutual action between the coils may be balanced by

the force exerted by gravity on a known mass.

It is clear that if in a measurement of current a force is measured with accuracy no other measurement of length, of mass, or of time need be made absolutely, but accurate ratios may be necessary. In such a case, since measurements of force are in general based on measurements of the earth's gravitational intensity any error associated with a determination of "g" is necessarily introduced in half-measure in the determination of current.

§ (24) Galvanometer Methods.—In these the intensity of the magnetic field produced by an electric current is compared, by means of a galvanometer system of coils, with the horizontal intensity of the earth's magnetic field.

The general expression for the couple acting on a magnet (*Fig.* 10) with its centre on the axis of a coil and deflected through an angle θ from

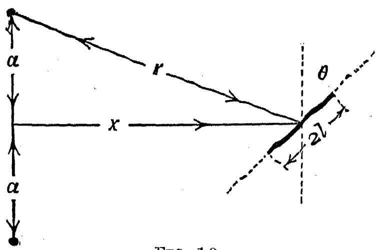

Fig. 10.

the magnetic meridian, the plane of the coil being also in the magnetic meridian, is as follows:

$$\text{Couple} = 2\pi \mathrm{N} i \mathrm{M} \frac{a^2}{r^3} \cos\theta$$

$$\left\{1 + \frac{3}{2^2}\frac{l}{r^4}(a^2 - 4x^2)(1 - 5\sin^2\theta) + \frac{3^2}{2^2}\frac{5}{4_2}\frac{l^4}{r^8}\right.$$

$$\left.(a^4 - 12a^2x^2 + 8x^4)(1 - 14\sin^2\theta + 21\sin^4\theta + \ldots)\right\},$$

where N = number of turns in coil,
i = current in coil,
M = moment of magnet,
$2l$ = length of magnet,
θ = angle of deflection of magnet,
x = distance between centre of coil and centre of magnet,
a = effective radius of coil,
r = distance of effective edge of coil from centre of magnet.

For the use of the method this couple is balanced against that due to the earth's magnetism, which is given by $\mathrm{MH}\sin\theta$.

The value of l is definite only in the case of ideal magnetisation of the magnet. In practice the terms l, l^2, l^4, etc., depend on the distribution of magnetism. When l is very small, as it is in good modern instruments, and when also $x=0$, as it is in the tangent and sine galvanometers, the couple is very approximately equal to

$$2\pi \mathrm{N} i \mathrm{M} \cos\theta / a.$$

So far the assumption has been made that the N turns of wire are coincident, but in general the coil cannot be regarded as a simple circular conductor, and corrections have to be made for its cross-section. If the coil is of rectangular cross-section, $2b$ being its axial length and $2d$ its radial depth, and if n is the number of turns crossing unit of area of cross-section, the intensity of the field produced at a point on the axis is

$$2\pi n i \left\{(x+b)\log\frac{a+d+\sqrt{(x+b)^2+(a+d)^2}}{a-d+\sqrt{(x+b)^2+(a-d)^2}}\right.$$

$$\left. -(x-b)\log\frac{a+d+\sqrt{(x-b)^2+(a+d)^2}}{a-d+\sqrt{(x-b)^2+(a-d)^2}}\right\},$$

which, when $x=0$, reduces to

$$\frac{\mathrm{N}\pi i}{d}\log\frac{a+d+\sqrt{(a+d)^2+b^2}}{a-d+\sqrt{(a-d)^2+b^2}},$$

where N is the total number of turns in the coil (see Gray, *Absolute Measurements*, vol. ii. part i.).

§ (25) Tangent Galvanometer.—In the ideal case of a tangent or sine galvanometer not only is $x=0$ but the centre of the magnet is coincident with the centre of the coil. When this is not the case but nearly so, and the co-ordinates of the centre of the magnet relative to the centre of the coil are δx, δy, and δz, δx being measured parallel to the axis of the coil, the correcting factor is

$$1 + \tfrac{3}{2}\frac{\delta y^2 + \delta z^2 - 2\delta x^2}{a^2},$$

a being the radius of the coil. Thus, if $a=20$ cm., $\delta y=0{\cdot}1$ cm., $\delta z=0{\cdot}1$ cm., and $\delta x=0$, the correcting factor is $1{\cdot}00007$.

It is apparent that l the length of the magnet cannot be made equal to zero, and in accurate measurements the terms involving l^2, etc., may not be negligibly small, but it will be observed that in the equation for the couple the second correction term involving l may be made to vanish if $5\sin^2\theta=1$. When $\theta=26°\ 34'$ this relation is satisfied, and some observers have arranged for θ to have this value in their measurements.

The chief difficulty with galvanometer methods is associated with H the horizontal intensity, for not only does H vary, but its value is as difficult to determine as that of current. Indeed in recent years galvanometer apparatus has been constructed to determine H when the value of the current has been found by some independent method. Owing to variation in the intensity of the field

near the centre of a coil, the magnet used must be very small or the distribution of its magnetism accurately known; if a small magnet is used it is of great importance to eliminate the torsional control due to the fibre. In all methods the effective radius of the coil must be measured with great accuracy, and there is a distinct gain in using a coil of one layer.

(i.) *Measurements.*—Measurements of current by means of the tangent galvanometer have been made by W. Weber (1840), Bunsen (1843), and by Joule (1851). More precise measurements have been made by F. Kohlrausch (*Pogg. Ann.*, 1873, cxlix.) and later by F. and W. Kohlrausch (*Wied. Ann.*, 1886, xxvii. 1). The most recent experiments are those by van Dijk and Kunst (*Roy. Acad. Proc.*, Amsterdam, 1904) and by Haga and Boerema (*Konink. Akad. Wetensch. Amsterdam Proc.*, 1910, p. 587).

(ii.) *Results.*—These are sometimes expressed in terms of the weight of silver deposited by 1 coulomb, and at other times the electromotive force of a standard cell is given. This latter involves knowledge of the absolute unit of resistance.

* The international ohm was used as the standard of resistance.

§ (26) Sine Galvanometer.—In this instrument the coil, or coils, can be moved round a vertical axis, and when the magnet is deflected the coil is turned until its plane contains the axis of the magnet. The difficulties and probable errors are of the same order of magnitude as those for the tangent galvanometer.

(i.) *Measurements.*—In 1872 Latimer Clark (*Roy. Soc. Phil. Trans.*, 1874, Part I.) measured the E.M.F. of a Clark cell by means of a sine galvanometer, and in 1886 Thomas Gray (*Phil. Mag.*, 1886) designed a special sine galvanometer and determined the electrochemical equivalent of silver. In Gray's instrument the coil was about 10 cm. in diameter and 100 cm. long. Such a coil, if uniformly wound with n turns per cm. length, produces a field at its centre of intensity equal to $4\pi nil/(a^2+l^2)^{\frac{1}{2}}$, where l = half the length of the coil and a the radius. As l was great compared with a the exact determination of the radius was not of very great importance. Great care was taken to obtain a uniform winding.

(ii.) *Results.*—In 1872 Latimer Clark found the E.M.F. of the Clark cell to be 1·4562 volts at 15°·5 C. The B.A. unit was the standard of resistance. In 1886 T. Gray found the electro-chemical equivalent of silver to be 1·118 mgm. per coulomb.

§ (27) Helmholtz-Gaugain Galvanometer.—In order to eliminate the correction involving l (see general equation for couple on the magnet) Gaugain constructed a galvanometer in which $4x^2$ was equal to a^2, *i.e.* the magnet was suspended not at the centre of the coil but at an axial distance from it equal to half the radius. It was, however, of great importance to place the magnet in the correct position.

Helmholtz improved Gaugain's system by placing a second coil, similar to the first, on the other side of the magnet. If for one coil (a^2-4x^2) is slightly positive, then for the other coil it is equally negative, and the total correction term involving l becomes negligibly small. The necessity for accurately locating the axial position of the magnet is thus avoided. When $a^2=4x^2$ the expression for the couple reduces to

$$4\pi NiM\frac{a^2}{r^3}\cos\theta\left\{1-\frac{3}{2}\cdot\frac{45}{64}\frac{l^4a^4}{r^8}(1-14\sin^2\theta+21\sin^4\theta)\right\}.$$

As a further simplification the correction term involving l^4 can be made negligibly small by choosing a small magnetic needle, or it can be made to vanish by making $14\sin^2\theta$ equal to $1+21\sin^4\theta$. This is the case when $\theta=16°\ 34'$, and also when $\theta=49°\ 55'$.

The principal difficulty in using the instrument is in the measurement of H and of the dimensions of the coils. The latter should be single layer coils on marble or other non-magnetic material.

Measurements.—Gehrcke and Wogan (*Verhandlungen der Deutschen Phys. Gesellschaft*, Jan. 1911) used a Helmholtz-Gaugain galvanometer and found 1 C.G.S. unit of current equal to 10·002 international amperes.

Watson (*Roy. Soc. Phil. Trans.*, 1902, cxcviii.) used the method to find H, the current being known. More recently Schuster (*Terr. Mag.*, 1914, xix.) has proposed to measure H with such a galvanometer. This [1] instrument has been constructed at the National Physical Laboratory and a similar instrument has been set up by the Department of Terrestrial Magnetism of the Carnegie Institution of Washington.

§ (28) Electromagnetic Current Weigher.—In this the mutual action between a current and a magnet is measured by comparing it with the force exerted by gravity on a known mass.

This method fails as one of precision because of the lack of knowledge of the distribution of magnetism in a magnet. A very small magnet cannot be used or the force to be measured would be too small.

[1] See "Magnetism, Terrestrial, Electromagnetic Methods of Measuring."

Measurements were made by this method by A. Becquerel in 1837, and by Lenz and Jacobi in 1839. In recent years the method has been revived by W. Hibbert for teaching purposes. In Hibbert's balance the beam is made of a long thin cylindrical magnet and a coil is placed under one end of it in such a position that one pole of the magnet lies approximately on the axis of the coil. The force due to the current is measured by a rider weight on the beam. The pole strength of the magnet is determined in C.G.S. units by the use of two similar magnets and directly measuring the forces between combinations of any two of them. The forces and distances between the poles being known, three equations are obtained which enable the pole strength of any one of the magnets to be calculated.

§ (29) Electrodynamometer Methods.—In these the mutual action between the currents in two or more coils takes the form of a torque which may be measured by the torsion of a wire or by a bifilar suspension.

§ (30) Gray Electrodynamometer.—Gray (*Absolute Measurements*, vol. ii. part i. p. 274) shows that the torque between two concentric coils can be written

$$\text{Torque} = \pi^2 n_1 n_2 i^2 a_1^2 a_2^2 \sin\phi(K_1 k_1 Z_1 + K_3 k_3 Z_3 + K_5 k_5 Z_5 + \ldots),$$

where

$$K_1 = \frac{4\rho_1}{a_1 D}, \qquad k_1 = 2\rho_2 a_2,$$

$$K_3 = \frac{-\rho_1 a_1}{D^5}, \qquad k_3 = \rho_2 a_2^3(4\rho_2^2 - 3),$$

$$K_5 = \frac{-\rho_1 a_1^3}{4D^9}(4\rho_1^2 - 3), \qquad k_5 = 2\rho_2 a_2^5(2\rho_2^4 - 5\rho_2^2 + \tfrac{15}{8}),$$

etc., and Z_1, Z_3, Z_5 are the zonal surface harmonics corresponding to the respective terms, the angle between the axes of the coils being the argument. ρ_1 and ρ_2 are the respective ratios of length to diameter, n_1 and n_2 the number of turns per centimetre, a_1 and a_2 the radii of the fixed and movable coils respectively, and D the half diagonal of the fixed coil (see *Fig.* 11). i is the current, supposed to be the same in the two coils.

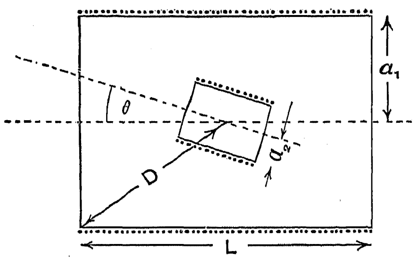

Fig. 11.

Gray further shows that if the dimensions of the coils are so chosen that the length and the radius of each are in the proportion $\sqrt{3/1}$, the terms involving K_3 and K_5 vanish. The next terms in the series involving K_7, K_9, etc., may be made negligibly small if the moving coil is small compared with the fixed coil. Thus the term involving K_7 amounts to about 1/4700 if the ratio of the radii of the coils is 2/3 and 1/27000 if the ratio is 1/2. The expression for the couple then reduces to

$$\frac{2\pi^2 N_1 N_2 i^2 a_2^2}{D} \sin\phi.$$

N_1 and N_2 are respectively the total number of turns on the fixed and movable coils. An electrodynamometer constructed so that the ratio of length to radius of each coil is $\sqrt{3}$ is known as the *Gray* type of instrument.

Electrodynamometers have an advantage over galvanometer systems inasmuch as no magnet is necessary and there is therefore no uncertainty as to distribution of magnetism. A further advantage is that no knowledge of the intensity of the earth's magnetic field is required in order to reduce the observations. The disadvantages are inferior sensitiveness and the difficulty of accurately measuring force by a torsional or bifilar suspension. In all measurements of current, coils are used, but, as Lord Rayleigh has shown, it is not necessary in all cases to measure the dimensions of the coils; a ratio of radii sometimes suffices. In the Gray electrodynamometer, however, the lengths and diameters must be measured. Rosa (*Bureau of Standards Bull.*, 1906, ii. No. 1) has shown that the spiral winding of the coils is practically equivalent to a current sheet, and further shows that large errors may be produced by irregular winding of the coils. The correction due to this effect in Guthe's experiments (*Bureau of Standards Bull.*, 1906, ii. No. 1) was particularly large. Regularity of pitch may, however, be obtained if the bobbins are first screw cut on a precision lathe.

When the couple between the coils is balanced against the torsional moment of a wire, the latter moment is determined by vibrating a cylinder of calculated moment of inertia and taking the period of a complete vibration. The probable error of such a determination is not negligible, as has been shown by Guthe, who made experiments with four cylinders and obtained results differing by as much as 1 part in 3000.

(i.) *Measurements.*—Latimer Clark (*Roy. Soc. Proc.*, May 30, 1872), in determining the electromotive force of his standard cell, used a bifilar electrodynamometer in which the Helmholtz-Gaugain arrangement of two coils was adopted both for the fixed and suspended systems. The suspension consisted of two

wires attached to a silk thread passing over a small pulley; in this way the tension was maintained reasonably uniform and the suspension wires allowed of the passage of the current. The suspended coil could be moved vertically and horizontally in two directions by means of screw adjustments.

A similar instrument was employed at the McGill University, Montreal, by R. O. King (*Roy. Soc. Phil. Trans.*, 1902), and later by A. N. Shaw (*Roy. Soc. Phil. Trans.*, 1914). The experiments with this instrument merit special attention as the modifications introduced enable measurements of very high accuracy to be made. The principal sources of error in previous instruments of this type were (1) the uncertainty of insulation of the coils; (2) the difficulty of determining the mean radii of the coils which were wound with silk-covered wire; (3) the want of rigidity of the suspension arrangement for equalising the tensions of the suspending wires; and (4) the imperfect elasticity of the control, which depended too much on torsion. To overcome these difficulties Shaw wound the coils with a double winding to give a perfect check on the insulation. The large coils were wound with a carefully measured length of hard rolled copper tape, which gave a very high order of accuracy in the determination of the mean radius. The coils were also made reversible and interchangeable to eliminate possible errors of symmetry, especially in the measurement of the distance between their planes. The dimensions of the suspended coils were determined by a method based on that due to Bosscha, and great accuracy was obtained in this way. A good deal of time was spent in selecting a suitable suspension, and Callendar, who was associated with the measurements, estimated the error introduced by it to be very small.

A Gray electrodynamometer in which the coils were of single layers of wire was constructed by Patterson and Guthe (*Phys. Rev.*, 1898, vii.) for the determination of the electro-chemical equivalent of silver and was also used by Carhart and Guthe (*Phys. Rev.*, 1899, ix.) for the measurement of the E.M.F. of the Clark cell. In these experiments the couple was balanced by the torsional moment of a single wire the mechanical properties of which had been previously determined. Guthe (*Bureau of Standards Bull.*, 1906, ii. No. 1) used single layer coils wound on bobbins of plaster of Paris, the larger coil being about 50 cm. in diameter and the smaller coils 7·5 cm. and 9·9 cm. respectively. Two movable coils were used in order to increase the accuracy of the result. A great deal of time was spent in the attempt to find a suspension which would show the smallest elastic after-effect and not change its elastic properties in course of time. The attempt was only partially successful.

(ii.) *Results.*—In 1872 Latimer Clark found the electromotive force of the Clark cell at 15°·5 C. to be 1·4573 B.A. volts. The standard of resistance was the B.A. ohm.

Patterson and Guthe in 1898 measured the electro-chemical equivalent of silver to be 1·1192 mgm. per coulomb, and in the following year Carhart and Guthe obtained the value 1·4333 volts for the electromotive force of the Clark cell at 15° C.

Guthe (1906) arrived at the values 1·43296 volts for the Clark cell at 15° C. and 1·01853 volts for the Weston normal cell at 20° C. He concluded that the electro-chemical equivalent of silver is 1·11773 mgm. per coulomb.

King (1914) found the electromotive force of the Weston normal cell at 20° C. to be 1·01831 volts.

§ (31) McCollum Type of Electrodynamometer.—B. McCollum (*Bureau of Standards Bull.*, Nov. 1910) has described a type of electrodynamometer which appears to be free from most of the difficulties associated with the Guthe type with torsional or bifilar control.

The instrument (*Fig.* 12) consists essentially of a relatively large fixed coil C_1 with horizontal axis, and a smaller suspended coil C_2 with its axis coincident with that of C_1 when the system is at rest. Rigidly attached to C_2 is a cylinder K of non-magnetic homogeneous material placed with its axis vertical and in line with the suspending wire W. When a current is passed through the two coils appropriately connected in series the effect is to hold the movable coil with its axis coincident with that of the fixed coil, and if the movable coil be given an angular displacement and released, it will oscillate as a torsion pendulum. If the restoring couple is proportional to the angular displacement, the period is independent of the amplitude and the system is subject to the laws of a damped oscillation. The time T of vibration of the moving system is given by the equation [1]

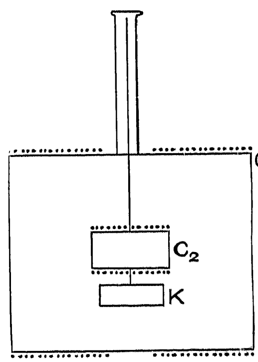

Fig. 12.

$$T_1=\frac{2\pi}{\sqrt{\frac{c}{K}-\frac{b^2}{4K^2}}},$$

[1] See "Galvanometers," § (10).

where c is the restoring couple per unit angular displacement, b is the counter torque due to the damping forces at unit angular velocity, and K is the moment of inertia of the moving system.

When the coils are so proportioned that the torque due to the current i is proportional to the deflection

$$c = Ci^2 + a,$$

where C is a constant of the coil system, a a constant depending on the suspending wire, and R the total restoring couple. The period T_1 may therefore be written

$$T_1 = \frac{2\pi}{\sqrt{\frac{Ci^2+a}{K} - \frac{b^2}{4K^2}}}.$$

With no current through the coils the time of vibration T_2 is

$$T_2 = \frac{2\pi}{\sqrt{\frac{a}{K} - \frac{b^2}{4K^2}}}.$$

From the last two equations it follows that

$$i = \frac{2\pi}{T_1}\sqrt{\frac{K}{C}\left(1 - \frac{T_1^2}{T_2^2}\right)}.$$

McCollum shows that the torque is proportional to the deflection when the coils are so wound that the ratio of length to diameter of the fixed coil is $\sqrt{3/2}$ and that of the movable coil is either 2·062, 0·92, or 0·38. For deflections of 8° from the central position the time of vibration is then independent of amplitude within about 1 part in 100,000. The constant of the instrument can be either calculated or determined by measuring the mutual inductance in the coaxial position. In the Gray type of electrodynamometer the torque is proportional to the sine of the angle of deflection, and the period would not be isochronous except for values of θ not exceeding about one-half degree.

Unfortunately the foregoing method has not yet been subjected to experimental tests, so that the limits of accuracy cannot be stated with precision. It is clear, however, that the torsion of the suspending wires is eliminated. The value of K must be accurately known and the determination may present difficulties; also much depends on the correct measurement of the times of vibration. McCollum describes the method he would adopt for measuring T_1 and T_2 which involves observations over a considerable period of time (20 minutes), but has the advantage that if the current varies its mean value is accurately measured.

The writer has made somewhat similar measurements with a current balance and is of opinion that the McCollum type of electrodynamometer can be used for the accurate measurement of steady currents lasting less than a minute. In such a case the period should be taken photographically on a rapidly running film on which an accurate time trace is simultaneously photographed, the trace enabling time intervals to be measured within 0·00001 second. The writer further suggests that in order to remove the uncertainty attending the determination of K the suspended coil should be mounted centrally on the beam of a balance and appropriate measurements made to determine the distance between the centre of support and the centre of mass. K can then be calculated.

§ (32) Current Weighers.—In these the mutual action between currents in coils is balanced by a force exerted by gravity on a known mass.

The acceleration of gravity at any place can be determined with great accuracy, and therefore force can be measured accurately by means of a balance. For this reason instruments in which the mutual action between two circuits, or two portions of the same circuit, is measured by means of a gravity balance have been much favoured.

In most current weighers two or more coils are placed in series with their planes parallel and their axes coincident. If M is the mutual inductance between the coils and x the distance between their centres, the mutual attraction[1] between them is $i^2(dM/dx)$, where i is the current. dM/dx is calculated from the dimensions of the coils and the force $i^2(dM/dx)$ is balanced by the force exerted by gravity on a mass on the balance pan. Thus i can be determined. This type of current weigher in which the axes of the coils are coincident will be considered first.

In a primitive form the first current weigher appears to have been constructed by Cazin (*Ann. de Chim.* i.) in 1863. This consisted of two rectangular coils with their planes parallel, one hanging from the beam of a balance directly above the other. In 1864 Joule made a current balance having three circular flat coils, one being suspended from the beam of a balance so that its mean plane, which was horizontal, was midway between those of the other two fixed coils. The principal constant of the instrument was determined by comparison with a standard tangent galvanometer. Joule employed it in his electrical determination of the mechanical equivalent of heat.

In 1882 Mascart (*Journ. de Physique*, March 1882) suspended a long solenoid from one end of a balance beam, the lower end of the solenoid being in the mean plane of a large flat coaxial coil of much larger radius. If the solenoid is uniformly wound it is equivalent to a simple magnet, with poles at the terminal

[1] See "Electromagnetic Theory," § (10).

faces. The mutual action then depends upon the difference between the mutual inductances of the fixed coil and the lowest and uppermost windings of the movable coil.

§ (33) The Rayleigh Balance.—In 1882 Lord Rayleigh (*B.A. Report*, 1882) pointed out that in a measurement of current depending on the mutual attraction between two coils the absolute dimensions of the system are of no importance. If M is the mutual inductance and i the current, the force between the coils is $i^2(d\mathrm{M}/dx)$, where x is the axial distance between the coils. In this expression i^2 is already of the dimensions of a force and $d\mathrm{M}/dx$, though a function of the radii of the coils and their distance apart, is itself a pure number. If A and a be the mean radii of the coils the value of $d\mathrm{M}/dx$ depends only on the ratios a/A and x/A. If we write $(d\mathrm{M}/dx)=f(\mathrm{A}ax)$ and consider the variation of f as a function of the three linear quantities, the coefficients in the equation

$$\frac{df}{f}=q\frac{d\mathrm{A}}{\mathrm{A}}+r\frac{da}{a}+s\frac{dx}{x}$$

are subject to the relation $q+r+s=0$.

Lord Rayleigh pointed out that if the coils are placed at such a distance apart that the attraction is a maximum, $s=0$, and the calculation is independent of small errors in the value of x. In these circumstances $q+r=0$, so that proportional errors in A and a affect the result in the same degree and in opposite directions. This is a result of great importance, as the attraction becomes practically a function of the ratio A/a only. In this way all that is necessary for the absolute determination of currents can be obtained without measurements of length, or of moments of inertia, or even of absolute angles of deflection. To measure the ratio of the radii the method of Bosscha (*Pogg. Ann.*, 1854) can be used. This consists in placing the two coils concentric and with their planes in the magnetic meridian, the coils being connected in parallel and in series with suitable resistances. When a current is passed through this compound circuit the magnetic fields at the centre will be opposed; equality is obtained by adjusting one of the resistances until the torque exerted upon a small magnetic needle suspended at the centre of the coils is zero. For a very short magnetic needle the ratio of the galvanometer constants is then equal to the ratio of the two resistances. In determining this latter ratio the difficulty due to the heating of the coils by the measuring current is overcome by arranging the coils and resistances in such a way that, after balancing the magnetic fields, the removal of a single link suffices to place the resistances, of which the ratio is desired, into the adjacent arms of a Wheatstone bridge.

All current weighers have not been constructed on the Rayleigh system, but there is so much in common that the probable errors of all can be considered together.

In any current balance the coils must have a sufficient number of turns and the wire be of such cross-section as to permit of the passage of such a current as will produce a force large enough to be measured with precision. As the coils are warmed by the current the dimensions change slightly, and by whatever method the dimensions, or ratio of dimensions, are determined, the same value current should be used as in the weighing experiments. In the case of coils with many layers the heating may be very troublesome and will vary with the position of the coils; some uncertainty may therefore be introduced in the Bosscha method, because in this the coils must be vertical while in the balance they are horizontal. With a view to avoiding this difficulty Heydweiller in 1891 placed the coils with their common axis horizontal, the moving coil being carried directly below the centre of the balance beam in the position usually occupied by the pointer. The heating of the coils also produces convection currents of air inside the balance case, which in precision measurements may be very serious in their effects; duplicating the system on the other side of the balance arm is a partial remedy. Any attempt to increase the force by increasing the number of turns is limited not only by the heat developed in the coil but also by the increase of voltage required to overcome the resistance of the coils. When this voltage is moderately great it gives rise to serious electrostatic attractions due to differences of potential between various parts of the balance. Again, since the coils are of copper and the current must usually be maintained very steady, a ballast resistance of small temperature coefficient has to be employed. In the cases of current balances where single layer coils have been used, it is necessary to know the radii and lengths of all coils with very great accuracy, and in the Rayleigh balance corrections must be made for the cross-sections of the coils. In all current weighers care must be taken that no magnetic material is used which may invalidate the results, and the current in all leads to and from the coils must have a negligible or calculable effect.

(i.) *Measurements.*—In 1884 Lord Rayleigh (*Roy. Soc. Phil. Trans.*, 1884, part ii.) made measurements of the electro-chemical equivalent of silver using a current weigher to determine the mean value of the current. The coil system was a single one, *i.e.* on one side only of the balance, two equal fixed coils about 25 cm. in radius and one suspended coil about 10 cm. in radius being employed. The number of turns on each fixed coil was

225, and there were 242 turns on the suspended coil. The current used usually was about 0·3 ampere, and on reversal through the suspended coil the change of force was about one gram. The weighings were recorded to milligrams only, but the accuracy of weighing was considerably greater than one part in 1000. The current was led into the suspended coil by means of fine flexible copper wires, bent so as to place themselves naturally in the required positions before soldering them; these wires would carry a current of an ampere without getting unduly hot. Lord Rayleigh concluded that, apart from errors in the constant of the instrument, the determination of the mean value of a current of half an hour's duration should easily be correct within 1 part in 10,000.

Janet, Laporte, and Jouast (*Bull. de la Soc. Internat. des Électriciens*, 1908) used a current balance approximating to the Rayleigh type in experiments made at the Laboratoire Central d'Électricité. The system was a duplex one, two fixed coils and one suspended coil being arranged on each side of the balance. The distance between the fixed coils was greater than that which would give the maximum force upon the suspended coil, and hence the force varied less rapidly for small variations in the axial position of the latter. The exact placing of the suspended coil therefore was of less importance than in the Rayleigh system, but the distance between the fixed coils had to be determined with greater accuracy; an error of 0·01 mm. in this distance produced an error of 5 parts in 100,000 in the measurement of the current. The radii of the coils were determined from the length of wire wound on them, the mean radius of a fixed coil being about 36 cm. and that of a suspended coil being about 19 cm. Each of the fixed coils consisted of 414 turns of wire, and each of the suspended coils had 192 turns.

In their first calculation of the constant of the instrument Janet, Laporte, and Jouast assumed that the axial breadth of a coil was given by the total breadth of the channel in which it was wound, but that the radial depth was given by the distance from the axis of the wire in the bottom layer to the axis of the wire in the top layer. Later (*Comptes Rendus*, Oct. 1911, p. 718) Janet, Laporte, and Jouast recalculated the value of the constant of their coils, using the correct sectional dimensions. In their current measurements the total resistance of the circuit was 94 ohms, the current employed about 0·3 ampere, and the balancing mass about 4·5 grams.

Guillet (*Bull. de la Soc. Internat. des Électriciens*, 1908) also used a duplex current weigher with multi-layered coils, but the fixed coils were placed very close together, and the moving coils were but slightly smaller than the fixed coils. There were 960 turns on each of the fixed coils and 452 turns on each of the moving coils. The constant of the instrument was not determined from its dimensions, but the mutual inductance between the fixed and moving coils for various axial positions of the latter was determined by direct comparison with an absolute standard of mutual inductance of the Lippmann type. An equation enabling dM/dx to be calculated was thus obtained. This method has the advantage that the standard of mutual inductance may consist of coils of very few turns wound so as to enable their dimensions to be accurately determined, whereas the coils in the current balance may be wound irregularly conditionally that the dimensions keep reasonably constant. A disadvantage in practice appears to be the difficulty of determining dM/dx with sufficient accuracy owing to the rapid variation of M with x, and the practical impossibility of measuring x with the requisite accuracy.

Pellat and Potier (*Journ. de Physique*, 1890) in 1890 used an electrodynamometer with a very long fixed coil and a short moving coil, and in 1908 Pellat (*Bull. de la Soc. Internat. des Électriciens*, 1908) used an instrument similar in principle. The fixed coil consisted of a long multi-layered solenoid placed with its axis horizontal. Inside this a small single-layered coil is supported on a knife edge with its axis vertical and its centre coincident with that of the fixed coil; it is free to oscillate about an axis at right angles to the axis of the two coils. In addition to the small coil the knife edge supports the beam of a balance, and the torque between the two coils is measured by means of weights in the ordinary manner.

Ayrton, Mather, and Smith (*Roy. Soc. Phil. Trans.* A, 1908, ccvii.) made measurements with an elaborate current weigher designed to measure current in absolute measure with a probable error of a few parts in 100,000. The instrument was constructed and erected at the National Physical Laboratory.

The system is a duplex one, and both fixed and suspended coils are of single layers of bare wire wound in spiral grooves cut on marble bobbins. Each cylinder has double-threaded screw grooves cut on the surface, and into these grooves separate coils are wound with the wire under tension. The coils form adjacent helices, which in the use of the instrument are connected in series and act as one coil; they can, however, readily be disconnected and an insulation test made between them. This applies to each of the six coils forming the current weigher; there are, therefore, 12 helices in all, and these are

connected in series by means of small concentric cables running to a plug board and commutators outside the balance case. The mean diameter of the fixed coils is about 33 cm. and that of the suspended coils is about 20 cm., the respective axial lengths being 12·7 cm. and 13 cm. The number of turns on each fixed coil is 90 and on each suspended coil 92. The normal current is about 1 ampere, and the change of balancing mass on reversal of this current is about 16 grams.

The fixed cylinders are supported on phosphor bronze brackets, the tops of which are similar to the tables of small milling machines, and the motion of the fixed coils is controlled by screws of large diameter enabling their positions to be read within about 0·0025 mm. An adjustment in an axial direction can also be made. The fixed and suspended coils are set coaxial and coplanar by electrical methods which are exceedingly sensitive; the scheme is to arrange the circuits so that a suspended coil is subject to no restoring force when it is coplanar and coaxial: the rate of change of force for a small displacement is then a maximum. In this electrical method of setting the coils in their correct positions one-half of the system, *i.e.* a system on one side of the balance, is arranged to exercise no force, whatever be the relative position of its coils; the current flows through these coils, however, and compensates approximately for the disturbance due to convection currents of air and also for any effect due to the earth's magnetic field. Changes in position of the fixed coils on the other side of the balance are then made until they are coaxial and coplanar with the suspended coil. It is concluded that the vertical position can be fixed within less than 0·01 mm., and that the coils can be set concentric so that the greatest error due to faulty radial setting is 1 part in 5 millions.

The advantages of the duplex system were investigated experimentally. The results show that marked compensation for the effect of convection currents is obtained. In addition, the duplex system has the advantage that two independent determinations of current can be made by using the sets separately; also the setting of the coils in their correct positions is much facilitated.

Current was led into and out of the suspended coils by means of 80 silver wires, each 0·025 mm. in diameter and 10 cm. long. The sensitiveness of the balance was reduced 6 per cent by these wires, but there was no disturbing effects due to convection currents of air.

The force between the fixed and suspended coils was calculated by an elliptic integral formula due to J. Viriamu Jones (*B.A. Report*, 1889), which is rigorously exact for a helix and a current sheet and a very close approximation for two helices of fine pitch. With a duplex system the fixed coils of one system exert a force on the suspended coil of the other system, but by properly arranging the circuits these secondary forces can be added to or subtracted from the principal force. This was done and the secondary effects eliminated. Dr. G. F. C. Searle has calculated the value of this secondary effect with great accuracy.

Electrostatic effects of appreciable magnitude were measured and found to be due principally to the electrostatic forces between the suspended coils and metal guard discs underneath them. The effects were easily eliminated, and in any case would have produced no error, as in the observations they occurred twice with opposite signs.

The physical balance was specially constructed, the principal novelties being an arrangement for removing the beam from the central agate plane while leaving the suspended cylinders and scale pans swinging and a method of hanging of the cylinders from planes separate from those supporting the scale pans. Any motion of the scale pans had no effect, therefore, on the cylinders.

Considerable difficulty was experienced in obtaining all metal parts sufficiently free from magnetic material, and very exhaustive tests were made to ensure that the error due to magnetic material should be negligible. After completion a current was sent through one suspended coil only, and the rest point of the balance observed. The same test was made with the current reversed but no change in the rest point could be detected.

Ayrton, Mather, and Smith conclude that the determination of current by means of their current balance is subject to errors of the following magnitude:

(1) Due to uncertainty in the dimensions of the coils: possible error about $\pm 0{\cdot}001$ per cent.

(2) Due to uncertainty in the value of "g": possible error about $\pm 0{\cdot}0015$ per cent.

(3) Other possible errors less then $\pm 0{\cdot}001$ per cent.

The total probable error is therefore about ± 2 parts in 100,000.

Rosa, Dorsey, and Miller (*Bureau of Standards Bull.*, 1912, viii. No. 2) have made measurements at the Bureau of Standards, Washington, with a beautifully constructed and carefully designed current balance of the Rayleigh type. It has a single system of coils of large proportions, and to allow for independent sets of measurements to be made four suspended coils and six fixed coils were used. The suspended coils varied in radius from 10 to 12·5 cm. and the fixed coils from 20 to 25 cm. All the coils are on forms

of cast brass and are wound bifilarly with wire insulated with enamel, the channels of the forms being lined with paper soaked in paraffin wax. The fixed coils are cooled by a water-jacket, and the moving coil is surrounded by a cylindrical copper jacket, double walled on the sides, completely closed at the bottom and covered by a lid having a central aperture through which passes the tube from which the moving coil is suspended. The space between the two cylindrical walls is filled with circulating water, which carries away the heat generated by the current in the moving coil and enables a steady state to be quickly brought about. The coils are not contained in the balance case proper, but in a lower chamber, and no disturbing effects on the beam of the balance were experienced.

The ratio of the radii of the coils was measured in several ways. In one of these, called the potentiometer method, the ratio measured was that of the currents through the coils when the same field intensity was produced at the centres. In another measurement, called the shunt method, which is applicable only to coils having very nearly the same galvanometer constant, the two coils are connected in series, and the coil with the larger galvanometer constant, together with an added resistance, is shunted so as to obtain a zero field at the centre of the coils. One of the coils was so constructed that when its two windings were in series it had nearly the same galvanometer constant as another coil with its two windings in parallel. A third method, being a combination of the potentiometer and shunt methods, was also experimented with and satisfactory results obtained. The probable error of the measurements was about 2 parts in a million.

In computing the force between the coils it was shown that ample accuracy is secured by assuming that a fixed coil is equivalent to the eight turns obtained by quartering it and replacing each quarter by its two equivalent turns, and that the suspended coil is likewise equivalent to eight turns. The effect of errors in the sectional dimensions was most carefully considered, and it is concluded that the uncertainty due to errors in measuring the cross-section of the coils may amount to about 5 parts in a million.

When making current measurements, the windings of the suspended coil were directly connected to the water-jacket by means of a wire running from the commutator. Thus the water-jacket and all of the surrounding framework were brought to the potential of the moving coil; electrostatic effects were thus eliminated. The authors conclude that the possible uncertainty of the mean result obtained by them is not greater than 2 parts in 100,000.

(ii.) *Results with Current Weighers.*—The results are expressed either as the mass of silver deposited by one coulomb, or as the electromotive force of a standard cell (Clark or Weston normal cell), the value of the resistance used being assumed as known in C.G.S. units, or known in terms of some other standard. The standard employed is stated in columns 4 and 5 of the table.

Date.	Observer.	Electro-chemical Equivalent of Silver.	E.M.F. of Clark Cell.	E.M.F. of Weston Normal Cell.
		mgm.		
1882	Mascart	1·1156	..	..
1884	Lord Rayleigh	1·11794	1·435 at 15° C. (Ohm = 10^9 C.G.S.)	..
1890	Pellat and Potier	1·1192	..	..
1908	Ayrton, Mather, and Smith	1·11827	..	1·01818 at 20° C. (Int. Ohm)
1908	Janet, Laporte, and Jouast	1·11821	..	1·01836 at 20° C. (Int. Ohm)
1908	Guillet	..	..	1·01812 at 20° C. (Int. Ohm)
1908	Pellat	..	..	1·01831 at 20° C. (Int. Ohm)
1911	Rosa, Dorsey, and Miller	1·11804	..	1·01822 at 20° C. (Int. Ohm)

The differences between the results given in column 3 are no doubt largely due to the different forms of voltameters employed and to the use of impure solutions of silver nitrate.

The differences between the results given in column 5 may be due in part to a real difference in the cells measured.

§ (34) Smith's Pendulum Balance.—In 1912, F. E. Smith made some experiments with the current balance at the National Physical Laboratory with a view to measuring the mean value of a slightly varying current. The balance was used as a pendulum system, and in addition to the mutual inductance of the system of coils, the moment of inertia

of the swinging mass and the periods of swing have to be known.

In a current balance of suitable form let m be the total mass of the swinging system, K its moment of inertia about the central knife edge, and h_1 the distance of the centre of gravity below the central knife edge. Then, if b is the counter torque at unit angular velocity due to the damping forces, and T_1 the period, we have

$$T_1=\frac{2\pi}{\sqrt{\frac{mgh_1}{K}-\frac{b^2}{4K^2}}}.$$

Let M be the mutual inductance between the coils, and suppose the latter to be such that for relatively large displacements dx of a moving coil, the force tending to restore the coil to the central position is $i^2(dM/dx)$, where i, the current, circulates through all the coils in the same direction. Under these conditions the new period T_2 is given by

$$T_2=\frac{2\pi}{\sqrt{\frac{mgh_1+i^2l\frac{dM}{dx}}{K}-\frac{b^2}{4K^2}}},$$

where l is the length of an arm of the balance.

From the equations for T_1 and T_2 we have

$$i^2=\frac{4\pi^2}{T_2^2}\cdot\frac{K}{l\frac{dM}{dx}}\left(1-\frac{T_2^2}{T_1^2}\right).$$

In this equation dM/dx is calculated from the dimensions of the coils, T_1 and T_2 are observed, and l is easily measured with great accuracy. It remains to find K the moment of inertia. This would be exceedingly easy if the beam did not bend with varying load and so alter the position of the centre of gravity. However, as this does happen it is better to find K indirectly by finding the change of position of the centre of gravity when there is a redistribution of mass without any change of K.

Let there be two small masses m_2 and m_3, the one being vertically above the central knife edge and the other directly below it. Let m_2 be much smaller than m_3, and let both be provided with such markings that the distance between them can be readily measured. Let m_2 be centrally situated at a distance l_2 above the knife edge and m_2 at a corresponding distance l_3 below it. l_2 should be equal, or nearly equal, to l_3. Let the remainder of the swinging system have a mass m_4, so that

$$m=m_2+m_3+m_4.$$

If the centre of mass of m_4 be at a distance l_4 below the central knife edge, then

$$m_4l_4+m_3l_3-m_2l_2=mh_1.$$

Let m_2 and m_3 be now interchanged in position, thus altering the period of the balance (without current) to T_3. Then

$$T_3=\frac{2\pi}{\sqrt{\frac{mgh_2}{K}-\frac{b^2}{4K^2}}}$$

and $$m_4l_4+m_2l_3-m_3l_2=mh_2.$$

Hence $$(m_3-m_2)(l_3+l_2)=m(h_1-h_2).$$

Eliminating $b^2/4K^2$ from the equations for T_1 and T_3 we have

$$K=\frac{T_1^2}{4\pi^2}\cdot\frac{mg(h_1-h_2)}{\left(1-\frac{T_1^2}{T_3^2}\right)}.$$

Hence $$K=\frac{T_1^2}{4\pi^2}\cdot\frac{g(m_3-m_2)(l_3+l_2)}{\left(1-\frac{T_1^2}{T_3^2}\right)}.$$

(m_3-m_2) can be determined with great precision, and if m_3 and m_2 are supported from pivots, the distance between the effective centres of mass can also be accurately measured.

Preliminary measurements of current have been made with satisfactory results, and it has been planned to use the current balance at the National Physical Laboratory both as a "weigher" for steady currents and as a pendulum balance for slightly varying currents.

§ (35) Summary of Results.—The table on following page summarises the results of absolute measurements of current made since 1872.

§ (36) Electro-chemical Equivalent of Silver.—In the section[1] dealing with the International ampere many sources of error in the silver voltameter are explained. In many of the very early voltameter experiments there is little doubt that impure silver nitrate solutions were used, and these led to more silver being deposited than would have resulted from pure solutions. Filter paper as a septum between anode and cathode was quite common, and the reducing effect of this resulted in abnormal deposits being obtained from otherwise pure solutions. The presence of acid causes a reduction in the weight of silver, but on the whole there is little doubt that previous to 1910 most of the values given for the electro-chemical equivalent of silver are too large because of the presence of impurities in the electrolyte. With very pure silver nitrate solutions, and using no septum between the anode and cathode, the true value for the electro-chemical equivalent of silver is obtained. A close review of recent determinations leaves little doubt that within 1 part in 10,000 the electro-chemical equivalent of silver is

1·1181 milligrams per coulomb.

[1] See § (40).

* The E.M.F. is expressed in terms of the ampere (10^{-1} C.G.S.) and the international ohm.

† The E.M.F. is expressed in terms of the ampere (10^{-1} C.G.S.) and the B.A. unit.

Various forms of voltameters were used and the numbers given for the electro-chemical equivalent do not enable a good comparison to be made (see § (40) on "International Ampere").

§ (37) E.M.F. OF WESTON CELL.—In recent years the electromotive force of the Weston normal cell at 20° C. in terms of the ampere (10^{-1} C.G.S. unit) and the international ohm has been determined by eight observers, the results being as follows:[1]

Year.	Observers.	E.M.F. of Weston Normal Cell at 20° C.
1908.	Ayrton, Mather, and Smith	1·01818
1908.	Janet, Laporte, and Jouast	1·01836
1908.	Guillet	1·01812
1908.	Pellat	1·01831
1910.	Smith	1·01818
1910.	Haga and Boerema . .	1·01826
1911.	Rosa, Dorsey, and Miller .	1·01822
1913.	Shaw	1·01827
	Mean .	1·01824

The most probable value of the international ohm is $1{\cdot}0005_2$ ohms (10^9 C.G.S. units), so that the most probable value of the Weston normal cell in C.G.S. measure is $1{\cdot}0182_4 \times 1{\cdot}0005_2$ or

1·0188 volts (10^8 C.G.S. units) at 20°·0 C.

[1] For a further discussion of the latest values see § (41).

III. INTERNATIONAL ELECTRIC STANDARDS

§ (38) INTRODUCTION.—It is generally agreed that the fundamental electric units should be defined in the C.G.S. system, and the usual definitions of the ohm, ampere, and volt are universally accepted. Very few countries have, however, made measurements of the ohm and ampere in absolute measure, and it is only in recent years that such measurements have been made with comparatively great accuracy. While, therefore, the world possesses ideal definitions for the electric units, material standards do not necessarily closely represent these units.

In the section on the absolute measurement of resistance it will be seen that the first attempt of the British Association Committee in 1863 to measure a resistance in C.G.S.

units was in error by about 1½ per cent. The resistance actually measured was that of a coil of wire, and this resistance was compared with those of other coils which afterwards served as reference standards. In particular, one coil of German silver wire known as "June 4" was compared with the resistance of the rotating coil, and its value was given by the observers as 107,620,116 metres per second. This coil afterwards served as a "standard." When subsequently other coils were compared with this and other "standards" the observed values, instead of being stated in metres per second, were stated in B.A. units. While therefore the magnitude of a standard was determined on the electromagnetic system of measurement a new unit was at the same time adopted which probably was not identical with, but for all practical purposes was sufficiently equal to, the C.G.S. unit.

The ampere cannot be represented in a concrete or material form in the sense in which the ohm can, but having once measured within certain limits the electro-chemical equivalent of silver it is the silver voltameter which afterwards forms the basis of reference, and therefore acts as a "standard."

Now it has always been possible to compare electric quantities with greater accuracy than to determine their values in absolute measure. If, therefore, for either purely scientific or commercial purposes the value of an electric quantity must be known in terms of some definite unit with a greater precision than is possible if that unit is one in the C.G.S. system, the obvious course is to measure the value of some concrete material in C.G.S. units and to assume the measured value to be correct within the desired limits. In practice this has been done, and the "unit" and "standard" have thus become distinct. Fortunately, with progress of time new standards have been set up and endeavours made to reduce the difference between the assumed and real values. To prevent confusion, qualifying names have been given to the standards, such as "legal ohm," "Siemens' unit," "international ohm," etc.

The history of the efforts made to bring about international uniformity in electric standards is a very long one, and for full information reference should be made to the Reports of the Electrical Standards Committee of the British Association. The last Conference to consider the subject met in London in 1908, and delegates were present from Australia, Canada, India, the Crown Colonies, and twenty-two foreign countries. The conference was presided over by Lord Rayleigh. As a result of its deliberation the Conference passed the following resolutions:

I. The Conference agrees that, as heretofore, *the magnitudes of the fundamental electric units shall be determined on the electromagnetic system of measurement with reference to the centimetre as the unit of length, the gramme as the unit of mass, and the second as the unit of time.*

These fundamental units are (1) the ohm, the unit of electric resistance which has the value of 1,000,000,000 in terms of the centimetre and second; (2) the ampere, the unit of electric current which has the value of one-tenth (0·1) in terms of the centimetre, gramme, and the second; (3) the volt, the unit of electromotive force which has the value 100,000,000 in terms of the centimetre, the gramme, and the second; (4) the watt, the unit of power which has the value 10,000,000 in terms of the centimetre, the gramme, and the second.

II. *As a system of units representing the above, and sufficiently near to them to be adopted for the purpose of electrical measurements and as a basis for legislation, the Conference recommends the adoption of the international ohm, the international ampere, and the international volt defined according to the following definitions:*

III. The ohm is the first primary unit.

IV. The international ohm is defined as the resistance of a specified column of mercury.

V. The international ohm is the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice, 14·4521 grammes in mass, of a constant cross-sectional area and of a length of 106·300 centimetres.

To determine the resistance of a column of mercury in terms of the international ohm, the procedure to be followed shall be that set out in Specification I. attached to these resolutions.

VI. The ampere is the second primary unit.

VII. The international ampere is the unvarying electric current which, when passed through a solution of nitrate of silver in water, in accordance with Specification II. attached to these resolutions, deposits silver at the rate of 0·00111800 of a gramme per second.

VIII. The international volt is the electric pressure which, when steadily applied to a conductor whose resistance is one international ohm, will produce a current of one international ampere.

IX. The international watt is the energy expended per second by an unvarying electric current of one international ampere under an electric pressure of one international volt.

It will be seen that a distinction is drawn between the fundamental C.G.S. units and the international units which are regarded as representing them with a sufficient degree of accuracy. One of the important questions discussed at this Conference was: Shall the ohm and the ampere, or the ohm and the volt be defined for practical purposes by material standards? The international ohm as defined

by the resistance of a specific column of mercury under standard conditions is acceptable to all. The international ampere cannot be represented in a material form in the same sense in which the ohm can, but the international volt might be specified in terms of the electromotive force of a standard cell. The accuracy and ease of reproduction of the voltameter was thought to be not well established, and it was urged that the standard cell had many advantages. The difficulties of both are dealt with in sections which follow, but the Conference resolved that the ampere should be the second primary unit.

§ (39) THE INTERNATIONAL OHM.—More than sixty years ago Dr. W. Siemens (*Poggendorff's Annalen*, cx. 1) proposed to adopt as a unit of resistance that of a column of mercury at 0° C. a metre long and one square millimetre in cross-section, and in a letter to the British Association Committee on Electric Standards (1862) he described the method by which he had constructed such standards. The measurements involved were those of length and mass, but a knowledge of the density of mercury was required in order to determine the cross-section. In 1892 Dr. von Helmholtz pointed out that any difficulty due to uncertainty of the density of mercury could be avoided by defining the mass of the mercury column of a given length which has unit resistance. The length recommended by the B.A. Electrical Standards Committee in 1892 was 106·3 cm. and 14·4521 grammes was chosen as the mass. The London Conference in 1908 modified this definition; the correction to be applied for the ends was given, and the length was stated to six significant figures, viz. 106·300 cm. The more essential parts of the 1908 specification are as follows:

"*The international ohm is the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice,* 14·4521 *grammes in mass, of a constant cross-sectional area and of a length of* 106·300 *centimetres.* The resistance which has to be added to the resistance of the tube to allow for the effect of the end vessels is to be calculated by the formula

$$A=\frac{0\cdot80}{1063\pi}\left(\frac{1}{r_1}+\frac{1}{r_2}\right)\text{ ohm},$$

where r_1 and r_2 are the radii in millimetres of the end sections of the bore of the tube.

"For the purposes of the electrical measurements the end vessels are to carry connections for the current and potential terminals. These end vessels are to be spherical in shape and of a diameter of approximately 4 centimetres.

"The mean of the calculated resistances of at least 5 tubes shall be taken to determine the value of the international unit of resistance."

If L_0 be the length, and s_0 the uniform cross-section of a column of mercury at 0° C. its resistance R_0 is given by the equation

$$R_0=\rho_0 L_0/s_0,$$

where ρ_0 is the resistivity of mercury.

By definition of the international ohm (London Conference, 1908), when $L_0=106\cdot300$ cm. and the mass of mercury is 14·4521 grammes, the resistance R_0 is unity; hence the resistance of any uniform column of mercury is given by

$$R_0=\frac{14\cdot4521}{(106\cdot300)^2}\cdot\frac{L_0^2}{M_0^2},$$

where M_0 is the mass of the column. To realise the international ohm, therefore, any length of column can be taken, and it is sufficient to measure the length and mass provided the column is of uniform cross-section and the end corrections are known.

The simplicity of the above formula is disturbed by the inevitable departure of the mercury column from the truly cylindrical form. In a well-chosen glass tube the column is conical, preferably uniformly so, but in general it may be regarded as a series of truncated cones of various lengths. As a result a correction, termed the conical correction, or calibre factor, has to be applied.

The true resistance R_0' of a column of variable cross-section is given by the expression

$$R_0'=\rho_0\int_0^{L_0}\frac{dl}{s}.$$

If Δ_0 is the density of mercury at 0° C. the mass M_0 is given by

$$M_0=\Delta_0\int_0^{L_0}s\,dl,$$

and we may write

$$R_0'=\rho_0\frac{\Delta_0}{M_0}\int_0^{L_0}s\,dl\int_0^{L_0}\frac{dl}{s}.$$

The resistance R_0 calculated on the assumption that the cross-section is uniform is $\rho_0 L_0/s_0$, or since $M_0=\Delta_0 L_0 s_0$ we have $R_0=\rho_0\Delta_0 L_0^2/M_0$, and therefore

$$\frac{R_0'}{R_0}=\frac{1}{L_0^2}\int_0^{L_0}s\,dl\int_0^{L_0}\frac{dl}{s}.$$

The ratio R_0'/R_0 is slightly greater than unity and is called the calibration factor.

(i.) *Calibration.*—It is clearly impossible to determine the cross-section of a tube from point to point, and therefore mean cross-sections of finite lengths must be taken. The methods adopted for the calibration of tubes intended for mercury standards of resistance vary considerably. If the tubes vary in cross-section by more than about 4 per cent a very complete and often laborious calibration is necessary, but simpler calibrations suffice for more uniform tubes.

In a simple calibration the length of a short mercury thread approximately l cm. long is measured when placed in n sections of the tube, the length of the tube being nl. The lengths are corrected for the menisci, and the cross-sections are proportional approximately to the reciprocals of the lengths. In a complete calibration $(n-1)$ mercury threads are employed; these have lengths L/n, $2L/n$, $3L/n$ . . . $(n-1)L/n$ respectively, so that when n is large the work is very long and tedious. Details of a complete calibration are given by Benoît (*Construction des étalons prototypes de resistance électrique*, Paris, Gauthier-Villars, 1885). A very simple yet accurate method of calibrating tubes has been used by Smith, who divides the tube first into two, three, or more equal lengths and introduces approximately equal lengths of mercury to occupy these sections. These mercury threads are weighed and the relative mean cross-sections are proportional to the masses. The number of such separate lengths into which the tube is divided is governed by the condition that none of these lengths shall vary in cross-section by more than 1 per cent. In a well-chosen tube the number of such separate sections is rarely more than four. Each section is then divided into centimetre lengths, and the length of a mercury thread approximately 1 cm. long is measured in each division; the menisci are ignored. Percentage differences from the mean length are then tabulated, and the calibre factor obtained from tables previously prepared. By this method a tube can be calibrated and its calibre factor calculated within about four hours.

In recent years tubes have been chosen with very great care. In some cases the uniformity of section is so good that the calibre factors are as small as 1·00002. Values of the factor for mercury standards recently constructed in Great Britain, Japan, and America are given in the following table:

Great Britain.		Japan.		United States.	
No. of Tube.	Calibre Factor.	No. of Tube.	Calibre Factor.	No. of Tube.	Calibre Factor.
2	$1{\cdot}00010_1$	1	1·000021	1	1·000089
6	$1{\cdot}00007_7$	3	1·000051	2	1·000066
9	$1{\cdot}00011_6$	4	1·000052	3	1·000047
11J	$1{\cdot}00018_1$	5	1·000079	4	1·000096
27	$1{\cdot}00007_3$	6	1·000093		
S	$1{\cdot}00002_6$				
G	$1{\cdot}00012_8$				
1	$1{\cdot}00002_9$				
130	$1{\cdot}00007_3$				
137	$1{\cdot}00000_8$				
5	$1{\cdot}00007_1$				
11V	$1{\cdot}00007_0$				
12	$1{\cdot}00010_0$				
13	$1{\cdot}00013_3$				

An uncertainty arises from lack of knowledge of the condition of the axis of the tube. The specification assumes the axis to be straight, but since the cross-section varies it is probable that the axis also departs from the straight line. Thus if the axis of a tube is of an undulatory character, such that the curvature is everywhere equal to 1/40 cm. and points of inflexion occur on the assumed axis at equal distances of 0·7 cm., the resistance of a mercury column filling the tube will be greater by 0·0036 per cent than that calculated on the assumption of an absolutely straight axis. The true axis, if drawn on paper, could not be distinguished by the unaided eye from a straight line.

(ii.) *End Correction.*—A correction which does not admit of absolutely definite solution is that required to take account of the resistance offered by that part of the mercury in the terminal cups. The problem is practically identical with that of the correction necessary in calculations of pitch for the open ends of organ pipes (see Rayleigh's *Theory of Sound*, § 307). Lord Rayleigh calculated that the maximum correction would be equivalent to adding to the actual length of the tube 0·82 of the mean diameter of the ends; this supposes that the diameter of the mercury column suddenly becomes infinite. It has been found by experiment for terminal bulbs a few cm. in diameter that the correction is equivalent to adding to the length of the tube 0·795 of the mean diameter of the ends. For specified terminal vessels the London Conference chose as the correction 0·80 of the mean terminal diameters.

(iii.) *Measurement of Length.*—The length of a tube is comparatively easy to measure conditionally that the ends are either ground or polished. In recent years the end planes of such tubes have been polished plane within a wave-length of light, and this enables good measurements to be made by direct sighting on the ends, or by contact methods.

(iv.) *Measurement of Mass.*—Three methods have been used to measure the mass of mercury filling the tube. In the first of these a mass of mercury in the form of a continuous column is introduced into the tube so as to approximately occupy the whole length chosen for standard purposes. Its length and the menisci are measured, and these, together with the mass of the column and the calibration data, enable the mass required to fill the tube to be calculated.

The second method consists in filling the tube with mercury, closing one end by a plane surface and removing the excess mercury at the other end. The plane surface is clamped to the tube by means of a steel screw with an intermediate ball-and-socket joint. After exhaustion of the tube sufficient mercury is

admitted to completely fill it, and after closing the lower end it is removed to an ice bath, suitable precautions being taken to prevent the introduction of moisture. The excess of mercury at the upper end is removed by the motion of a plane glass plate in a gimbal mounting. This method was perfected at the Reichsanstalt and has also been used in the United States and Japan.

The third method devised by Smith (*Researches of the National Physical Laboratory,* 1909, v.) consists in rendering the meniscus correction negligible and at the same time reducing the influence of errors in the measurement of thread length by means of capillary extensions coupled to the ends of the tube. Measurements can be rapidly made with the tube immersed in ice, but it is desirable that the tubes have thick walls in order that good connections can be made.

No single institution has made measurements on the same tube by all of these methods, but the Bureau of Standards have made measurements on one tube by the Reichsanstalt method and by that proposed at the National Physical Laboratory by Smith. The means of six measurements by each method agreed within 7 parts in a million, the probable error by the Reichsanstalt method being 2 parts in a million, and that by Smith's method being about 4 parts in a million.

(v.) *End Vessels.*—To compare the resistance of the mercury column with wire coils the spherical terminal vessels must be so fitted to the tube that there is no fear of contamination of the mercury. In addition the latter should be at 0° C. The glass tube and vessels containing mercury should therefore be surrounded by melting ice, and the terminal vessels and junctions should be such that there is no danger of leakage of water into the tube. Also it must be possible to measure the insulation resistance between the mercury column and the mixture of ice and water surrounding it. These requirements are satisfied when the terminal vessels and connections are of the form shown in *Fig.* 13. This form of terminal vessel is used at the National Physical Laboratory and modifications of it are in use in other countries.

A is one end of the standard tube and B is one end of the auxiliary tube, which serves, when partly filled with mercury, as a current lead. C is a second auxiliary tube with a platinum wire sealed in its lower end: C serves as a potential lead. The ends of the three tubes are ground slightly conical and are a good fit into the ground necks of the terminal vessel. The shaded pieces represent rubber bungs which are first slid over the glass tubes, and after these latter have been adjusted in position the bungs are pressed into the enlarged portions of the necks of the vessel. The external surfaces of the bungs

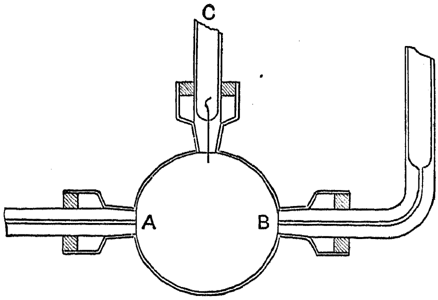

Fig. 13.

may, if necessary, be coated with paraffin wax.

(vi.) *Erection.*—With such end vessels there is no fear of contamination of the mercury by the ingredients of the rubber, and there is no danger of water leaking into the tube. The filling of the tube with mercury, which must be carefully purified, may be made under atmospheric pressure, or the tube may be first exhausted of air; the pressure should be equal to that holding when the mass was determined of the mercury filling the tube. As a change of temperature of mercury of 0°·01 C. is accompanied by a change of resistance of 8 parts in a million, the cross-sections of the current and potential leads must be sufficiently small to prevent the flow of heat through them raising the mean temperature of the mercury column by more than 0°·001 C. A limiting value is likewise placed on the testing current unless a correction for its heating effect is made. In the latter case two different currents, preferably in the ratio of 1 to 2, are used; as the increase of resistance is proportional to the square of the current used, it follows that for a current of negligibly small intensity the resistance is that of the smaller value measured less one-third of the difference between the two measured values.

(vii.) *Measurement of Resistance.*—The comparison of wire resistance coils with mercury standards of resistance presents some difficulties which do not arise in general resistance comparisons. The difficulties are due to the comparatively great resistance of the current leads and the considerable thermoelectric effects in the circuit.

Lord Rayleigh, Glazebrook, and Smith made measurements by the Carey Foster bridge, using special terminal vessels which allowed of high conductivity current leads being employed. The principal difficulty was due to the heat conducted through the current leads, and because of this a correction had to

be made. At the Reichsanstalt the Kohlrausch differential galvanometer method has been used, and modifications of the Kelvin double bridge have been employed at the National Physical Laboratory and the Bureau of Standards. A simple modification of the Wheatstone bridge has also been used at the National Physical Laboratory and at Tokyo. As the modifications of the Kelvin double bridge are not in general use for other resistance comparisons, one form is described here.

The leads of the mercury standard are indicated by L_1, L_2, L_3, and L_4, and in the bridge

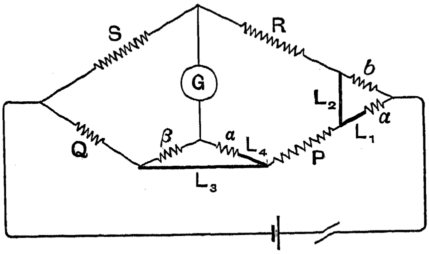

FIG. 14.

shown in *Fig.* 14 L_2 is shunted by $(b+a+L_1)$ and L_3 is shunted by $(\beta+\alpha+L_4)$.

When the connections are as shown in the figure the condition for balance is

$$\frac{P+\dfrac{(\alpha+L_4)L_3}{(\alpha+\beta+L_3+L_4)}+\dfrac{(a+L_1)L_2}{(a+b+L_1+L_2)}}{Q+\dfrac{\beta L_3}{\alpha+\beta+L_3+L_4}}=\frac{R+\dfrac{bL_2}{a+b+L_1+L_2}}{S}, \quad (1)$$

and the expression for P is

$$P=\frac{QR}{S}+\frac{\beta L_3}{\alpha+\beta+L_3+L_4}\left(\frac{R+\dfrac{bL_2}{a+b+L_1+L_2}}{S}-\frac{\alpha+L_4}{\beta}\right)+\frac{bL_2}{a+b+L_1+L_2}\left(\frac{Q}{S}-\frac{a+L_1}{b}\right). \quad . \quad . \quad . \quad (2)$$

In practice the second and third terms on the right-hand side of this equation are made negligibly small, and then

$$P=QR/S. \quad . \quad . \quad . \quad (3)$$

To do this the resistance coils are so chosen that approximately $R/S=\alpha/\beta$ and $Q/S=a/b$. In the general case the bridge is adjusted before commencing comparisons of the mercury standard with wire coils. In this adjustment α is disconnected from L_4, and by adjustment of Q and a a balance is obtained whether L_2 is connected to $R{\cdot}b$ or not. The following two equations then hold good:

$$\frac{P+L_3+a+L_1}{Q}=\frac{R+b}{S} \quad . \quad . \quad (4)$$

and

$$\frac{P+L_3+(a+L_1)\left(\dfrac{L_2}{a+b+L_1+L_2}\right)}{Q}=\frac{R+b\dfrac{L_2}{a+b+L_1+L_2}}{S}. \quad (5)$$

From these we have

$$\frac{a+L_1}{b}=\frac{Q}{S}. \quad . \quad . \quad . \quad (6)$$

Afterwards, by adjustments of Q and a and of α or β, a balance is obtained which holds good whether L_3 is connected to $Q{\cdot}\beta$ or not. In these circumstances

$$\frac{P+\alpha+L_4+\dfrac{(a+L_1)L_2}{a+b+L_1+L_2}}{Q+\beta}=\frac{R+\dfrac{bL_2}{a+b+L_1+L_2}}{S}, \quad (7)$$

and the relation (1) also holds good. From (1) and (7) we have

$$\frac{\alpha+L_4}{\beta}=\frac{R+\dfrac{bL_2}{a+b+L_1+L_2}}{S}, \quad . \quad (8)$$

and from (1), (6), and (8) it follows that

$$P=QR/S. \quad . \quad . \quad . \quad (9)$$

One of the coils Q, R, S is shunted in order that this equation may hold good.

The value of the combination having been obtained, a 1-ohm wire coil is substituted for P and the bridge rebalanced by altering the shunt on either Q, R, or S. From the change in the shunt the value of the wire coil is calculated in terms of the mercury standard.

It is convenient to choose as nominal values R=5 ohms, S=500 ohms, $\alpha=9{\cdot}85$ ohms, $\beta=1000$ ohms, and $b=500$ ohms. Q and a are equal variable resistances and are changed together. In such a case, if the resistance of each of the leads of the mercury standard be not greater than 0·15 ohm, and if the ratio R/S is equal to $(\alpha+L_4)/\beta$ within 4 parts in 1000, and the ratio Q/S is equal to a/b within 1 part in 10,000, the greatest error introduced by neglecting the preliminary adjustments cannot exceed 4 parts in a million.

Other modifications of the Kelvin double bridge for the comparison of mercury standards with wire coils are described by Smith (*Roy. Soc. Phil. Trans.*, 1904, p. 85) and by Wolff (*Bureau of Standards Bull.*, 1915, No. 256). A simple modification of the Wheatstone bridge is also described by Smith (*British Association Report*, 1906).

(viii.) *Measurements.*—Mercury standards of

resistance were first set up by W. Siemens in 1860, who was followed by Matthiessen and Hockin in 1863 (*B.A. Report*, 1863). These two authorities differed considerably, and Lord Rayleigh in 1881 (*Phil. Trans.*, 1883, Part I.) prepared four tubes for the purpose of determining the resistivity of mercury in absolute measure. The maximum difference between the mean value and those obtained from individual tubes was about 8 parts in 100,000. Carefully prepared standards were set up by Benoît in 1884 (*Construction des étalons prototypes de résistance électrique*, Paris, Gauthier-Villars, 1885), and a determination of the change of resistance with temperature was made by Guillaume (*Bureau International des Poids et Mesures*, 1892). In 1888 Glazebrook (*Phil. Trans.* A, 1888) erected six tubes and found that a column of mercury 1 metre long and 1 sq. mm. in cross-section had a resistance at 0° C. equal to 0·95352 B.A. unit. The largest calibre factor was 1·00079 and the smallest 1·00002. In more recent years most of the National Standardising Laboratories have set up mercury standards of resistance and the results obtained are in remarkable agreement. The principal references are Jaeger and Kahle (*Wiss. Abhandlungen Phys. Techn. Reichsanstalt*, 1900, iii.), Smith (*Roy. Soc. Phil. Trans.* A, 1904), Wolff, Shoemaker, and Briggs (*Bureau of Standards Bull.*, 1915), Obata (*Report of Electrotechnical Laboratory*, Tokyo, 1914), and *Report of the Bureau of Weights and Measures*, St. Petersburg, 1911.

The reproducibility of the international ohm appears to be very satisfactory, and mercury standards set up during the past forty years form our most satisfactory links with past standardising work. This is well illustrated in the B.A. Electrical Standards Committee Report for 1906, in which it is shown that if the mean value of six standard wire coils is taken as remaining constant from 1881 to 1908 two of the coils (of platinum wire) decreased in resistance by 63 parts in 100,000. These actual coils were, however, compared by Lord Rayleigh in 1881, by Glazebrook in 1888, and by Smith in 1908 with mercury standards newly constructed in these respective years, and the resistance values of the two platinum coils as given by these observers differ by only 3 parts in 100,000. The obvious conclusion is that the platinum coils remained reasonably constant in resistance and that the mercury standard of resistance is reproducible with a high degree of accuracy. The latter conclusion is also borne out by recent comparisons of mercury standards between Great Britain, the United States, Japan, Russia, and Germany. Taking the mean value as correct, the differences between it and the mean values of the standards of the various countries are as follows:

	Mean Mercury Unit minus that of the respective Countries.
Great Britain	0 parts in a million
United States	−10 „ „
Japan	− 4 „ „
Russia	− 5 „ „
Germany	+18 „ „

Measurements of the change of resistance of mercury with change of temperature have been made by Guillaume (*Bureau International des Poids et Mesures*, 1892), by Kreichgauer and Jaeger (*Wiedemann's Annalen*, 1892, xlvii.), and by Smith (*Roy. Soc. Phil. Trans.* A, 1904). According to these measurements the resistances of a constant volume of mercury at 0° C., 10° C., and 20° C. are in the following proportions:

Observers.	Resistance at		
	0° C.	10° C.	20° C.
Guillaume	1·000000	1·008987	1·018167
Kreichgauer and Jaeger	1·000000	1·008953	1·018158
Smith	1·000000	1·008984	1·018175

(ix.) *Relation between the International Ohm and the Ohm* (10^9 *C.G.S. Units*).—Absolute measurements of resistance show that the most probable value of the international ohm is

$$\mathbf{1{\cdot}0005_2}\ \text{ohm}\ (10^9\ \text{C.G.S. units}).$$

§ (40) The International Ampere.—By resolution of the London Conference on Units and Standards (1908):

"*The international ampere is the unvarying electric current which, when passed through a solution of nitrate of silver in water, in accordance with Specification II., deposits silver at the rate of* 0·00111800 *of a gramme per second.*"

Specification II. reads:

"The electrolyte shall consist of a solution of from 15 to 20 parts by weight of silver nitrate in 100 parts of distilled water. The solution must only be used once, and only for so long that not more than 30 per cent of the silver in the solution is deposited.

"The anode shall be of silver, and the cathode of platinum. The current density at the anode shall not exceed 1/5 ampere per square centimetre and at the cathode 1/50 ampere per square centimetre.

"Not less than 100 cubic centimetres of electrolyte shall be used in the voltameter.

"Care must be taken that no particles which may become mechanically detached from the anode shall reach the cathode.

"Before weighing, any traces of the solution adhering to the cathode must be removed, and the cathode dried."

This specification was not regarded as more than a provisional one. It was hoped that further experiments would be carried out and a more complete and more satisfactory specification drawn up. The conditions imposed by the specification were, however, believed to be sufficiently stringent to ensure reproducibility. Immediately previous to the Conference, researches at the National Physical Laboratory, the Reichsanstalt, and by Professor Kohlrausch indicated that the electrolyte does not alter appreciably because of electrolysis, but the researches of most previous investigators indicated that such a change does result. The specification makes no reference to temperature or pressure. While some observers have obtained results varying with temperature and with pressure, researches at the National Physical Laboratory indicated that the temperature and pressure coefficients are either zero or negligibly small. The silver nitrate, silver, and water are not specified as "pure," but it is to be concluded that all materials should be as pure as it is possible to obtain them.

A very large number of papers dealing with the silver voltameter have been published since Mascart (*Journ. de Physique*, 1882, Series II.) made the first absolute measurement of the electro-chemical equivalent of silver. In 1884 Carhart (*Am. J. Sci.*, 1884, p. 374) used the silver voltameter to measure the E.M.F. of a Daniell cell, and in the same year Lord Rayleigh and Mrs. Sidgwick (*Roy. Soc. Phil. Trans.* A, 1884) made a systematic study of the instrument. They employed large platinum bowls for the cathodes and silver sheet enclosed in filter-paper for the anodes. This type became known as the "Rayleigh form" of voltameter.

In 1886 F. and W. Kohlrausch (*Wied. Ann.*, 1886, xxvii.) published some results obtained with a form of voltameter in which a small platinum cup formed the cathode, a silver rod the anode, and underneath the latter a small glass dish was supported. This form is known as the "Kohlrausch form." They also used a siphon-form voltameter.

In 1899 Richards, Collins, and Heimrod (*Amer. Acad. Proc.*, 1899 and 1902) suspended a porous cup of porcelain under the anode, thus abolishing the use of any organic material in the electrolyte and at the same time providing a more efficient septum. This has been known as the Richards, or porous cup form.

The Rayleigh, Kohlrausch, and Richards voltameters together with the syphon form were in use up to the time of the London Conference in 1908. At times the forms were slightly modified, as by the use of silk as a septum in the Kohlrausch type.

(i.) *Principal Measurements up to* 1908.—In 1884 Lord Rayleigh and Mrs. Sidgwick, wishing to make the deposit adhere better to the platinum bowl, added to the silver nitrate solution a very small proportion of acetate of silver. They found the deposit to be much more adherent and of much closer texture, but the mass of silver deposited was greater than when silver nitrate alone was used. In addition chlorate of silver was employed, but in this case the deposits substantially agreed with those obtained from nitrate solutions alone. For a current of 0·25 ampere Lord Rayleigh thought that a 4 per cent solution was strong enough, but in general he urged the use of solutions containing 15 or 30 per cent of silver nitrate. A deposit made at 50° C. was found to be heavier than one at 4° C. by about 0·04 per cent.

In 1892 Schuster and Crossley (*Roy. Soc. Proc.* l. 344) discovered that the mass of silver deposited was related to the pressure and also to the size of the anode. The deposits *in vacuo* were about 0·04 per cent heavier than at atmospheric pressure, a result which they attributed to the effect of oxygen.

In 1892 Kahle (*Brit. Assoc. Report*, 1892) found that the addition of silver oxide caused an increase in the mass of the deposit. He made a solution of silver nitrate saturated with silver oxide and found an increase in the deposit of 0·05 per cent. He also confirmed Schuster and Crossley's discovery that the deposit *in vacuo* is about 0·04 per cent greater than at atmospheric pressure.

In 1892 Glazebrook and Skinner (*Roy. Soc. Phil. Trans.* A, 1892) followed the procedure of Lord Rayleigh. Two voltameters were included in the circuit and the general difference in the mass of the deposit was about 0·05 per cent.

Novak (*Proc. Roy. Bohem. Ac. Sci.*, Prague, 1892) appears to have been the first to suggest that a cause of disturbance in the silver voltameter was the formation of a complex silver ion at the anode, and in 1895 Rodger and Watson (*Roy. Soc. Phil. Trans.* A, 1895, p. 631) independently put forward the same idea. The continued use of the same solution was found to increase the deposit, but new solutions gave the same weight of deposit. They further proved that the change was not due to impurities in the silver of the anode. The following are, in chronological order, the results obtained with an old solution :

0·09983	0·09995
0·09987	0·10002
0·09990	0·10005
0·09999	0·10006
0·09995	0·10002
0·09993	

Behn (*Wied. Ann.*, 1894, li. 105) studied the striations which others had observed in silver deposits. He changed the concentration of the electrolyte and the density of the electric current. The striations were more distinct and farther apart in the stronger solutions and also more distinct as the current density at the cathode was reduced. With increasing temperature the striations were more marked, but with purer solutions the tendency was for striations to disappear. By having a horizontal cathode at the top and the anode underneath he succeeded in producing deposits without striae, and concluded that when there are no convection currents in the electrolyte near the cathode, striae cannot occur.

Myers (*Wied. Ann.*, 1895, lv. 288) verified the effect of pressure previously observed by Schuster and Crossley, and by Kahle, and reported a decrease in deposit in an atmosphere of carbon dioxide.

In 1898 Kahle (*Zeits. Instrumentenk.* xviii. 229-267) made a very large number of measurements using both platinum and silver bowls as cathodes, and silver nitrate solutions treated in various manners and from many sources, as electrolytes. He found the deposit of silver per coulomb to be greater on a silver surface than on one of platinum; that it increased with the continued use of a solution, and that the nature of the deposit also varied with the solution employed. His results for the electromotive force of the Clark cell at 15°·0 C. are

1·4327 volts from new electrolyte,
1·4341 volts from used electrolyte.

In 1899 Kahle (*Ann. d. Physik*, 1899, lxvii. 1) used several large voltameters of the Kohlrausch type and found many of the deposits to be striated. In some cases he found acid was liberated, which he concluded accompanied the formation of oxidation products at the anode.

Merrill (*Phys. Rev.*, 1900, x. 167) studied the influence of temperature, pressure, used solutions, and size of anodes. He found no definite effect due to temperature and no marked effect due to pressure alone. The results of three experiments on the effect of pressure were:

Experiment No.	1.	2.	3.
Pressure in Atmospheres	103	95	103
Deposit in grams at atmospheric pressure	1·1371	1·23745	1·08205
Deposit in grams under pressure	1·1370	1·23740	1·08190
Difference in grams	0·0001	0·00005	0·00015

Used solutions were found to give heavier deposits than fresh solutions, and this was thought to be due to some reduction of the valence of the silver in the electrolyte. The relative sizes of anodes, except possibly in extreme cases, was concluded to have no appreciable influence.

Another point, tested by several experiments, was whether the filter-paper wrapped about the anode in the Rayleigh form of voltameter has any influence on the deposit. It was found that the deposits were either the same in amount or their difference was within 0·2 milligram.

In 1899 Richards, Collins, and Heimrod (*Am. Acad. Sci. Proc.*, 1899, xxxv. 123) published a paper on the electro-chemical equivalents of copper and silver. The most noteworthy change was the introduction of a porous cup of unglazed porcelain between the anode and cathode. They concluded that the Rayleigh voltameter always gave erroneous results because a complex silver ion was formed at the anode and passing through the filter-paper deposited silver on the cathode. The porous pot was supposed to serve as a more perfect separator between anode and cathode. Under certain circumstances silver was found to be deposited on the cathode from an anode solution without an electric current. Heavier deposits were obtained at 60° C. and 0° C. than at 20° C., the difference between the masses deposited at 60° C. and 20° C. being about 6 parts in 10,000.

In 1900 Leduc (*Journ. de Physique*, 1902, I. 561) concluded that the anode current density should be small, and that with high current densities the formation of acid occurs. The presence of hydroxide of silver in solution was believed to be free from objection. A decrease in the mass of the deposit was found to result from an increase of temperature.

Guthe (*Bureau of Standards Bull.* Reprint 1, 1904, and Reprint 16, 1905) compared the Rayleigh form with that due to Richards, using the usual electrolytes and also others saturated with silver oxide. He also made special experiments with large silver anodes. The use of filter-paper was avoided in the preparation of the solutions, and only in the Rayleigh type was filter-paper employed. He found the Rayleigh form gave a heavier deposit than the Richards form by 0·48 per cent, and concluded that the cause was due to the heavy anode liquid. He fully corroborated Richards' results.

Van Dijk and Kunst (*Ann. d. Physik*, 1904, xiv. 569) determined the electro-chemical equivalent of silver by a tangent galvanometer method. The Rayleigh form of voltameter was used and twenty-four deposits were made, the resulting values of the electro-chemical

equivalent being in satisfactory agreement. Later, van Dijk (*Arch. Néerland. des Sci.* Series II. ix. 442) made a careful comparison of the Rayleigh, Richards, and syphon forms. He found the Richards type to give a deposit lighter by 0·023 per cent than the deposit in a Rayleigh voltameter and 0·015 per cent lighter than the deposit in a syphon form voltameter. In addition he observed a difference due to the size of the cathodes, the smaller cathode invariably giving the lighter deposit for the same form of voltameter.

Duschak and Hulett (*Am. Electrochem. Soc. Trans.*, 1907, p. 257) made some very careful comparative experiments using the Richards voltameter. They concluded that a deposit from a water solution of pure silver nitrate free from air and *in vacuo* is distinctly lighter than one formed under ordinary conditions; the observed difference was about 7 parts in 100,000. Further, they believed that with proper care the Richards form was trustworthy within 1 part in 100,000.

In 1907 Smith, Mather, and Lowry (*Roy. Soc. Phil. Trans.*, 1908, ccvii.) made an extended investigation, using various forms of voltameter and various electrotypes. They concluded that samples of silver nitrate could be prepared to give in various types of voltameter, values of the electro-chemical equivalent not varying by more than 3 parts in 100,000. A method of purifying silver nitrate was described. High values for the electrochemical equivalent were obtained when the solution contained oxide, carbonate, chloride, or hyponitrite. The presence of acid caused low values. The impurities which increase the mass of the deposit were found to be, in general, substances which are insoluble in water, but soluble in silver nitrate solutions; they are therefore precipitated during electrolysis from the impoverished solution at the cathode. They concluded that there might be slight changes in the electrolyte due to its interaction with filter-paper, but did not believe the mass of the deposit to be seriously affected during one electrolysis in the size of voltameter they had used. At higher temperatures it was thought the effects might be important. The most important conclusions were: (1) The Rayleigh, the Richards, and the syphon form voltameters give identical results when the electrolyte is pure. (2) The deposit is independent of the pressure. (3) The deposit is independent of the temperature. (4) The complex ion effects observed by Richards and Guthe could not be repeated, and they believed that no complex ions were formed. (5) Striae indicates an impure solution. (6) In general the size of anode has no effect. (7) The deposits are independent of the nature of the cathode, *i.e.* whether of platinum or of silver. In most of the experiments anodes of electrolytic silver were used for the first time. They found it difficult to free porous pots from acid without baking, and a theory explaining the formation of striae was given. The electro-chemical equivalent was found to be 1·11827 mgm. per coulomb.

In 1908 Jaeger and von Steinwehr (*Zeits. Instrumentenk.*, 1908, p. 327) gave a detailed account of experiments carried out at the Reichsanstalt. The Richards and Kohlrausch forms of voltameter were found to be in agreement.

Also in 1908 Janet, Laporte, and de la Gorce (*Bull. Soc. Int. Élect.*, 1908, viii. 523), working at the Laboratoire Central d'Électricité, found 1·11821 mgm. as the electrochemical equivalent of silver using the Rayleigh form of voltameter.

It was largely on the evidence obtained from the national laboratories of Great Britain, America, France, and Germany, that the London Conference of 1908 based its provisional specification. It was, however, obvious that the very appreciable differences between the results of many observers demanded further experiments.

In 1910 an important step was taken. By invitation of the United States Bureau of Standards an International Technical Committee consisting of E. B. Rosa (Bureau of Standards, United States), F. Laporte (Laboratoire Central d'Électricité, Paris, France), F. E. Smith (National Physical Laboratory, Great Britain), and W. Jaeger (Physikalisch-Technische Reichsanstalt, Germany) made experiments with standard cells and silver voltameters at Washington in order to discover the causes of certain discrepancies. Previous to this meeting much work had been conducted at the Bureau of Standards and the results communicated to other laboratories. One of the main discoveries was the effect of filter-paper, which in certain cases was proved to produce very important results. This influenced the work elsewhere and must be regarded as an important discovery. There were, however, decidedly different opinions respecting the various forms of voltameters, etc., as is shown in the Reports which were submitted by the delegates before the commencement of the experiments (*Report to the Int. Committee on Electrical Units and Standards*, Washington, 1912, and Supplement to same). The general conclusions arrived at, together with the conclusions of the special Technical Committee, are given under appropriate headings in the following sections. These also contain the results of the investigations carried out by Rosa, Vinal, and McDaniel at Washington (*Supplement to Report to Int. Committee*, 1912, and *Bureau of Standards Bull.*, 1912, ix. 154-207, 208-282,

495-551; 1913, x. 475-536, and Reprint No. 285, 1916), and by others. The work at Washington covered a much wider field than had ever before been anticipated, and the number of silver deposits made total more than the combined totals of all previous investigations.

(a) *Effect of Filter-paper.*—Kahle (*Zeits. Instrumentenk.*, 1902, xxii. 155) was the first to point out that filter-paper may have an effect on the electrolyte, but it was not until the work of Rosa, Vinal, and McDaniel that any definite evidence of its effect was obtained. These latter urged that the effect of filter-paper was highly detrimental for general voltameter work, although in certain cases with large voltameters the effect might be small. This was subsequently confirmed by the National Physical Laboratory, who admitted that their work suffered slightly because of filter-paper. In the experiments carried out by Smith, Mather, and Lowry, all silver nitrate solutions were filtered before using in any form of voltameter. Thus, although silver nitrate recrystallised by them was probably pure, the filtering of the electrolyte contaminated the solution sufficiently to increase the masses of the deposits in all forms by about 1 part in 10,000. The small quantity of filter-paper used in the large Rayleigh form appeared not to increase the contamination sufficiently to affect the result appreciably. The Reichsanstalt also agreed with regard to the general effect of filter-paper, and stated that their experiments showed no effect on the deposits when small quantities of filter-paper were present, but appreciable effects when large quantities were used. Rosa, Vinal, and McDaniel repeated the difference of 1 part in 10,000 under the conditions holding for the National Physical Laboratory experiments, but by increasing the contamination with large quantities of filter-paper differences of 1 part in 1000 were obtained. The results of experiments carried out by the International delegates confirmed, in general, the effect of filter-paper, although, owing to many of the electrolytes being impure from sources of contamination other than filter-paper, the results were far from consistent. In all 10 experiments were made with the Rayleigh form of voltameter, and the mean error of these was about 2 parts in 100,000; 35 experiments were made with voltameters of about the same size not containing filter-paper, and the mean deposits were less than with the Rayleigh form by 11 parts in 100,000; the mean error was about the same.

In later experiments Rosa, Vinal, and McDaniel showed that the constituents of the filter-paper which are active in the voltameter are soluble in water since aqueous extracts of filter-paper produce even more pronounced effects than the filter-paper itself. These active substances are not foreign impurities in the paper, since repeated extraction with water does not diminish the activity of the filter-paper in the voltameter. A preliminary washing of the filter-paper with dilute alkali and water reduces the effect, but does not eliminate it.

As first pointed out by Smith, Mather, and Lowry, impure solutions invariably give striated deposits, and the contamination of the electrolyte with "filter-paper extracts" causes the deposits to be markedly striated when the contamination is excessive. Other substances can, however, also produce these striations. Filter-paper effects are further dealt with in the section dealing with impurities in the electrolyte.

The International Technical Committee agreed not to recommend the Rayleigh form as a standard type.

(b) *Effect of Silk.*—Raw silk used as a septum instead of filter-paper gives at first, according to the Bureau of Standards, an effect somewhat similar to that of filter-paper, due to its decomposition into an aldehyde; if used repeatedly, acid is produced and this acts in the opposite direction, decreasing the weight. Sometimes, therefore, the effect of silk may be to increase and sometimes to decrease the weight of the deposit, according to how long it has been used. Pure raw silk thoroughly washed produced the effect only slightly. Measurements made by the International Technical Committee were not conclusive on this point: the mean of 14 deposits with silk as a septum agreed within 2 parts in 100,000 with the mean deposit in voltameters without septa of any kind, and from previous measurements made at the Reichsanstalt the conclusion was drawn that the effect is negligible.

(c) *Impurities in the Electrolyte.*—In the chemical part of their work Smith and Lowry showed that if the electrolyte contains oxide, carbonate, chloride, or hyponitrite, the mass deposited is heavier than the mass deposited from a pure solution of nitrate. Subsequently, Lowry (*Roy. Soc. Proc.* A, 1914, pp. 53-71) determined the solubility of many silver salts in solutions of silver nitrate of different concentrations and at different temperatures. Smith and Lowry found that solutions saturated with silver oxide gave deposits 0·025 per cent heavier than those from pure solutions; they found the chloride to be freely soluble in concentrated silver nitrate solutions, especially when hot, but on dilution the major portion is precipitated and then there is little effect on the deposit. Sulphide also is very soluble in silver nitrate solutions, but the mass of the silver deposit is not affected to any appreciable extent. The presence of

silver nitrite appeared to have no appreciable influence, a result afterwards confirmed by Rosa, Vinal, and McDaniel, although Richards and Heimrod found an effect of the order of 50 parts in 100,000. It is probable that these latter observers were using impure solutions. On the other hand Smith and Lowry found a solution saturated with hyponitrite of silver to give a striated deposit and to be 0·046 per cent heavier than from a pure solution, while Rosa, Vinal, and McDaniel found no striations in such a deposit. The latter observers proved, however, that electrolytes containing nitrates of hydrazine and hydroxylamine gave deposits which are distinctly striated. It appears highly probable that these impurities were present with the hyponitrite in Smith and Lowry's experiment. The fact that these two reduction products of nitric acid are definite chemical compounds which possess the peculiar property of producing striated deposits caused a careful examination to be made of solutions contaminated with filter-paper in order if possible to detect the presence of these compounds. No trace was discovered. It was finally concluded that a strongly reducing character was an essential property of any impurity which produces striations, and a large number of strong reducing agents, mostly aldehydes and phenols, were separately added to the electrolyte and their effect noted. The deposits were striated in all cases, the more marked effects in general being produced by the stronger reducing agents of the group. The similarity in the effects of filter-paper and the reducing agents already referred to furnished evidence that the activity of the cellulose is due to its action as a reducing agent. This was confirmed by experiments in which permanent colloidal solutions of metallic silver were prepared from filter-paper and silver nitrate, and the metallic silver coagulated and identified by its properties. It is concluded, therefore, that paper, cotton, linen, etc., act chemically upon silver nitrate solutions with the production of colloidal metallic silver. Upon electrolysis these colloidal particles are deposited partly by the current and partly by gravity upon the cathode, thus increasing the weight of the silver deposit above the true electrochemical equivalent of silver.

(*d*) *Effect of Free Acid.*—Leduc, and Smith and Lowry made experiments with free acid in their voltameters, and in general concluded that abnormally low values could only be explained by the presence of free acid. No systematic quantitative work on the subject was however attempted until the experiments of Rosa, Vinal, and McDaniel. The International Technical Committee at Washington tested their solutions for acidity, but made few special experiments; in general the attempt was to have neutral solutions. The results of the special experiments are:

Parts of Added Acid.	Proportional Decrease in Deposit.
5×10^{-6}	$-\ 5\times 10^{-5}$
10 „	− 8 „
100 „	− 12 „
100 „	− 6 „

To test the acidity of silver nitrate solutions the silver is first precipitated with neutral sodium chloride or potassium chloride and the filtrate titrated with one-thousandth normal H_2SO_4 or NaHO, using as indicator iodeosine in ether water solution or an alcoholic solution of methyl red. It is of great importance to test the effect of the filter and all glass vessels upon the neutrality of "conductivity" water. Especially must the experimenter guard against the use of newly bought vessels unless of high-resistance glass. Acidities and alkalinities within less than 1 part in a million can be readily measured.

Rosa, Vinal, and McDaniel (*Bureau of Standards Bull.*, 1914, x. 482) made experiments with the Richards and Smith form of voltameters, and found that for acidities (y) below 10 parts in 1,000,000 equivalents of HNO_3, the correction x (in parts per million) to be applied is given by the formula

$$x=-y/4{\cdot}5.$$

For acidities ranging from 10 to 100 parts in 1,000,000 the following formula represents the results

$$y=-4{\cdot}5x+0{\cdot}02x^2.$$

Dr. von Steinwehr (*Zeits. Instrumentenk.*, 1913, xxxiii. 321) denies the effect of acid, but Obata (*Math. Phys. Soc. Tokyo Proc.*, May 1916), using the Smith form voltameter, confirmed the Bureau of Standards work. He obtained the following relation:

$$y=-4{\cdot}2x+0{\cdot}02x^2,$$

where x and y represent the same quantities as before.

There are two possible ways by which acid may lower the mass of the deposit. The one is by direct action on the deposit and the other by the deposition of hydrogen ions in place of silver ions. Experiments have been made in which slightly acid in water solutions have remained in contact with silver deposits for many hours. At the Bureau of Standards no definite conclusion could be drawn from these experiments, but Obata (*Report No. 11 of the Tokyo Electrotechnical Laboratory*, 1917) states with certainty that acidified water dissolves a much larger amount of silver than natural water. It should be noted, however, that such

experiments present great difficulties, and the change in mass of deposit which is recorded does not in any instance amount to 1 milligram. The second possibility is also largely discredited by experiments made by Rosa and Vinal, who made experiments with acid solutions and deposited only 1 milligram of silver. Preliminary deposition of hydrogen was not caused by the acid. It appears, however, to be established that the presence of acid causes a diminution in the mass of silver, and this is of importance in choosing a type of voltameter for precision work.

(*e*) *The Porous Cup as a Septum.*—Richards originally used a porous cup to prevent the heavy liquid formed at the anode from reaching the cathode. Smith and Mather proved that no complex silver ions were contained in this liquid, and concluded that it had no detrimental effect; this was afterwards verified by Rosa, Vinal, and McDaniel. The porous cup continued to be employed, however, as a convenient means of separating the anode and cathode liquids. In 1910 Rosa and Vinal (*Supplement to Report to Int. Committee on Units*, Washington, 1912) were of opinion that some form of septum was necessary, but Smith, Laporte, and Jaeger were of the opposite opinion.

That porous cups are very efficient separators between anode and cathode chambers is shown by the fact that contaminated liquid may be placed inside the porous cups without altering the appearance or weight of the deposit on the cathode. Smith, Mather, and Lowry found difficulty in removing completely the acid from the pores of a cup, and later Smith produced pronounced stenolysis in such septa. This latter phenomenon is an electro-deposition of silver in the capillaries of the cups which results in the formation of acid and a complex silver salt having the formula Ag_7NO_{11}. If platinum is used as an anode in a silver voltameter (*Roy. Soc. Phil. Trans.*, 1908, ccvii. 588) crystals of this substance separate at the anode and the electrolyte becomes strongly acid, resulting in a diminution in the mass of the silver deposit.

In 1911 Smith made a study of the electrostenolytic action of porous cups, and with very dilute silver nitrate solutions succeeded in making the effects visible. With all capillaries the phenomenon of "endosmose" must take place to some extent during electrolysis, and hence some electrolyte must flow through the pores of the cup. In the usual voltameter experiments Smith calculated that the silver ions travel through the pores of a cup at a velocity of about 4 mm. in a minute, and in the course of an experiment about 2 grams of silver ions pass through the pores. Following Helmholtz, it is assumed that even before electrolysis a double layer charge is formed at the surface of contact of pot and electrolyte. When a current passes, a fall of potential is produced in the electrolyte and the positive part of the double layer moves towards the cathode leaving the walls of the capillaries negatively charged. The positive silver ions in the solution may now give up their charge to neutralise the negative charge on the walls, and hence silver may be deposited in the capillaries. Smith did not suggest that the whole of the capillaries are thus covered with an exceedingly thin layer of silver, but suggested that the deposit would be in patches owing to the capillaries being irregular in section and the velocity of the ions through them being variable. As the conductivity of silver is more than a million times that of the electrolyte, the silver patches will take an appreciable part in the conduction of the current. They will not, however, necessarily increase in size because of this; they will only do so if the anode ends of the patches are covered with an insoluble substance such as Ag_7NO_{11}. Even if the action takes place to a slight extent the deposition of silver in the capillaries will result in an excess of hydrogen ions in the electrolyte, *i.e.* the latter will become slightly acid.

The possibility of detecting a minute quantity of silver in the capillaries of a porous cup was attempted by chemical means and some positive evidence was obtained. However, Smith concluded that the passage of a strong current through a weak solution of silver nitrate contained in the capillaries should produce complex actions where the current leaves the silver patches, and this might lead to their detection. In such a case the silver would grow towards the anode of the voltameter and should become visible. Twenty separate experiments were made and in 6 of these the insides of 6 different cups were lined with silver within ten minutes from the start; in the remaining 14 experiments no silver was detected. In 5 of the 6 cases a small quantity of Ag_7NO_{11} was formed on the outside of the cups. Some of the cups were broken, and microphotographs showed a dark line of silver deposited on the inner wall. In another experiment with a new cup no silver was observed, but crystals of Ag_7NO_{11} were discovered on the outside. In order to prevent any slime from the anode reaching the cup the anode was, in some of the experiments, enclosed in well-washed silk. In other experiments cracks were produced in glass tubes and similar effects produced. Experiments of this latter nature had previously been made with success by Coehn (*Zeitschr. f. Elektrochemie*, 1898, pp. 501-503).

Smith further found that filtering a solution of silver nitrate through a porous cup rendered the formation of visible silver far more diffi-

cult. The process of filtering leads probably to the action of stenolysis and deposits some silver in the capillaries; in such a case the filtrate should be slightly acid. When tested this was found to be so. The final conclusion was that the behaviour of the Richards form with pure electrolyte depended on the condition of the cup. If the latter were clean but quite new the resulting silver deposit would probably be too low; if much used and kept continually soaked in electrolyte the resulting deposits would be much nearer normal. These conclusions appear to be largely confirmed. With freshly prepared porous cups the deposits are in general smaller than with cups much used and permanently stored in electrolyte.

A very complete investigation of the Smith and Richards forms of voltameter has been made by Obata (*Electrotechn. Research Lab. Tokyo*, Reprints No. 71 (1918) and No. 76 (1919)), who measured the acidity of the electrolyte before and after each run. He used very fine-grained Pukal cups which required from twenty to thirty hours to filter half their volume of water and an alundum cup which filtered the same volume in a few seconds. With the latter cup stenolysis effects would be small. In 7 out of 7 measurements the mean observed increase in acidity in the Smith form was 1 part in 10 millions; Obata concludes that with this form the acidity does not change. In 4 experiments with a small porous cup (in which stenolysis should be most marked) the mean increase was 77 parts in 10 millions. Before comparing the masses of the deposits Obata corrected them for the acidity of the electrolyte by assuming that the mean acidity during the experiment is twice that calculated from the initial and mean acidities. His general conclusion is *not* that the formation of acid in the Richards form must be produced by and subsequently give rise to some disturbance but that the anode liquid in the Smith form contains a small quantity of some complex silver ion. As the acidity remains constant this assumption appears to be untenable.

Smith concludes that deposits in the Richards form will in general be lighter than in the syphon and non-septum forms. The difference should be greatest when the cups are new and least when they have been much used and kept immersed in neutral silver nitrate solutions. The procedure adopted at the Bureau of Standards for getting the cups in a condition of equilibrium (*Bureau of Standards Bull.*, 1910, x. 513) probably gives very satisfactory results, and the difference between the Richards form and non-septum forms will be in such cases very small; experiments indicate differences from 2 to 3 parts in 100,000.

(*f*) *Complex Silver Ion in Anode Solution.*—From the time of Richards' experiments in 1899 until the work of Smith, Mather, and Lowry in 1907, it was the generally accepted view that certain anomalous substances were formed at the anode which interacted with the silver at the cathode and by deposition of silver increased the mass of the deposit. Smith, Mather, and Lowry first conclusively proved that the effects found by Richards could not be due to the formation of a complex silver ion. The results obtained by the International Technical Committee in 1910 confirmed this conclusion. With a non-septum (Smith) form of voltameter in which anode liquid may pass to the cathode the mean deposit in 11 experiments was 1 part in 100,000 less than the mean deposit in 4 voltameters of the Richards form containing the same amount of electrolyte, and 2 parts in 100,000 greater than the mean deposit in 9 voltameters of the latter form containing a smaller volume of electrolyte. The Committee agreed that there was no evidence to support the theory advanced by Richards and supported by Guthe.

Buckner and Hulett (*Am. Electrochem. Soc. Trans.*, 1912, xxii. 367-383) made experiments with four Richards voltameters in series. In most cases the anode liquid was lower in level than the cathode liquid, and the former was stated not to flow through the porous cups except in special cases. In these cases deposits heavier by 0·019 per cent were obtained, and they concluded the anode liquid had a detrimental effect. Richards and Anderegg (*Am. Chem. Soc. Journ.*, 1915, xxxvii. 675-693) also do not entirely accept the view of an inert anode liquid, but believe that the anode liquid may really augment the weight of the silver deposit. Rosa, Vinal, and McDaniel have failed to confirm the conclusions of Richards, and there is now a fairly general consensus of opinion that with the usual sized anodes no complex silver ions are formed.

(*g*) *Purity of the Deposit.*—The question of inclusion of electrolyte in the silver deposited in a voltameter has received much attention and the results are contradictory. Lord Rayleigh found a loss in weight of 0·01 per cent on heating the deposits to incipient redness. Richards and Heimrod found a loss of 0·018 per cent. Van Dijk heated the platinum bowls with their silver deposits in an electric furnace and found no appreciable loss in weight. Smith, Mather, and Lowry, using very large bowls, confirmed the results found by van Dijk. Jaeger and von Steinwehr also found the loss to be insignificant. Duschak and Hulett made elaborate measurements and concluded that the total inclusions averaged about 0·011 per cent, and were distributed

through the crystals. Later, Laird and Hulett by a new method found the included silver nitrate to be not greater than 0·005 per cent. In 1916 Vinal and Bovard (*Bureau of Standards Bull.* Reprint 271) heated a number of silver deposits to temperatures slightly above 600° and found the loss in weight to indicate inclusions of foreign matter in the deposits of about 0·004 per cent. It appears that with large cathode surfaces the included matter must be very small, and Smith in more recent experiments has again failed to detect any loss on heating the deposits when large bowls are used and the deposit is not too heavy.

(*h*) *Temperature Coefficient of Silver Voltameter.*—As already stated, Lord Rayleigh obtained a higher deposit at 50° C. than at 15° C., and a higher deposit at 15° C. than at 4° C. The temperature coefficient was about +0·001 per cent per 1° C. Leduc found a negative coefficient. Richards, Collins, and Heimrod found a positive coefficient between 20° C. and 60° C. Merrill, using fused silver nitrate, found no temperature effect. Smith, Mather, and Lowry used the syphon forms only in two experiments at 15° C. and 90° C., and found the coefficient, if any, was less than 1 part in a million. They concluded that the temperature coefficient is zero. This was also the opinion of F. Kohlrausch and of the Reichsanstalt. The International Committee made no experiments on the effect of temperature, but in 1910 Rosa, Vinal, and McDaniel made two experiments with four voltameters and found in the first experiment a positive coefficient of 3 parts in a million and in the second experiment one of 1 part in a million. They concluded that the coefficient is probably zero. For a pure electrolyte there is no doubt that this is so, but when the electrolyte contains reducing impurities these will be more active at the higher temperature and therefore a positive temperature coefficient will appear, as in the experiments of Lord Rayleigh and Richards and Heimrod.

(*i*) *Preparation of Pure Silver Nitrate.*—The first serious attempt to prepare pure silver nitrate for work with the silver voltameter was made by Smith, Mather, and Lowry in 1907. Their method was one of repeated crystallisation, and there is little doubt that the salt obtained was very pure. Laporte also prepared the salt by recrystallisation, and some of this was used by him at Washington. In 1908 Smith studied the effects of small quantities of acid in the electrolyte, and finding that a relatively small quantity of acid had an appreciable effect he recrystallised silver nitrate from distinctly acid solutions and subsequently fused the salt in an electric furnace. From 500 to 1000 grams of the slightly acid salt were fused in a platinum bowl screened by a clock glass, and in order not to decompose the nitrate the heating current was switched off when about half of the salt was melted. Time was then allowed for the whole mass to become fluid when the nitrate was removed and allowed to cool. The salt thus prepared was beautifully white throughout, except, at times, on the surface; before using for voltameter work the surface salt was therefore removed by washing with distilled water.

When the International Technical Committee met at Washington in 1908 this fused salt was the only nitrate which satisfactorily complied with all the tests made for detecting reducing impurities and acid and alkali, and the method adopted by Smith forms the basis of the present methods of purification. Previous to 1910, while hundreds of experiments had been made with the silver voltameter and various causes of error detected, very few of the electrolytes could have been quite pure except by chance. This naturally led to a number of false conclusions being drawn. Subsequently, at Washington, Dr. McDaniel prepared some fused silver nitrate by Smith's method, and this was found to answer satisfactorily to all the tests made. The electrolytes containing silver nitrate prepared by Smith and McDaniel were the only ones which gave practically the same deposits in large and in small voltameters. In further experiments made at the Bureau of Standards (*Bureau of Standards Bull.*, 1913, ix. 549) it was found practicable to fuse the salt at considerably higher temperatures than the melting-point, but there appears to be no advantage in this except to save a little time; in fact, Rosa, Vinal, and McDaniel say that their best results have been obtained by removing the salt as soon as melted.

The tests for acidity and alkalinity have already been described. A sensitive test for reducing agents and colloidal silver has been suggested by Dr. McDaniel and is most convenient. The test is made with a solution of potassium permanganate and is as follows: 10 c.c. of a 66·6 per cent solution of the $AgNO_3$ to be tested is placed in a glass stoppered cylinder of 25 c.c. capacity and acidified by the addition of 1 c.c. of concentrated HNO_3 (free from reducing substances). After thorough mixing of the acid and solution, 0·5 c.c. of 0·001 normal permanganate solution is added and the mixture again shaken. The addition is continued in portions of 0·5 c.c. until the colour persists undiminished in intensity for five minutes or longer. From the amount of permanganate added the quantity of reducing substances present is calculated.

(*j*) *Explanation of Striations.*—In 1894 Behn (*Wied. Ann.*, 1894, v. 105) published a work on striated deposits in the silver voltameter,

and gave photographs of deposits illustrating the nature of these striations. He found that the direction of the striae was determined by the convection currents circulating in the liquid, and when the cathode was horizontal and at the top of the electrolyte no striae appeared. He further investigated the effect of varying the concentration of the electrolyte and the density of the electric current. With increase in concentration the striae were more distinct but farther apart, and the same effect could be produced by reducing the current density.

Smith, Mather, and Lowry in 1907 found that in pure electrolytes striae did not appear and regarded the formation of striations as evidence of an impure electrolyte. They traced out the general direction of the convection currents near the cathode and showed why the upper portion of a deposit may have a matt surface and the lower portion a striated surface. They explained striations by assuming instability in the thin layer of liquid near the cathode which rapidly loses much of its silver. When this film is very thin it is supposed to be unstable and break up into cylindrical columns of liquid which ascend near the cathode surface. Hence in contact with the cathode surface there are columns of liquid of low concentration, and in between these the electrolyte is of approximately normal concentration. The latter electrolyte has the higher conductivity, and since in addition there is an electromotive force acting from the columns of low concentration towards the main body of the electrolyte, the current passes into the cathode through the liquid between the columns. If these assumptions are correct, an increase in the current should result in the cathode film becoming thicker and more stable, and when it is sufficiently stable to remain as a film a striated deposit should not be formed. This was tested by experiment and found to be so. In special experiments conducted in glass vessels the breaking up of a layer into cylindrical columns was observed.

Rosa, Vinal, and McDaniel confirmed the conclusion that the direction of the striae is determined by the convection currents of the electrolyte, but believe the production of striae is due in the first place to the deposition of colloidal silver on the silver crystals. From a pure solution the silver is deposited in a crystalline form and these grow with perfect faces and angles in a pure electrolyte. With impure electrolytes the crystalline character disappears, the deposits being masses which under the microscope look like molten metal. It is supposed that in a pure electrolyte the force of crystallisation constrains the silver atoms to be deposited in a regular order, in spite of the tendency of the convection currents in the liquid to distort the crystals by building them upwards. In an impure solution, however, the regular crystalline growth is interfered with by the deposit upon the initial crystals of particles of colloidal silver. It is found, however, that if the relative velocity of the liquid be great, as it may be with forced rotation of the cathode, a striated deposit may be obtained from pure electrolytes.

(*k*) *Forms of Voltameters.*—In 1910 the International Technical Committee recommended that the Rayleigh form be not adopted as a standard owing to the effect of the filter-

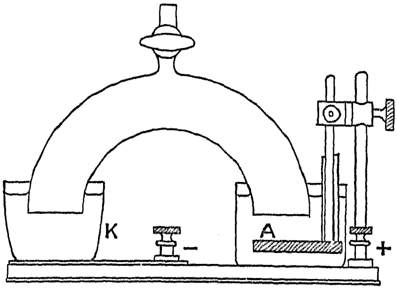

FIG. 15.

paper. Four other forms have, however, been frequently used, and the respective merits of these have been much discussed.

The first form (*Fig.* 15) is the Syphon form. This is for comparison purposes only, but is regarded by Smith as the form by which all others should be judged. If there are any impurities of a reducing nature in the electrolyte these will cause the deposit to be too heavy, but no complications due to actions at the anode can have the slightest effect. The resistance is too high and variable to maintain a steady current through it with ease, and it is used therefore for comparison purposes only. As modifications of this type, Smith, Mather, and Lowry put a porous cup over the anode or cathode end of the syphon. The same procedure was afterwards adopted by Rosa, Vinal, and McDaniel.

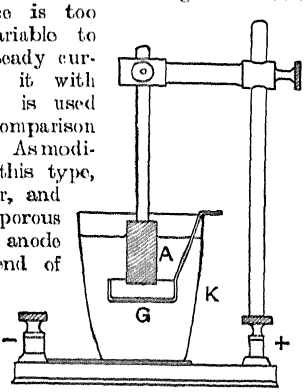

FIG. 16.

The Kohlrausch form (*Fig.* 16) consists of a silver rod for the anode and a platinum bowl for the cathode, the only partial separa-

tion between anode and cathode being a glass dish placed under the anode to catch any particles falling from it. In practice this dish is not found sufficient to confine the anode slime which is often carried to the top of the electrolyte by bubbles of gas. In the experi-

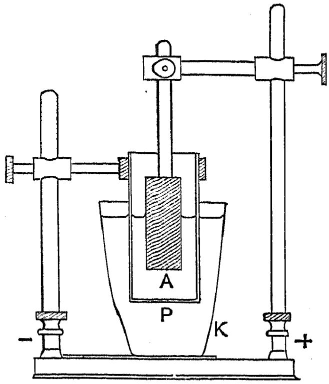

FIG. 17.

ments made by the International Technical Committee Dr. Jaeger used the form on two occasions only; on fourteen other occasions, owing to trouble with floating scum, he surrounded the anode with silk. In a modified form, introduced by Rosa, the difficulty is partly surmounted by supporting a ring of glass in the surface of the liquid.

In the Richards type (*Fig.* 17) a porous cup of unglazed porcelain serves as a means of separating the anode and cathode. The cups used are of the finest porcelain, have thin

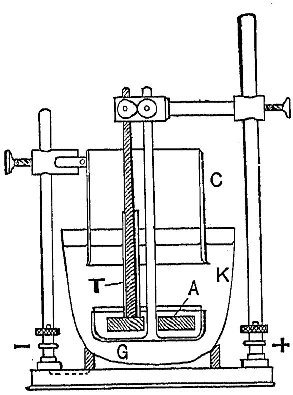

FIG. 18.

walls, and are of very fine grain. Pukal cups made by the Königlich Porzellan Manufaktur of Berlin have been used by the majority of experimenters.

The Smith voltameter (*Fig.* 18) is designed to avoid the use of a septum of any kind. It differs from the Kohlrausch form inasmuch as there is no trouble with anode slime even if the latter floats with tiny bubbles to the surface of the electrolyte, and no difficulty is experienced in removing the slime from the voltameter at the conclusion of an experiment. The anode is in the form of a silver disc coated with electrolytic silver and afterwards baked in an electric oven. This disc is contained in a shallow glass basin with a ground edge, the basin being supported by a glass rod passing through a hole in the centre of the disc. A glass cylinder, the lower end of which is ground, fits over the basin and is used before and after the electrolysis to separate the electrolyte into two parts. A silver rod supports the silver disc (anode) and a glass tube fits over its lower end to prevent undue electrolysis of the rod. During electrolysis the glass cylinder is raised, but its lower end is always immersed in the electrolyte.

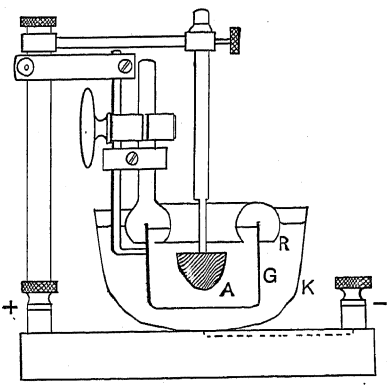

FIG. 19.

A modified syphon voltameter (*Fig.* 19) has been used by Rosa, Vinal, and McDaniel. In this a small glass dish supported by a glass rod is submerged in the electrolyte. From the top edge of this dish there project four short glass rods that support an annular syphon whose lower edge is just below the surface of the electrolyte. The chief difficulty is in the escape of anode slime when the voltameter is dismantled.

With impure electrolytes all of these forms will give deposits which are abnormal. Examples of this are numerous in experiments made previous to 1910.

In 1907 Smith, Mather, and Lowry stated that all forms of voltameter experimented with by them gave identical values within a few parts in 100,000. In 1909 Rosa, Vinal, and McDaniel (*Supplement to Report of Int. Committee*, 1912, p. 7) found that the Kohlrausch form without silk or other septum gave an abnormally heavy deposit. They

expressed the opinion that some form of septum was necessary. The syphon form was found to give a larger deposit than the Richards and Kohlrausch forms, but they did not believe it to be a reliable criterion by which to judge other forms. Pure silver nitrate had not then been used by them. With the electrolytes employed they found larger deposits in large voltameters than in small ones, but with purer electrolytes the difference became smaller.

The results obtained with initially pure electrolytes by the International Technical Committee (1910) are as follows:

No. of Measurements.	Form of Voltameter.	Relative Masses of the Deposits.	E.M.F. of Weston Normal Cell at 20° C.
11	Smith's form, 370 c.c.	$1{\cdot}00000_0$	$1{\cdot}01829_5$
9	Richards' form, small, 100 c.c.	$0{\cdot}99997_7$	$1{\cdot}01827_2$
4	Richards' form, large, 300 c.c.	$1{\cdot}00000_9$	$1{\cdot}01830_4$

A special sub-committee made a comparison between the syphon form and the Smith and Richards forms, and found as the result of one experiment the relative deposits to be

Syphon.	Smith's Form.	Richards' Form.
1·00000	0·99988	0·99990

In 1910 and 1911 Smith and Vinal working at the National Physical Laboratory and using pure electrolyte obtained the following relative values for the silver deposits:

No. of Measurements.	Form of Voltameter.	Relative Masses of the Deposits.	E.M.F. of Weston Normal Cell at 20° C.
11	Smith's form, 370 c.c.	$0{\cdot}99996_8$	$1{\cdot}01829_4$
8	Smith's form, 120 c.c.	$0{\cdot}99999_1$	$1{\cdot}01831_7$
13	Richards' form, small, 100 c.c.	$0{\cdot}99988_3$	$1{\cdot}01820_9$
2	Richards' form, large, 300 c.c.	$0{\cdot}99994_7$	$1{\cdot}01827_3$
2	Syphon form	$1{\cdot}00000_0$	$1{\cdot}01832_6$
1	Syphon. Porous pot over anode end	$0{\cdot}99999_7$	$1{\cdot}01832_3$
1	Syphon. Porous pot over cathode end	$0{\cdot}99987_7$	$1{\cdot}01820_3$

In January 1911 three further experiments showed that the syphon and Smith forms agreed within 1 part in 100,000, but the Richards form gave deposits which were lighter by about 7 parts in 100,000. In further experiments made by Smith in 1911 a difference of only 4 parts in 100,000 was measured, and the same difference was independently found by Vinal at Washington. Since April 1910 a large number of most carefully planned experiments have been carried out by Rosa, Vinal, and McDaniel, who particularly studied the Richards and Smith forms, using pure electrolytes. The results are given in the following table:

No. of Measurements.	Form of Voltameter.	E.M.F. of Normal Cell at 20° C.	Weighted Mean.
32	Smith, large size	$1{\cdot}01826_3$	
21	Smith, medium size	$1{\cdot}01827_3$	$1{\cdot}01827_4$
2	Smith, small size	$1{\cdot}01830_4$	
47	Richards, large size	$1{\cdot}01826_9$	
22	Richards, medium size	$1{\cdot}01824_4$	$1{\cdot}01826_7$
87	Richards, small size	$1{\cdot}01826_0$	
6	Syphon	$1{\cdot}01832_4$	$1{\cdot}01832_4$
7	Modified Syphon	$1{\cdot}01834_6$	$1{\cdot}01834_6$
9	Kohlrausch	$1{\cdot}01829_7$	$1{\cdot}01829_7$

This is the largest number of observations so far made with pure electrolyte, and the results indicate that in the experiments at Washington the porous cups were carefully prepared and pure electrolytes used. Rosa, Vinal, and McDaniel state in their Summary (*Bureau of Stands. Bull.* Reprint 285, 1916) that with electrolyte of highest purity the syphon voltameter probably agrees with other forms. This agrees with the conclusions of Smith and Mather. The present position is therefore that the deposits obtained with all forms of voltameters agree conditionally that the electrolyte is pure and does not become contaminated during electrolysis.

§ (41) Specification of the Silver Voltameter.—The International Conference on Units and Standards (London, 1908) did not specify the silver voltameter in detail, but recommendations for a complete specification were expected from the International Technical Committee. Unfortunately the work of this Committee was not completed at Washington, but in 1910 Rosa and Smith agreed on a specification, and work since then has shown that if the specification is complied with accurate results are obtained.

The specification is as follows:

Specification

1. The electrolyte shall consist of a solution of silver nitrate in distilled water, having from 10 to 20 grams of silver nitrate in 100 c.c. of the solution.

2. The electrolyte must be free from organic or other reducing substances, as shown (*a*) by a suitable chemical test, (*b*) by giving a crystalline deposit free from striations, and (*c*) by giving the same weight of deposit in a large and in a small voltameter.

3. The silver nitrate is purified by crystallisation from slightly acid solutions and fusion, and if the chemical test for purity is omitted it should be purified until further crystallisation does not change the weight of the deposit.

4. The voltameter should contain not less than 75 c.c. in the cathode chamber, and the deposit should not continue long enough to reduce the mean concentration of the electrolyte in the cathode chamber below 5 per cent. If no septum is used, no greater weight of silver should be deposited in a single experiment than is contained in the electrolyte at the start.

5. The electrolyte when ready for use must be neutral or very *slightly* acid, as tested by iodeosine. As one part in a million of alkali may increase the deposit appreciably, it may be better to have a slight acidity (say one part in a million) than to take the risk of slight alkalinity in attempting to make it strictly neutral. The electrolyte must be neutral or slightly acid at the end of the experiment, no alkalinity, and only a trace of acid, if any, being present. Any septum or other substance which contaminates the electrolyte or produces appreciable alkalinity or more than a trace of acid must be avoided.

6. The cathode should be a crucible or bowl, preferably of platinum (although gold may be used) of from 125 c.c. to 400 c.c. capacity. The surface should preferably be smooth and bright, and the deposited silver should be removed by electrolysis or by acid, without scratching or marring the surface of the platinum by any instrument.

7. The anode should be of pure silver and is preferably coated with electrolytic silver. This is conveniently done when a previous deposit is being removed from the cathode bowl, using a relatively small current. The anode should have as large an active area as the size and type of voltameter permit.

8. The current during a deposit should be maintained constant, and is preferably not more than one ampere, and the time not less than one hour.

9. If the surface of the platinum is perfectly clean and the electrolyte pure the silver will be adherent and there will be little if any loose silver. After thorough washing the cathode bowls are dried at about 150° C., preferably in an electric oven, and after cooling are weighed. In the weighing a similar platinum dish adjusted to the same weight is advantageously used as a tare.

10. The electromotive force of the standard cell employed is calculated from the weight of silver deposited, the resistance, and the time, using 1·11800 mg. per second as the electro-chemical equivalent of silver.

Rosa, Vinal, and McDaniel add an additional paragraph specifying:

11. If a septum between the anode and cathode is used, it must not contaminate the electrolyte with organic or reducing impurities; it must not produce acid or alkali in the electrolyte, and it must be of sufficiently fine grain to hold back the anode slime without introducing any high resistance into the voltameter.

§ (42) Results.—The results obtained from time to time have usually been expressed in terms of the electromotive force of the Weston normal cell at 20° C. Since 1908, the time of the meeting of the London Conference, the values given in the annexed table have been obtained:

Date.	Observer.	Form of Voltameters.	No. of Deposits.	E.M.F. of Weston Normal Cell at 20° C.
1908–10	Rosa, Vinal, and McDaniel	Richards	86	$1·01828_1$
1909–10	Smith	Smith and Richards	17	1·01827
1910	International Technical Committee	Smith	8	$1·01828_7$
		Richards	14	$1·01828_6$
1910	Smith and Vinal	Smith	19	$1·01830_4$
		Richards	15	$1·01821_8$
1910	Von Steinwehr	Kohlrausch	40	$1·01829_0$
1910–12	Rosa, Vinal, and McDaniel	Smith	55	$1·01826_7$
		Richards	156	1·01826
1912–13	Haga and Boerema	Smith	32	1·01826
1914	Foehringer	Smith	4	$1·01829_5$
1916	Obata	Smith	40	$1·01826_9$
1918	Obata	Richards	61	$1·01826_6$

By a Resolution of that Conference:

The international volt is the electric pressure which when steadily applied to a conductor whose resistance is one international ohm will produce a current of one international ampere.

The results obtained since 1908 show that to a high degree of accuracy the electromotive force of the Weston normal cell at 20° C. is

1·0183 international volts at 20°·0 C.

The mean of all the values given in the last table is 1·01827, and the greatest difference

from this mean is 5 parts in 100,000. The measurements were made in England, the United States, Holland, Japan, Germany, and Russia. In 1910 the value 1·0183 international volts at 20° C. was recommended for universal adoption by Lord Rayleigh's Committee on Electrical Units and Standards, and this value is now adopted in all civilised countries.

The agreement is remarkably good, especially since there must be slight differences between the cells employed. The international ampere may therefore be regarded as one which may be satisfactorily specified.

In terms of the volt (10^8 C.G.S. units) the most probable value of the electromotive force of the Weston normal cell at 20° C. is 1·0188. This follows from recent absolute measurements of current, which show that the electromotive force of the Weston normal cell at 20° C. in terms of the ampere (10^{-1} C.G.S. unit) and the international ohm is $1{\cdot}0182_4$. The most probable value of the international ohm is $1{\cdot}0005_2$ ohms (10^9 C.G.S. units), so that in C.G.S. measure the electromotive force of the Weston normal cell at 20° C. is $1{\cdot}0182_4 \times 1{\cdot}0005_2$ or

1·0188 volts (10^8 C.G.S. units).

§ (43) THE INTERNATIONAL VOLT AND STANDARD CELLS.—As a working method for the realisation of the international volt the Conference recommended the use of a Weston normal cell whose electromotive force has been determined in terms of the international ohm and the international ampere. A complete specification of the Weston cell was not, however, approved by the Conference, but the duty of preparing such a specification was assigned to a scientific committee nominated by Lord Rayleigh. An International Technical Committee which met at Washington in 1910 determined the electromotive force of the Weston normal cell to be 1·0183 international volts at 20° C. A specification for the cell, which it is believed will meet all needs, is given at the end of this section.

§ (44) TYPES OF STANDARD CELLS.—A standard cell of any type should comply with the following conditions:

(*a*) It must be made up of chemicals which can be purified and reproduced with great exactness.

(*b*) No chemical or electro-chemical reactions must take place inside the cell except when a current passes through it.

(*c*) When the cell passes through a cycle of temperature it must give the same electromotive force at any stated temperature whatever its past thermal history has been, subject to certain limitations of temperature.

(*d*) When current passes through the cell its electromotive force may vary slightly, but it must recover completely within a reasonable time.

No cell is known which satisfies these conditions absolutely, but the Clark and Weston systems do so very nearly.

Cells which have from time to time been used as standards are given in the following table:

Name.	Positive Element.	Negative Element.	Electrolyte.	Depolariser.
Daniell	Copper	Zinc	Zinc Sulphate	Copper Sulphate
Fleming type of Daniell	”	”	”	”
Clark	Mercury	Zinc	”	Mercurous Sulphate
Gouy	”	”	”	Mercurous Oxide
De la Rue	Silver	”	Zinc Chloride	Silver Chloride
Helmholtz	Mercury	”	”	Mercurous Chloride
Hibbert	”	”	”	”
Weston	”	Cadmium	Cadmium Sulphate	Mercurous Sulphate

The Daniell cell as commonly used is an imperfect standard, for when a current passes through the cell the concentrations of the electrolytes are permanently changed. Also copper sulphate is an easily soluble salt, and it diffuses in appreciable quantities into that part of the cell containing the zinc. If a porous partition is added to keep the two liquids apart, it serves as a separator for a short time only. The other cells tabulated are great improvements with regard to the depolariser, and in the case of the Clark, Gouy, Helmholtz, and Weston cells, diffusion of the depolarising liquid to the negative element serves only to further amalgamate the latter and so produces a negligible change in the electromotive force.

In practice the cells containing mercurous sulphate as a depolariser are more satisfactory than the Gouy cell with mercurous oxide as depolariser; they are also better than the Helmholtz and Hibbert cells; this is due to the mercurous salt in the latter three cells being so insoluble as to incompletely protect the cells from polarisation. At the present time the Weston and Clark cells are the only ones used as standards, and these only will be described.

§ (45) Clark and Weston Cells.—The Clark cell is a voltaic combination which has a saturated solution of zinc sulphate as its electrolyte, mercury as the positive element, and zinc or zinc amalgam as the negative element. To ensure saturation of the solution at all working temperatures crystals of zinc sulphate are added, and to prevent polarisation of the cell the positive element is covered with mercurous sulphate. Latimer Clark first introduced this cell in 1872,[1] and investigations of it were first conducted by Lord Rayleigh,[2] and by Glazebrook and Skinner;[3] these investigators proved that the principal difficulty lay with the mercurous sulphate.

The Weston cell was patented by Dr. Edward Weston in 1892. As originally made it contained an electrolyte which was an unsaturated solution at most working temperatures, but since 1908 the cell known as the Weston normal cell, the electrolyte of which is saturated at all working temperatures, has been most used. The Weston normal cell is a voltaic combination which has a saturated solution of cadmium sulphate as its electrolyte, mercury as the positive element, cadmium amalgam as the negative element, and mercurous sulphate as the depolariser. Crystals of cadmium sulphate are added to ensure saturation of the solution.

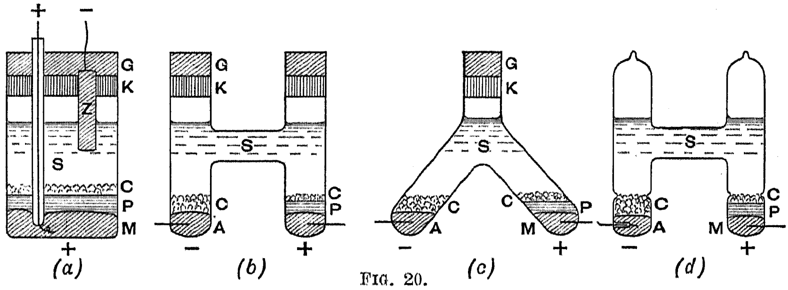

Fig. 20.

Researches on standard Clark and Weston cells have revealed many causes of variations, but the chief difficulty is with the mercurous sulphate. Minor variations have been traced to the negative element and the electrolyte, especially when the latter contains a minute quantity of acid. The type of cell, the preparation of the chemicals, and the causes of instability are considered in the following sections:

(i.) *Form of Cell.*—The original shape of Clark cell was tubular (*Fig.* 20 (*a*)), mercury being contained in the base of the tube, and a zinc rod supported by a cork occupied the upper part. Lord Rayleigh pointed out that this form was objectionable because the concentration of the mixed solutions of zinc and mercurous sulphates might be greater over the mercury surface than over the surface of the zinc rod; moreover, zinc amalgam could not be used in this form of cell. He devised therefore the H form (*Fig.* 20 (*b*)), in one leg of which there is zinc amalgam and in the other pure mercury; electrical contacts with the amalgam and with the mercury are made by platinum wires sealed into the glass. In the original H vessel evaporation was prevented by closing the upper ends of the tubes with corks and marine glue, but Lord Rayleigh pointed out that the cell could if necessary be hermetically sealed. Whether the cell be tubular or of the H form there is a tendency to aggregation of the zinc sulphate crystals by alternate melting and crystallisation as the temperature rises and falls. It is desirable, therefore, that only sufficient crystals be introduced to ensure saturation.

In 1904 F. E. Smith[4] showed that Kahle's conclusions[5] that the E.M.F. of the H form of cell was 0·0004 volt less than that of the tube form was erroneous. No such difference exists because of any difference of form.

Wright[6] introduced the inverted Y form of cell (*Fig.* 20 (*c*)). This is a variation of the H form, and in practice is a little more difficult to fill.

In 1886 Lord Rayleigh observed that in many H cells breakages occur in the amalgam limb, and he concluded that some alloying takes place between the zinc amalgam and the platinum wire making contact with it, resulting in an expansion of the wire which may crack the glass near the point where the platinum is sealed into it. To delay this action he introduced a little marine glue into the cell so as to protect part of the platinum wire from the amalgam. Hulett substituted a glass bead for the marine glue, and Smith sealed a fine glass tube about 4 mm. long over the platinum wire inside the cell (*Fig.* 20 (*d*)). This glass tube forms an extension of the H vessel and may be cracked by the alloyed platinum wire, and in time no doubt the cracking of the H vessel by the same cause

will take place. In practice, however, Clark cells so protected have been kept at the National Physical Laboratory for twelve years and not one has cracked. Recently M'Kelvy and Shoemaker [1] have employed platinum wire previously subjected for a short time to the action of hot 10 per cent zinc amalgam and have used a lead sealing-in glass. The first hermetically sealed cells appear to have been made by Callendar and Barnes.[2]

The universal practice now is to employ H vessels for standard cells, but there is no variation in electromotive force due to the *type* of cell, conditionally that the electrolytes in contact with the positive and negative elements are saturated.

(ii.) *The Positive Element, Mercury.*—All observers have used distilled mercury. Mercury which has been much used in a laboratory should be submitted to a preliminary purifying electrolytic process. The latter consists in making the mercury the anode in an electrolytic cell containing a mixture of dilute sulphuric and nitric acids as the electrolyte; the current density at the anode is conveniently about 0·002 ampere. Impurities of cadmium, zinc, etc., are thus removed. After being so treated the mercury should be washed, dried, and distilled *in vacuo.*

An alternative method of distillation which removes all readily oxidisable metals such as zinc, cadmium, bismuth, tin, copper, lead, etc., has been developed by Hulett.[3] An ordinary distilling flask with suction attachment is arranged so that a little air bubbles through the mercury in the still and passes over with the vapours. The air pressure is adjusted to be about 25 mm. and the temperature about 200° C. Any metallic vapour will completely oxidise under these conditions if the dissociation pressure of its oxide is less than the partial pressure of the oxygen maintained in the still. This is particularly true of all the common base metals. However, mercury vapour does not appear to oxidise at all under the conditions stated.

(iii.) *The Negative Element of the Clark Cell. Zinc or Zinc Amalgam.*—Hockin and Taylor [4] first showed that the presence of mercury on the surface of zinc makes practically no difference to its electromotive behaviour. They made cells with zinc as the negative element and a zinc amalgam as the positive element, and found that even when the mercury concentration reaches 98 per cent the electromotive property is the same, within a fraction of a millivolt, as that of pure zinc. Rayleigh [5] confirmed this result.

In 1892 Glazebrook and Skinner traced some of the irregularities of the tube form of Clark cell to the indifferent amalgamation of the zinc rods. They found that when the zinc was in the clear zinc sulphate solution amalgamation did not always take place, but when contact was made with the mercurous sulphate amalgamation invariably resulted.

In 1909 Cohen and Tombrock [6] made an elaborate study of the electromotive properties of zinc amalgams. They used H vessels to contain the amalgams and used a dilute solution of zinc sulphate as electrolyte. All measurements were carried out at 0·5° C. As metallic zinc does not show a sharply defined potential towards its salts except when it has been deposited electrolytically, a 10 per cent zinc amalgam was used as a standard of reference. The results showed that after a few hours the electromotive difference between amalgams containing from 2·57 per cent to 10 per cent of zinc was less than 0·0001 volt, but with amalgams containing 60 per cent of zinc differences of 0·0009 volt were observed.

J. L. Crenshaw [7] studied the electromotive behaviour of liquid zinc amalgams at 25° C. and of two solid amalgams containing 2·5 and 5 per cent of zinc respectively. After two months the electromotive effects of the latter were identical within one microvolt.

In the general use of the Clark cell, amalgams containing 10 per cent of zinc are used. The amalgams are preferably made by the electrodeposition of zinc on a mercury cathode using acid zinc sulphate solution as an electrolyte. In practice no investigator has traced abnormalities in the electromotive force of a Clark cell to zinc amalgams prepared by electro-deposition.

(iv.) *The Negative Element of the Weston Cell. Cadmium Amalgam.*—Dearlove [8] first showed that the electromotive properties of cadmium amalgams depend on the percentage content of cadmium.

W. Jaeger [9] made measurements at 20° C. with amalgams varying in content from 1 to 20 per cent of cadmium, and concluded that at 20° C. all amalgams containing from 5 to 14·3 per cent of cadmium could be used in the anode limb of a Weston cell with the same resulting E.M.F. In 1902 H. C. Bijl [10] examined the electromotive properties of a series of cadmium amalgams at 20°, 25°, 50°, and 75° C., and from the data he obtained the conclusion may be drawn that an amalgam containing 12½ per cent of cadmium cannot

[10] *Zeitschr. f. physik. Chemie*, 1902, xli.

be usefully employed below 14° C. In 1908 E. Cohen and H. R. Kruyt[1] found differences of 0·04, 0·23, 0·13, 0·16, 0·20, and 0·20 millivolt between amalgams containing 10 and 12½ per cent of cadmium when the electrolyte between the amalgams was a solution of cadmium sulphate and the temperature was maintained at 0° C. Cohen suggested the general use of an 8 per cent amalgam for Weston normal cells.

F. E. Smith[2] made experiments with amalgams containing from 1 to 25 per cent of cadmium at temperatures from 0° to 60° C. Some of the amalgams experimented with were chilled and others were allowed to cool in a normal fashion.

Later S. W. J. Smith[3] pointed out the limitations of the Weston cell as a standard of electromotive force owing to small variations in the cadmium amalgams.

The results given by F. E. Smith show that an all-solid amalgam gives a higher E.M.F. when solidified by chilling; they show also that the amalgam in a Weston cell must be partially liquid if the E.M.F. is to remain constant. When, by increasing the temperature, a solid amalgam is converted into a mixture of liquid and solid phases there is an abrupt change in the electromotive properties of the amalgam. When stable, however, the E.M.F. of such an amalgam towards a solution of cadmium sulphate does not depend on the relative amounts of the two phases: hence, stable amalgams containing different percentages of cadmium, but possessing the two phases, have the same E.M.F. towards a cadmium sulphate solution. With amalgams all liquid or all solid the E.M.F. varies with the cadmium content.

Experiments on chilled and slowly cooled amalgams indicate that cadmium amalgams of such composition that, if homogeneous, they would be completely solid below certain temperatures, may not, in a Weston normal cell, have that E.M.F. towards a cadmium sulphate solution corresponding to such a solid. The general result is a lowering of the E.M.F. of the cell, which is due to a lack of homogeneity of the amalgam, the surface in contact with the cadmium sulphate solution being of smaller cadmium concentration than parts of the interior. Diffusion tends to restore uniformity, and in consequence such a cell is unstable for a very considerable time, the E.M.F. rising. On the other hand, in a cadmium amalgam of such composition that, if homogeneous, it would be all liquid above certain temperatures, the upper part may be a two-phase system and the lower part an all-liquid system of less cadmium concentration than the average. Diffusion quickly equalises the concentration and the E.M.F. falls to a normal value.

Cadmium, as purchased, often contains a trace of zinc which is very injurious in a Weston normal cell, and to avoid this it is essential to prepare the cadmium amalgam by electro-deposition of cadmium on mercury, the electrolyte being a slightly acid (H_2SO_4) solution of cadmium sulphate.

The fall of voltage from anode to cathode should not exceed 0·3 volt, and the approximate weight of cadmium deposited should be calculated from measurements of the current and the time. From the weight of mercury used as cathode and the final weight of the amalgam the percentage of cadmium in the latter can be calculated. Mercury should be added to reduce the cadmium content to 10 per cent. *Fig.* 21 shows the range of temperature over which amalgams of various cadmium content may be safely used.

Temperature ° C.	Percentage of Cadmium in the Amalgam									
	2.	4.	6.	8.	10.	12.	14.	16.	18.	20.
0	−3·65	+0·34	+0·35	+0·36	+0·36	+0·40	+2·49	+5·60	+12·95	+16·13

The above table shows the differences in millivolts between Weston normal cells containing amalgams of different cadmium content and a Weston normal cell (always at 20° C.) containing an amalgam with 10 per cent of cadmium.

(v.) *The Electrolyte of the Clark Cell. Zinc Sulphate.*—At ordinary temperatures the salt occurs in the form $ZnSO_4 \cdot 7H_2O$ and is apt to contain sulphates of lead and iron and also free sulphuric acid. The latter has the greatest

[1] *Zeitschr. f. physik. Chemie*, 1909, xlv.
[2] *Phil. Mag.*, 1910, xix.
[3] *Phys. Soc. Proc.*, 1910, xxii.

effect upon the electromotive force of a Clark cell and promotes the formation of gas over the zinc amalgam. Lord Rayleigh added a little carbonate of zinc to neutralise the free

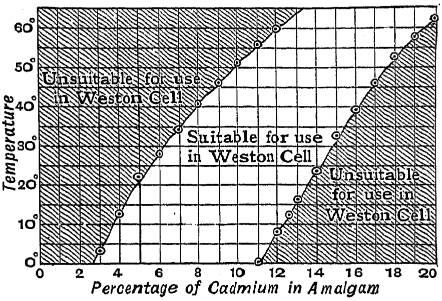

FIG. 21.

acid and found it a good plan to let the solution stand for a time, as a small quantity of iron salt was usually deposited even when so-called *pure* zinc sulphate was used. Examination of some cells of which the E.M.F. was low led him to believe that in these the zinc sulphate was supersaturated, but it appears probable that the low E.M.F. was due to the formation of the hexahydrate $ZnSO_4 \cdot 6H_2O$. The salt $ZnSO_4 \cdot 7H_2O$ when heated to 39° C. suffers the transition

$$ZnSO_4 \cdot 7H_2O \rightleftarrows ZnSO_4 \cdot 6H_2O + H_2O.$$

Below 39° C. a Clark cell containing $ZnSO_4 \cdot 7H_2O$ has the greater E.M.F. and is stable; above 39° C. the cell is unstable and one containing $ZnSO_4 \cdot 6H_2O$ has the greater E.M.F. These changes in the E.M.F. of a Clark cell in the neighbourhood of 39° C. were first discovered by Callendar and Barnes,[1] and were further investigated by Jaeger.[2] Callendar and Barnes found that the E.M.F. of cells with the heptahydrate could be measured at a temperature of about 42° C. but thereafter the E.M.F. became uncertain. A cell prepared with the hexahydrate can be measured down to 0° C. owing to the extreme slowness with which the hexahydrate changes to the heptahydrate form. Because of this, Clark cells should never be raised to temperatures above 39° C., and if the salt is recrystallised when purifying, the temperature of the solution should be less than 39° C.

Zinc sulphate, as purchased, often contains less than the theoretical amount of water of crystallisation owing to efflorescence. Callendar and Barnes[3] found the solubility of $ZnSO_4 \cdot 7H_2O$ to be 41·1 per cent of the solution at 39° C. and 29·4 per cent at 0° C. To purify the salt it is best to dissolve it in hot water and to add an excess of pure zinc oxide and hydrogen peroxide to oxidise any ferrous iron present. After keeping near 100° C. for several hours the solution should be filtered, acidified slightly, and evaporated on a water bath (electrically heated) until zinc sulphate commences to crystallise out. The mixture is then cooled with ice water, when much more of the zinc sulphate separates. The crystals which separate are washed, and dissolved in sufficient warm water at 35° C. to form a saturated solution. The solution is then made acid with H_2SO_4 to about 1 part in 10,000 and cooled to near 0° C. The crystals which now separate are drained in a funnel, using a suitable platinum or glass cone, and washed twice with a small quantity of cooled water.

(vi.) *The Electrolyte of the Weston Normal Cell. Cadmium Sulphate.*—At temperatures up to 74° C. a saturated solution yields crystals having the composition $CdSO_4 \cdot \frac{8}{3}H_2O$; above this temperature $CdSO_4 \cdot H_2O$ separates instead. The salt is very soluble and has a minimum solubility at a temperature of about 1° C. Over the ordinary range of temperature the increase of solubility with temperature is slight; thus at 1° C. about 75·5 parts by weight of $CdSO_4$ are dissolved in 100 parts of water and 76·8 parts at 25° C.

Kohnstamm and Cohen[4] concluded that a saturated solution of cadmium sulphate in water underwent a change in constitution at a temperature of about 16° C. and this they believed led to erratic changes in the E.M.F. of a Weston cell. This was disproved by H. v. Steinwehr[5] who made very careful solubility measurements and showed that such a change does not take place.

Hulett[6] states that 100 c.c. of water dissolves the following amounts of cadmium sulphate at the indicated temperatures.

Temp.	$CdSO_4$.	$CdSO_4 \cdot 8/3H_2O$.
	grams.	grams.
0° C.	75·5	112·5
15° C.	76·1	113·4
25° C.	76·8	114·7
40° C.	78·5	117·9

Cadmium sulphate does not appear to be isomorphous with any known salt and it can therefore be obtained in a very pure state by crystallisation. As purchased it often contains iron and some free acid. The latter may be eliminated by raising the temperature of the salt to about 700° C.; after such treatment the salt is dissolved in water, the solution filtered, and after making acid with H_2SO_4 to about 1 part in 10,000 the cadmium

[1] *Roy. Soc. Proc.*, 1897, lxii.

[5] *Ann. der Physik*, 1902, ix.
[6] *Phys. Rev.*, 1911, xxxii.

sulphate is crystallised out, very pure salt being thus obtained. Another method of purifying is to dissolve the purchased salt in hot water and render basic by adding an excess of cadmium oxide and some hydrogen peroxide. After heating the mixture at 100° C. for about four hours the solution is filtered, acidified slightly, and evaporated until the volume of liquid is reduced to rather less than one-quarter. The salt which separates is drained in a funnel having a glass or platinum cone and washed twice with cold water; it is then dissolved at room temperature in a slight excess of water containing about 1 part in 10,000 of H_2SO_4. The solution is filtered and set aside in crystallising dishes for the separation of cadmium sulphate crystals. After draining, the latter are washed twice with distilled water.

(vii.) *The Depolariser for Clark and for Weston Cells. Mercurous Sulphate.*—More than half of the researches on standard cells have really been investigations of the depolariser. In his first work on the Clark cell [1] Lord Rayleigh found irregularities due to the mixture of mercurous and zinc sulphates. He set up H type cells charged with pure mercury and depolariser in *both* limbs and filled up as usual with saturated zinc sulphate solution. There should, if the depolarisers were the same, have been no electromotive force, but he found one such cell to have an E.M.F. of 0·0059 volt and it remained tolerably constant for several days. To another such cell zinc carbonate was added and this greatly reduced the E.M.F. Believing the mercurous sulphate to be initially acid, cells were therefore set up with zinc carbonate added to neutralise the free acid and this reduced the irregularities. On neutralisation he observed that the paste turned yellow.

Glazebrook and Skinner [2] found that mercurous sulphate could not easily be purchased in a pure state and considered the depolariser to be the principal source of error in standard cells. The commercial preparations they met with were either grey or very white; the grey powder contained mercury in excess which was not harmful, but the white salt was found frequently to contain mercuric sulphate. When water is added to the latter it turns yellow in colour due to the formation of basic mercuric sulphate $3HgO{\cdot}SO_3$. This was believed to be not very harmful in small quantities, but at its formation a soluble acid mercuric sulphate $HgSO_4{\cdot}2SO_3$ is also formed. They recommended that the whole of the $HgSO_4{\cdot}2SO_3$ should be removed by washing. Further they recommended that mercurous sulphate contaminated with mercuric sulphate should be treated with mercury so as to convert the latter into mercurous salt.

[1] *Roy. Soc. Phil. Trans.*, 1885.
[2] *Ibid.*, 1892, clxxxix.

In 1901 Jaeger and St. Lindeck [3] confirmed the observations of Rayleigh and Glazebrook. They showed that cells containing mercurous sulphate from different sources may differ by more than 200 microvolts.

In 1904 Carhart and Hulett [4] advocated a standard method of preparing mercurous sulphate and expressed themselves strongly in favour of an electrolytic method of preparation. About the same time F. A. Wolff [5] also urged the adoption of a standard method of preparation and gave details of an electrolytic method used by him. F. E. Smith [6] made mercurous sulphate by three methods and found the products identical. Since that time many investigations have been made, and it is convenient to classify the methods and afterwards consider the electromotive properties of solutions of the salt.

(viii.) *Methods of Manufacture.* (*a*) *Electrolytic Method.*—Carhart, Hulett, and Wolff appear to have been the first to make mercurous sulphate by an electrolytic process and to use the product in a standard cell. The method has been largely employed at the Bureau of Standards, Washington. In a flat-bottomed glass vessel pure mercury is placed and is covered with dilute sulphuric acid to a depth of about 10 cm., the acid being prepared by adding one part by volume of concentrated H_2SO_4 to from 6 to 20 parts of distilled water. The solution is electrolysed by making the mercury the anode and a sheet of platinum hung in the acid the cathode; a current density of about 0·5 ampere per 100 sq. cm. surface of anode may be employed. A stirrer consisting of a glass rod bent at right angles at the bottom must be used to keep the surface of the mercury exposed and to stir the solution and the salt formed. A little over 4 grams an hour can be prepared in this way with a current of half an ampere. The preparation should be conducted in a dark room and the salt removed from the mercury by means of a separating funnel.

(*b*) *By Chemical Precipitation.*—This method has been much used at the National Physical Laboratory. Protonitrate of mercury is first made by the addition of nitric acid to mercury and the mercurous nitrate thus formed is added to hot dilute sulphuric acid; mercurous sulphate is precipitated. Fuller details of the method are given in the Specification at the end of this section.

(*c*) Other methods have been used but they are troublesome and are principally of interest

[3] *Zeitschr. f. Instrumentenk.*, 1901, xxi.
[4] *Trans. Am. Electrochem. Soc.*, 1904, v.
[5] *Ibid.*
[6] *British Association Report*, 1904.

because the products have been shown to have the same electromotive properties as the salts obtained by the methods already described. In one of these processes a purchased sample of mercurous sulphate is heated with concentrated H_2SO_4 to a temperature of about 150° C. and the hot clear acid is very carefully poured into dilute sulphuric acid (1 to 6), when precipitation of pure mercurous sulphate results. In another method fuming sulphuric acid is added to pure mercury and stirred well until the action between the two is practically at an end. Mercurous sulphate is thus formed in the cold and appears in the crystalline form after a few minutes.

Smith[1] first showed that the products obtained by these four methods had uniform electromotive properties, and other observers have confirmed this. Laporte[2] has employed an electrolytic method using alternating current of a frequency of about 40 cycles per second, and the product obtained has been proved to be quite satisfactory.

A special technical committee which met at Washington[3] set up standard cells with samples of mercurous sulphate made by chemical precipitation, by direct current electrolysis and by alternating current electrolysis. Cells set up with the mercurous sulphate prepared by the alternating current method were at first greater in E.M.F. by about 1 part in 10,000, but cells set up by the two other methods agreed within 1 part in 100,000.

(ix.) *Hydrolysis of Mercurous Sulphate.*—When pure mercurous sulphate is washed with water a yellow basic salt is produced the composition of which has been determined by Gouy[4] to be $(HgHO)_2 \cdot Hg_2SO_4$. This yellow product was formed and must have been present in most of the depolarisers of standard cells made previous to 1904, for until that date it was the invariable practice to wash the mercurous sulphate with water before using it as a depolariser.[5] Swinburne in 1891 favoured the washing of mercurous sulphate with zinc sulphate (for Clark cells), and Hulett[6] insists on the exclusion of the hydrolysed salt both in the preparation of Hg_2SO_4 and during the washing process. For Weston normal cells, saturated solutions of cadmium sulphate are recommended by Hulett for washing the salt free from acid, etc.

Measurements made by Hulett and by F. E. Smith, by totally different methods, show that 6 grams of Hg_2SO_4 are completely hydrolysed by about 3600 grams of water. Gouy has shown that the following equations represent the chemical actions:

$$3Hg_2SO_4 + 2H_2O = (HgHO)_2Hg_2SO_4 + Hg_2SO_4 + H_2SO_4,$$

or

$$3Hg_2SO_4 + 2H_2O = (HgHO)_2Hg_2SO_4 + 2HgHSO_4,$$

from which it follows that 6 grams of Hg_2SO_4 produce 3·75 grams of the hydrolysed salt. Further the addition of 0·395 gram of H_2SO_4 to this quantity of hydrolysed salt should result in the formation of Hg_2SO_4 and water. The presence of 0·395 gram of H_2SO_4 in 3600 c.c. of water (*i.e.* about 1 part in 9000 or 0·00224 normal H_2SO_4) should, therefore, prevent hydrolysis. For reasons which will be given later it is advisable for the final washing of mercurous sulphate to be made with 0·1 normal H_2SO_4, and if it is desired to preserve the salt for a considerable time it should be kept in a stoppered bottle in contact with acid of this strength.

The hydrolysis of mercurous sulphate in contact with cadmium sulphate solution has been studied by Smith, who added pure mercurous sulphate to solutions containing from ·06 x to 1·00 x parts of cadmium sulphate where x is the quantity of the salt in a saturated solution. With solutions containing up to 0·20 x parts of cadmium sulphate the mercurous sulphate was visibly hydrolysed, and with saturated solutions there was, after ten years, visible evidence of hydrolysis at the surface. Smith concludes, therefore, that even with saturated cadmium sulphate solutions mercurous sulphate is slightly hydrolysed, but the action is a slow one. In practice hydrolysis of the salt must be avoided. The reason for this will be apparent after consideration of the action of acids on solutions of cadmium and mercurous sulphates.

(x.) *Solubility of* Hg_2SO_4 *in Acid Solutions.*—The solubility of Hg_2SO_4 in water solutions of H_2SO_4 has been determined by Hulett and by Smith. Starting with water the solubility is about 0·47 gram of mercury in a litre. With the addition of acid the solubility at first diminishes to a minimum of 0·30 gram per litre, the normality of the acid being then about 0·04. Here there is a sharp change, and with a further increase in concentration of the acid the solubility increases to a maximum of about 0·44 for twice normal sulphuric acid. Hulett[7] says that hydrolysis of Hg_2SO_4 is effective unless the concentration of acid is as great as twice normal, but Smith

[3] *Ibid.*

[4] *Compt. Rend.*, 1900, cxxx.

[5] See "Specification of Clark Cell," *Report of British Association*, 1894.

[6] *Amer. Electrochem. Soc. Trans.*, 1904, vi.

[7] *Amer. Electrochem. Soc. Trans.*, 1904, vi.

regards hydrolysis to be impossible if the normality exceeds 0·0023. *Fig.* 22 shows the change of solubility (grams of mercury per litre) with varying concentration of H_2SO_4. The most interesting portion of the curve is that corresponding to a minimum

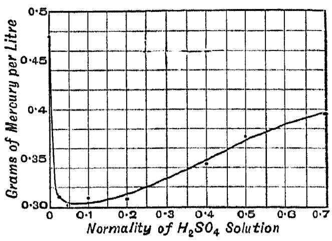

FIG. 22.

solubility of Hg_2SO_4 with a concentration of H_2SO_4 equal to about 0·05 normal.

(xi.) *Solubility of Mercurous Sulphate in Solutions of Zinc Sulphate.*—A saturated solution of zinc and mercurous sulphates contains about 0·84 gram of the latter. No measurements of the solubility of mercurous sulphate in unsaturated solutions of zinc sulphate appear to have been made.

(xii.) *Solubility of* Hg_2SO_4 *in Cadmium Sulphate Solutions.*—Smith has measured the solubility of mercurous sulphate in solutions containing various amounts of cadmium sulphate. The results obtained are:

Grams of $CdSO_4$ per Litre of Solution.	Approximate Weight of Mercury per Litre.	Grams of $CdSO_4$ per Litre of Solution.	Approximate Weight of Mercury per Litre.
	grams.		grams.
701*	1·1	7·0	0·25
561	1·00	1·8	0·27
350	0·92	0·9	0·30
140	0·61	0·45	0·31
35	0·33	0·00	0·45

* Saturated.

It will be observed that the minimum solubility corresponds to a normality of the cadmium sulphate solution of about 0·033. The change in solubility of mercurous sulphate with change of concentration of H_2SO_4 is, therefore, very similar to that occurring with change of concentration of cadmium sulphate, and since with the stronger solution the weight of mercurous sulphate in solution is greater than with the weaker solutions a complex salt is probably formed.

(xiii.) *Effect of Acid on the E.M.F. of the Clark Cell.*—Free acid in the Clark cell reduces the effective life of a cell owing to the formation of gas near the zinc amalgam. Hulett[1] gives the following values for Clark cells made with saturated solutions of zinc sulphate in x normal sulphuric acid:

E.M.F. (Volts).	x.	E.M.F. (Volts).	x.
1·42043	0·000 N	1·41810	1·012 N
1·42015	0·202 N	1·41595	2·024 N

(xiv.) *Effect of Acid on the E.M.F. of Weston Normal Cells.*—Hulett[2] rotated various cathode systems, with and without acid, for several days, and measured the change of E.M.F. produced by the acid, together with the weight of mercurous sulphate dissolved in a litre of the solution. The results are as follows:

Concentration of Sulphuric Acid.	Cathode Systems rotated for	E.M.F. of Cell at 25° C.		Weight of Hg_2SO_4 per Litre.
		Before rotation.	After rotation.	
Molar.	Days.			Gram.
1·012	8	1·01671	1·01678	0·90
0·506	5	1·01745	1·01747	0·93
0·2024	6	1·01802	1·01808	1·00
0·1012	10	1·01821	1·01823	1·04
0·0506	7	1·01834	1·01834	1·08
0·0202	13	1·01835	1·01847	1·13
0·0000	21	1·01836	1·01905	1·34
0·0000	21	1·01836	1·01940	1·47
0·0000	20	1·01836	1·02015	1·51

It is well known that acid decreases the E.M.F. of standard cells, and this may be seen at once from the tabulated results. On plotting the electromotive forces as a function of the acid concentration, curve A, *Fig.* 23,

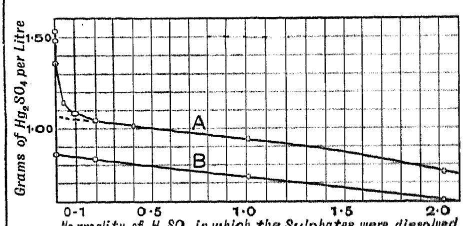

FIG. 23.

results. Curve B relates to corresponding observations with Clark cells, and it will be observed that the abnormal values with low acid concentration which occur in the Weston normal cell do not occur in the Clark cell. Indeed as a "standard" the Clark cell is undoubtedly better than the Weston. The high values obtained with non-acid cathode systems did not remain constant when the rotation was stopped, but decreased on standing.

[1] *Phys. Rev.*, 1908, xxvii.

[2] *Amer. Electrochem. Soc. Trans.*, 1908, xiv.

Smith has made a very extensive study of the effect of acid on the E.M.F. of the Weston normal cell. A large number of cells were set up with electrolytes consisting of cadmium sulphate dissolved in acids of varying strength, and these were kept under observation for ten years. *Fig.* 24 shows the relation between

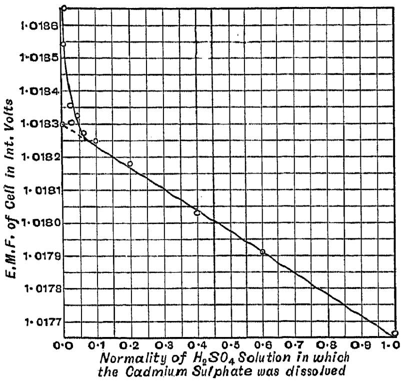

FIG. 24.

the E.M.F. of these cells and the normality of the sulphuric acid in which the cadmium sulphate was dissolved. When the solutions were made up with acid stronger than 0·4 normal, gas was produced after three years over the cadmium amalgam, but by gently warming the cell the gas could be displaced. The curve shows the values of the cells after the latter had been made up for two weeks. For cells containing from 0·10 normal sulphuric acid to 4·0 normal acid Smith found the following relation holds—

$$y = -(0{\cdot}00060x + 0{\cdot}00005x^2) \text{ volts},$$

where y is the change in E.M.F. and x is the normality of the sulphuric acid in which the cadmium sulphate is dissolved.

If the acid is in the negative limb (amalgam side) only the change in E.M.F. within the same limits of acidity is

$$y = 0{\cdot}01090x - 0{\cdot}00125x^2 \text{ volts},$$

and if the acid is in the positive limb only the change in E.M.F. is

$$y = -0{\cdot}01150x + 0{\cdot}00120x^2 \text{ volts}.$$

Thus, if there is 0·1 normal sulphuric acid in the positive limb only, the E.M.F. will be lowered because of it by 0·00114 volt. When, therefore, cells are made with acid solutions care should be taken to ensure that the acid is uniformly distributed.

Cells containing less than 0·05 N sulphuric acid are often very abnormal in behaviour. Cells containing no acid at all are at first usually quite normal, and often remain normal for many years if kept at a constant temperature. In many cases, however, the E.M.F. falls with time, and hysteresis effects can be obtained when the cells are subjected to a temperature cycle. Cells made up with cadmium sulphate dissolved in 0·1 normal sulphuric acid do not show such anomalous behaviour.

(xv.) *Interaction between Mercury and the Sulphates of Cadmium and Mercury in Solution.*—Hulett [1] found that when the cathode system (consisting of mercury, mercurous sulphate, and cadmium sulphate solutions) of a cell was rotated for a few hours a very decided change in the electromotive force was produced. In all cases the voltage rose, and in some cases a rise of two millivolts was experienced. After various experiments the conclusion was arrived at that the mercurous sulphate was hydrolysed by the cadmium sulphate solution, the action being a slow one. By direct analysis the amount of mercury in solution was also found to be increased by agitation of the cathode system for several days.

Wolff and Waters [2] rotated cathode systems of mercurous and cadmium sulphate solutions and solids together and found the changes in the E.M.F. of cells not to exceed 1 part in 10,000 even when the rotation was continued for four months. They concluded that all samples of mercurous sulphate do not behave abnormally.

Smith made a large number of experiments with rotated cathode systems, and concludes that no hydrolysis of Hg_2SO_4 is possible in the presence of 0·0023 normal sulphuric acid, but that the presence of this quantity of acid does not prevent an interaction between the two sulphates in solution which is detrimental to the Weston cell. At times the result of such interaction is to increase the electromotive force by 3 millivolts, an increase which is probably due to other mercury compounds being produced in solution the mercury ion concentrations of which are different from that of mercurous sulphate. In the general body of the solution (excluding that in contact with mercury) the mercury ion concentration appears to be greater than that corresponding to mercurous sulphate only, and as a result the electromotive force of the cell may be increased by agitation. This solution of high mercury ion concentration is not, however, in contact with mercury, and suffers a reduction on being brought into such contact. At the surface layer of the mercury, where solid mercurous sulphate is in contact with mercury, there appear to be exceedingly minute differences of potential causing parasitic currents which lower the mercury ion concentration in the surface layer of liquid, and as a result the E.M.F. slowly falls below the normal value.

To produce such parasitic currents in the

[1] *Amer. Electrochem. Soc. Trans.*, 1908, xiv.
[2] *Bureau of Standards Bull.*, 1907, iv.

surface layers Smith made cells containing pastes which were mixtures of hydrolysed and unhydrolysed mercurous sulphates. It was anticipated that the solutions of these salts in contact with the mercury would be similar and independent of the proportion of hydrolysed and unhydrolysed salts, since both were in excess. This was very nearly the case when the cells were first set up, the maximum difference between the E.M.F.'s of any two cells being 3 parts in 10,000. The second anticipation was that, since a cell containing only hydrolysed salt has an E.M.F. about 0·02 volt lower than a cell with unhydrolysed salt, and further since both of these salts were in contact with mercury in the cells under consideration, there must have been a slightly higher mercury ion concentration in the solution near particles of the unhydrolysed salt than in that near particles of the hydrolysed salt. At the mercury surface such a difference in the mercury ion concentration must result in a difference of potential between parts of the conducting surface. Such a difference cannot be maintained, and the tendency must be to *lower* the mercury ion concentration in the liquid near the surface of the mercury; also near the surface the proportion of unhydrolysed salt must gradually decrease. If this anticipation is correct the speed of the action should be related to the proportion of hydrolysed salt present in the original mixture. *Fig.* 25 shows the results obtained with six

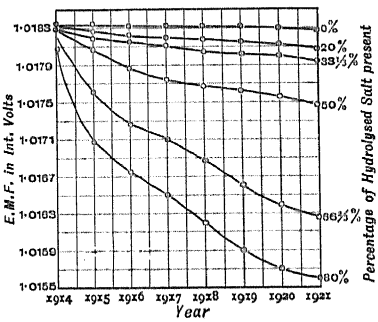

FIG. 25.

cells over a period of seven years. The results are in accordance with the explanation given. It follows also that finely divided mercury distributed throughout the paste should result in the elimination of abnormally high E.M.F.'s, but will not prevent a fall of E.M.F.

From these experiments it is concluded that hydrolysis and interaction between cadmium and mercurous sulphates must be avoided, and that the best way of doing this is by using an electrolyte of cadmium sulphate dissolved in 0·1 normal sulphuric acid.

(xvi.) *Influence of Size of Crystals.*—H. von Steinwehr [1] pointed out that the size of the mercurous sulphate crystals might influence the E.M.F. of a standard cell, and concluded from his experiments that the variations in E.M.F. were due almost entirely to variations in the size of the crystals. Smith [2] further investigated this matter and took microphotographs of crystals prepared by several methods; the conclusion is that no large crystals of mercurous sulphate which are sufficiently soluble to act as an efficient depolariser can result in the E.M.F. of a cell being appreciably less than when crystals from 0·003 to 0·030 mm. long are used. It is possible that in von Steinwehr's experiments the very small crystals more rapidly interacted with the cadium sulphate solution and produced a complex salt, and thus by their size indirectly affected the E.M.F.

Wolff and Waters [3] examined many samples of mercurous sulphate under the microscope and found very few particles possessed a length less than 0·001 mm., the average dimension being considerably greater. They concluded that, in general, any effect due to the size of the crystals may be disregarded.

(xvii.) *Change of E.M.F. with Temperature of the Weston Normal Cell.*—Wolff [4] made a very complete investigation on 200 cells for a cycle of temperature from 0° to 40° C. Some of the cells were abnormal in their behaviour, and the results with these were rejected. The conclusion is that the relation between E.M.F. and temperature is best represented by the formula

$$E_t = E_{20} - 0{\cdot}00004075(t-20) - 0{\cdot}000000944(t-20)^2 + 0{\cdot}0000000098(t-20)^3.$$

This formula was recommended for general use by the International Conference on Electrical Units and Standards (London, 1908). Other formulae have been obtained by Jaeger and Lindeck [5] and by Smith,[6] but the number of cells examined by these investigators was comparatively small, and the formulae are not, therefore, so reliable. The following table gives the electromotive force of a Weston normal cell from 0° C. to 40° C. when its E.M.F. is 1·01830 international volts at 20° C.:

Temperature ° C.	E.M.F. in International Volts.	Temperature ° C.	E.M.F. in International Volts.
0	1·01866	25	1·01807
5	1·01866	30	1·01781
10	1·01860	35	1·01761
15	1·01848	40	1·01718
20	1·01830

(xviii.) *Temperature Coefficient of each Limb.*—Smith[1] showed that although the temperature coefficient of the complete Weston cell is small, the temperature coefficients of the separate limbs are comparatively large, and in consequence it is important that in use the cell be at a uniform temperature. At 20° C. the temperature coefficient of the positive limb is + 0·00031 volt for a rise of temperature of 1° C., and that for the negative limb is − 0·00035 volt for a rise of temperature of 1° C.

(xix.) *Polarisation Effects.*—In 1884 Lord Rayleigh made some experiments on the polarisation of Clark cells and showed that the effect of short circuiting for a few minutes passed rapidly away. Smith[2] made tests on four Weston normal cells short circuited for one minute, five minutes, five hours, and five days respectively. The cell short circuited for one minute recovered within one ten-thousandth of a volt one minute afterwards; but forty minutes were occupied in its recovery within 1 part in 100,000. The cell which was short circuited for five minutes was nearly 0·001 volt low one minute afterwards; at the end of two minutes it was 0·0005 volt low, and after five minutes it had recovered within 0·0002 volt. The recuperation of the cell short circuited for five hours was very slow; after one minute its E.M.F. was about 0·1 volt; at the end of four minutes it was 0·9 volt, and five hours afterwards it had recovered within 0·0004 volt. It became nearly normal three weeks afterwards. The cell which was short circuited for five days had an E.M.F. less than 0·05 volt five minutes after breaking the circuit, but within twenty-four hours its E.M.F. was normal within 2 parts in 10,000. It appears clear, therefore, that accidental short circuits of standard cells do not, in general, result in permanent injury to them.

§ (46) Change of E.M.F. with Temperature of the Clark Cell.—Lord Rayleigh (1886) gave the equation

$$E_t = 1{\cdot}435\{1 - 0{\cdot}00082(t - 15)\}$$

to connect temperature and E.M.F. In 1892 Glazebrook and Skinner made observations with cells mostly in the neighbourhood of 0° to 15° C., and gave 0·00076 as the average value of the coefficient between these temperatures. Their experiments did not enable them to decide whether the relation between E.M.F. and temperature is linear or not.

§ (47) Stability of the Weston Normal Cell.—The stability of the Weston cell has been studied by many investigators, but more particularly by Hulett, Smith, Wolff, Carhart, Shaw, and Reilley. When made with neutral cadmium sulphate solution Hulett and Smith believe the cell to be slightly unstable, the electromotive force falling with time; they recommend the inclusion of acid to reduce the instability. There are, however, numerous instances of cells made up with neutral cadmium sulphate solutions remaining stable for many years, and it has been definitely established that new cells set up by observers in England, Canada, America, France, Japan, Holland, Russia, Germany, and other countries have, when first set up, electromotive forces which are the same within 20 or 30 microvolts.[3] The following table gives the results of some comparisons made in Washington in 1910 of Weston cells made in England, America, France, and Germany:

Place of Manufacture.	No. of Cells tested.	Mean Variation between Cells.	Difference of Groups from Mean of all.
		Microvolts.	Microvolts.
National Physical Laboratory . .	34	± 9	− 3
Bureau of Standards	40	± 6	− 8
Laboratoire Central d'Électricité . .	15	±25	+10
Physikalisch Technischen Reichsanstalt	15	±10	+ 1

All the cells were comparatively new ones.

In 1908 Smith[4] gave details of 10 cells which, although prepared in an apparently normal manner, fell slowly but steadily in electromotive force. In five years the fall in E.M.F. of one of these cells was more than a millivolt. Other cells of the same age kept constant in E.M.F. within 30 microvolts. Hulett[5] found a large number of cells to continually fall in E.M.F., and in one instance measured a change of over 5 millivolts in less than two years. Wolff and Waters[6] and Carhart[7] observed but very small changes in E.M.F., and Shaw and Reilley[8] observed changes not greater than 140 microvolts in ten years.

Smith made special cells containing 0·1 gram only of mercurous sulphate, and found the fall of E.M.F. to be more pronounced. From the results so far published it appears that while many cells may remain constant within 100 microvolts for many years, the chemical system of a Weston cell is not a stable one, and that the E.M.F. is subject to fluctuations owing to an interaction between

neutral solutions of mercurous and cadmium sulphates. With old cells and others comparatively new but abnormal, most investigators have observed that the E.M.F. increases slightly after agitation but falls again with time. The same effect is produced by increasing the temperature of the cell for a short time and then cooling to the original temperature. Both actions result in the surface layer of liquid, of low mercury ion concentration, being displaced by other liquid of higher mercury ion concentration with a consequent rise in E.M.F. The E.M.F. is not stable, however, but very slowly falls. A number of such cells were noted by Wolff [1] when measuring the mean temperature coefficient of a large number of Weston cells.

It follows that if the liquid of high mercury ion concentration is not stable when in intimate contact with mercury and mercurous sulphate, the distribution of mercury in fine globular form throughout the paste is advantageous. Data obtained by numerous experimenters appear to support this view. Such distribution of mercury throughout the paste does not, however, prevent a slow fall in electromotive force. To prevent the latter, free sulphuric acid must be present, the saturated cadmium sulphate solution being made up in 0·1 normal sulphuric acid.

§ (48) Specification for Clark and Weston Standard Cells.—The International Conference on Electrical Units and Standards, London, 1908, agreed on a brief but incomplete specification for the Weston normal cell, and assigned the duties of specifying more particularly the conditions under which the cell was to be set up to another Committee. No specification giving details of procedure has yet been issued. The following specifications are based on the work of numerous experimenters: that relating to the Weston cell contains the instructions of the London Conference together with notes on procedure, etc., based on information obtained since the Conference. The instructions are indicated by a numeral, and the added notes by a numeral and a letter.

§ (49) Specification for the Clark Cell.—(No specification was prepared by the London Conference, 1908.)

1. The Clark cell is a voltaic combination which has a saturated solution of zinc sulphate as its electrolyte, mercury covered with mercurous sulphate and zinc sulphate crystals as the positive element, and zinc amalgam covered with zinc crystals as the negative elements.

2. To prepare pure zinc sulphate, dissolve the purchased salt in hot water to form a saturated solution and add pure zinc oxide in excess and about 1 per cent of hydrogen peroxide. Heat over a water bath for about four hours, filter, acidify slightly with H_2SO_4, and again heat over the water bath until the salt begins to be deposited. Remove the mixture and cool with ice water or very cold liquid to ensure much of the zinc sulphate separating. Filter, re-dissolve the crystals in warm water (not exceeding 35° C.) to make a saturated solution, make slightly acid with H_2SO_4 (acidity of solution should not exceed 1 in 10,000), and again cool with ice water to separate the zinc sulphate. The latter crystals are filtered off, rinsed twice with cold water, and are then ready to use. Acid solutions must not be used.

3. Mercury.—This is prepared in the same manner as for the Weston cell.

4. Zinc Amalgam.—This is prepared in the same manner as for the Weston cell, except that slightly acid zinc sulphate solution is used as the electrolyte and a zinc rod as the anode. The final amalgam should contain 10 per cent of zinc.

5. The depolariser is a paste consisting of mercurous sulphate, fine globules of mercury, zinc sulphate crystals, and saturated solution of zinc sulphate. The mercurous sulphate is prepared in the same way as for the Weston cell, but to remove all traces of acid, saturated neutral zinc sulphate solution should be used as the washing liquid.

6. For setting up the cell the H form is the most suitable, but the platinum wire in the limb containing the zinc amalgam should be covered with a thin sheath of glass at least 4 mm. long (see *Fig.* 20 (*d*)). The general process of filling the cell is the same as for the Weston cell. Acid must be avoided.

7. The electromotive force of the Clark cell is

1·4326 international volts at 15·0° C.

and

1·4333 volts (10^8 C.G.S. units) at 15·0° C.

At any other temperature t between the limits 10° and 25° C. the electromotive force may be obtained from the equation

$$E_t = E_{15} - 0{\cdot}00119(t-15) - 0{\cdot}000007(t-15)^2.$$

§ (50) Specification for Weston Normal Cell.—1. The Weston normal cell is a voltaic cell which has a saturated aqueous solution of cadmium sulphate ($CdSO_4 \cdot 8/3H_2O$) as its electrolyte. The electrolyte must be neutral to Congo red.

1*a*. Cadmium sulphate crystals should be dissolved in hot water and the solution rendered basic by the addition of cadmium oxide and about 1 per cent of its volume of hydrogen peroxide. The mixture should be heated over a water bath for about four hours, after which the solution should be filtered,

[1] *Amer. Electrochem. Soc. Trans.*, 1908.

acidified slightly with H_2SO_4 and evaporated until its volume is reduced to about one quarter. The salt which has separated should be drained in a funnel, using a glass or platinum cone, and rapidly rinsed twice with cold water; it should then be dissolved at room temperature in a slight excess of water containing about 1 part in 10,000 of H_2SO_4, and after filtering, be set aside in crystallising dishes for the separation of cadmium sulphate crystals. The latter should be rinsed with cold distilled water. To make a saturated solution the crystals are to be powdered and agitated with the solvent for a long time.

For neutral solutions of cadmium sulphate the salt is dissolved in distilled water. For acid solutions the salt is finely powdered and dissolved in 0·1 normal sulphuric acid. No solution should be used until saturated.

2. The positive electrode of the cell is mercury.

2*a*. The simplest way to purify commercial mercury is to treat it electrolytically and afterwards distil it. Place the mercury in a large crystallising dish, and in the centre place a small dish or crucible of glass or porcelain also containing a little mercury. Over the mercury surfaces pour a sufficient quantity of a mixture of dilute sulphuric and nitric acids (90 of water, 5 of H_2SO_4, and 5 of HNO_3) to cover the top of the smaller dish at a depth of about 2 cm. Platinum wires sealed into glass tubes should make contact with the two lots of mercury, and a current of about half an ampere should be passed for two hours per 1000 grams of mercury, from the mercury in the large dish through the electrolyte to the mercury in the small dish. The mercury in the large dish should then be removed, washed and dried, and distilled *in vacuo*.

3. The negative electrode of the cell is cadmium amalgam, consisting of 12·5 parts by weight of cadmium in 100 parts of amalgam.

3*a*. The amalgam specified by the London Conference should not be used. An amalgam consisting of 10 parts by weight of cadmium in 100 parts of amalgam should be substituted.

To prepare the amalgam, deposit cadmium on mercury by electrolysis. Place a small dish containing a weighed quantity of mercury in a large crystallising dish, and add sufficient dilute slightly acid cadmium sulphate solution to cover the top of the dish at a depth of about 2 cm. A platinum wire sealed in a glass tube should make contact with the mercury. A rod of commercial cadmium enclosed in a sheath of filter-paper has its lower end immersed in the solution. A current of about half an ampere should be passed from the cadmium to the mercury sufficiently long to ensure that more than one-tenth of the cathode is cadmium. The cathode mixture should be removed, melted over dilute H_2SO_4 (1 of acid to 20 of water), washed, and weighed. Sufficient mercury should then be added to make the cadmium content 10 per cent, the mixture being again heated and stirred to render homogeneous.

4. The depolariser, which is placed in contact with the positive electrode, is a paste made by mixing mercurous sulphate with powdered crystals of cadmium sulphate and a saturated aqueous solution of cadmium sulphate. The different methods of preparing the mercurous sulphate are described in the Notes. One of the methods there specified must be carried out.

4*a*. The Notes referred to in 4 described chemical and electrolytic methods of preparation. The simplest method is that of chemical precipitation.

Protonitrate of mercury is first formed by adding about 30 c.c. of concentrated nitric acid to 200 grams of mercury; when the action is over or nearly over, the resulting salt and solution is added to about 400 c.c. of warm dilute nitric acid (1 of acid to 40 of water). This acid solution of mercurous nitrate is filtered, and then run as a very fine stream into two litres of hot dilute sulphuric acid (1 of acid to 3 of water), the liquid being well stirred during the mixing. A small quantity of mercury is added to the dilute H_2SO_4 before running in the mercurous nitrate. The dilute acid should be prepared immediately previous to the precipitation, as its temperature is then suited for the precipitation of well-defined crystals of mercurous sulphate. The salt thus formed is washed two or three times by decantation with dilute H_2SO_4 (0·1 normal) and filtered. After several washings of the filtrate with 0·1 normal sulphuric acid it is washed several times with saturated cadmium sulphate solution. The latter is to be neutral if the electrolyte of the cell is to be neutral, but if the electrolyte is to be an acid one the cadmium sulphate solution is likewise acid. In the case of an acid electrolyte, the mercurous sulphate, after washing, is placed in a clean stoppered bottle together with some of the acid cadmium sulphate solution, some powdered cadmium sulphate crystals, and about its own weight of mercury. These are agitated in order to produce a uniform distribution of acid.

If the electrolyte is to be neutral it is desirable to have a large number of fine globules of mercury distributed throughout the paste. This result may be achieved by the violent agitation of the mercurous sulphate with mercury, powdered crystals of cadmium sulphate, and sufficient saturated cadmium sulphate solution to form a thick paste. After such agitation the paste is ready for making up a cell.

5. For setting up the cell, the H form is the most suitable. The leads passing through the glass to the electrodes must be of platinum wire, which must not be allowed to come into contact with the electrolyte. The amalgam is placed in one limb, the mercury in the other.

The depolariser is placed above the mercury and a layer of cadmium sulphate crystals is introduced into each limb. The entire cell is filled with a saturated solution of cadmium sulphate and then hermetically sealed.

5*a*. The platinum wires inside the cell are to be amalgamated by passing an electric current from a platinum anode through an acid solution of mercurous nitrate to each of the wires as cathode. Afterwards, the vessel should be washed out twice with dilute nitric acid and several times with distilled water; it should be dried in an oven. The cadmium amalgam is fused, and sufficient of it to cover one of the amalgamated wires completely is introduced into one of the limbs of the H vessel. Into the other limb of the vessel sufficient mercury is introduced to cover the amalgamated wire; then the paste, finely divided crystals of cadmium sulphate, and saturated cadmium sulphate solution are added in the order named by means of small pipettes with wide orifices. To the cadmium amalgam, lime, cadmium sulphate crystals and electrolyte are added. Whenever, in filling the cell, the materials accidentally come in contact with the part of the glass which is to be heated in sealing, it is first cleaned by wiping with filter paper slightly moistened with distilled water and then with dry paper.

When cells with acid electrolyte are set up it is desirable, after making a saturated solution of cadmium sulphate in 0·1 normal sulphuric acid, to add to this solution all the cadmium sulphate crystals it is intended to use in the solid form. The crystals should be finely powdered. The whole of the solution and some of the cadmium sulphate crystals (about $\frac{1}{5}$ of the volume of mercurous sulphate) should be added to the washed mercurous sulphate, and the whole agitated to ensure a uniform distribution of acid. After standing, the liquid should be poured off and filtered, leaving the mixed solid sulphates in the form of a thick paste ready to insert in the cell. The filtrate is added to the residue of cadmium sulphate crystals, and these are introduced in the cell in the manner already described.

§ (51) E.M.F. of Weston Normal Cell.—The electromotive force of the Weston normal cell is

1·0183 international volts at 20·0° C.

and

1·0188 volts (10^8 C.G.S. units) at 20·0° C.

At any other temperature t between the limits 0° and 40° C. its electromotive force may be obtained from the equation

$$E_t = E_{20} - 0{\cdot}0000406(t-20) - 0{\cdot}00000095(t-20)^2 + 0{\cdot}00000001(t-20)^3.$$

Acid cells containing electrolyte made by dissolving $CdSO_4{\cdot}8/3H_2O$ in 0·1 normal sulphuric acid have a lower electromotive force by 62 microvolts.

Weston normal cells with neutral cadmium sulphate solutions have been set up in most countries. The electromotive force in international volts has been determined in England, the United States, Holland, Japan, Germany, and Russia. The mean value is 1·01827 international volts at 20° C. In 1910 the value 1·0183 international volts at 20° C. was recommended for universal adoption by Lord Rayleigh's Committee on Electrical Units and Standards. As previously stated, Weston cells set up with neutral electrolyte often remain constant for many years, but cells containing electrolyte made by dissolving cadmium sulphate in 0·1 normal sulphuric acid are much more constant. Clark cells if set up with care are even more reliable, but suffer the disadvantage of a large temperature coefficient.

Bronson and Shaw[1] found the ratio of the E.M.F. of the Weston normal cell at 25° C. to that of the Clark cell at 25° C. to be 0·71696.

Use of, as Detecting Instrument in Alternating Current Measurements. See "Inductance, The Measurement of," § (25).

ELECTROLYSIS: the decomposition of a conducting medium—usually a liquid—by the passage of an electric current. See "Electrolysis and Electrolytic Conduction," § (1) *et seq.*

Earliest Systematic Study of, made by Faraday. See *ibid.* § (1).

Experimental Results. These are found to be in accord, in certain particular cases, with the relation

$$\left(\frac{\lambda}{\lambda_\infty}\right)^2\left(\frac{N}{1-(\lambda/\lambda_\infty)}\right)=K,$$

where N is the number of gramme molecules per unit vol., λ the conductivity per equivalent per c.c., and K a dissociation constant; but there are many electrolytes for which the relation between λ and N is not that predicted by this formula. See *ibid.* § (9).

Faraday's Electrolytic Constant: the quantity F, the same for all ions, in the expression of Faraday's laws of electrolysis in the form $w=(W/nF)q$, where w is the weight in grammes of the ion deposited upon the electrode during the passage of q coulombs, W is the chemical atomic weight of the element from which the ion is derived (if it is elementary, or the group weight if it is complex), and n its chemical valency. The value of F is found by experiments upon an electrolyte for which the experimental data can be fixed with the greatest precision; within 1 part in 1000 F = 96,500 coulombs. See *ibid.* § (2).

Faraday's Laws of. The weight of the deposit upon either electrode during electrolysis is directly proportional to the quantity of electricity passed through the electrolytic cell, and also to a quantity known as the "electro-chemical equivalent" of the substance deposited. See *ibid.* § (2).

ELECTROLYSIS AND ELECTROLYTIC CONDUCTION

§ (1) INTRODUCTORY.—When an electric current passes through a metallic conductor there is no obvious change in the composition of the conductor either where the current enters or leaves, or indeed in any part of the conductor through which the current flows. It is otherwise when the conductor is an "electrolyte," for example a solution of a salt in water. In this case the conduction of the current is accompanied by the convection of material substances, parts of the electrolyte, which are frequently deposited upon the metallic "electrodes" by which the current enters and leaves the solution.

The deposit upon one electrode is different from that on the other, so that two currents of matter, flowing in opposite directions, accompany the passage of electricity through the solution.

The earliest systematic study of electrolysis was made by Faraday. It was through his work that the terms "anode" and "cathode," "anion" and "cation," came into use. The anode is the metallic conductor at which the current enters the electrolyte, and the cathode is that at which it leaves. The anion is the constituent of the electrolyte which migrates towards the anode, and the cation that which migrates towards the cathode.

The electrolytes with which we shall be concerned almost exclusively in this article are those in which the solvent is water. Perfectly pure water is a very feeble conductor of electricity. According to Kohlrausch, its conductivity at ordinary temperatures is about $0 \cdot 04 \times 10^{-6}$ ohm.$^{-1}$ cm.$^{-1}$ (cf. Washburn and Weiland, *Am. Chem. Soc. J.*, 1918, xl. 106, 131). Special precautions are, however, required in order to obtain water of this purity. The conductivity of ordinary carefully distilled water is usually thirty or forty times as great, say, from 1 to 2×10^{-6} ohm.$^{-1}$ cm.$^{-1}$.

Small quantities of dissolved substances produce large increases of conductivity. For example, the conductivity of a solution containing 1·5 parts by weight of KCl dissolved in 10,000 parts of water is about 250×10^{-6} ohm.$^{-1}$ cm.$^{-1}$. In this case, as in many others, the added substance has no appreciable conductivity before it is dissolved.

§ (2) FARADAY'S LAWS.—Faraday showed that the weight of the deposit upon either electrode during electrolysis is directly proportional to the quantity of electricity passed through the electrolytic cell, and also to a quantity known as the "electro-chemical equivalent" of the substance deposited.

The laws which he established can be expressed by the equation

$$w=\frac{W}{nF}q,$$

where w is the weight in grammes of anion deposited upon the anode, or of cation deposited upon the cathode, during the passage of q coulombs. In this equation the electro-chemical equivalent, or the deposit

per coulomb, is written in the form W/nF, in order to show how it depends upon the chemical properties of the substance deposited. W is the chemical atomic weight of the element from which the ion is derived (if it is elementary, or the group weight if it is complex), and n is its chemical valency; while F is a quantity, the same for all ions, known as the Faraday electrolytic constant.

Assuming the truth of Faraday's laws, the value of the electrolytic constant can be found by experiments upon any electrolyte; but preferably, of course, upon one for which the experimental data can be fixed with the greatest precision. If for silver we take $w/q=0{\cdot}0011183$ gramme per coulomb and $W/n=107{\cdot}88$ we get for F the value 96,470. For most practical purposes F can be taken as 96,500 coulombs.

§ (3) Theoretical Interpretation.—Faraday's laws are the result of direct experiment, and refer only to what happens at the electrodes; but they suggest a theory as to what happens within the solution. Thus suppose we take the case of a dissolved salt, say MA, which when electrolysed deposits the metal M at the cathode and the acid radicle A at the anode. Let us suppose also, for simplicity, that the chemical valencies of M and A are the same and each equal to n, and that their atomic weights are m and a respectively.

The experimental fact is that one gramme molecule ($m+a$ grammes) of the salt is electrolysed when nF coulombs of electricity are passed through the solution.

We may represent this fact by stating that m grammes of the metal carry $+nF$ coulombs of electricity with them from the solution to the cathode, during deposition, and that a grammes of the acid ion carry $-nF$ coulombs with them from the solution to the anode.

We may extend this result, hypothetically, to the interior of the solution and say that every m grammes of the metal taking part in the electrolytic conduction carry the charge $+nF$ coulombs, while every a grammes of the acid radicle taking part carry the charge $-nF$ coulombs.

In order to account for such charges on the ions we may suppose that originally every molecule of the substance MA is electrically neutral, but that the forces which bind together the basic radicle M and the acid radicle A are, partly at least, of electrostatic origin; so that when the components of the molecule separate they carry with them equal and opposite charges.

§ (4) Ionisation.—Granting the existence of such oppositely charged ions in solution, we see at once why there should be two currents of matter, in opposite directions, when an electromotive force is applied; but it still remains to account for their presence.

The "ionisation," as it is called, must be either a spontaneous effect accompanying solution or an effect produced by the electric field which causes the current to flow. If it were the latter, electrolytic conduction would not, as it does, obey Ohm's law. For the strength of the current must obviously depend upon the number of molecules split up at any moment and also upon the rates at which the separated portions move. The latter clearly depend upon the applied electromotive force, and if, by hypothesis, the former does also, then the current could not, in general, be proportional to the first power of the electromotive force, *i.e.* Ohm's law could not apply.

We are compelled, therefore, to turn to the other hypothesis, namely, that the ionisation is spontaneous and results from solution.

We have here to discriminate between various possibilities. Thus the ionisation may be complete or it may be partial. All the molecules or only a fraction of them may be ionised. In the latter case the ionisation may be permanent or it may be intermittent. It may be always the same molecules that are split up or merely the same fraction of the total number.

Later we shall see how far it is possible to decide between these different possibilities.

§ (5) Calculation of Conductivity.—Assuming the existence of ionisation, we can find a quantitative expression for the conductivity of a solution. For this purpose it is unnecessary to know the actual weights of the charged particles. It is sufficient (keeping to the case already considered) to assume only that the masses m and a grammes carry the charges $\pm nF$ coulombs. For convenience, such masses with their associated charges are called "gramme ions."

Suppose the solution to contain p grammes of a substance whose molecular weight is q dissolved in a volume r c.c. of the solution. The number of gramme molecules per unit of volume is then $N=p/qr$. Suppose that of this number the fraction αN is ionised and that each gramme molecule splits into two gramme ions of valency n carrying equal and opposite charges $\pm nF$ respectively. When a potential gradient is applied these ions will begin to move. The manner in which they move and their average velocities while under the influence of the electric field can be regarded from different points of view which lead to the same result, namely that the velocities are proportional to the potential gradient. Hence, if u_0 and v_0 denote the velocities of the cation and anion (in cms. per sec.) under unit potential gradient (1 volt per cm.), the velocities under any potential gradient dE/dl will be u_0dE/dl and v_0dE/dl respectively.

Across any small area S, within the solution at right angles to the direction in which the current is flowing, at which the potential gradient is dE/dl, the current (in amperes) will be

$$\alpha N(u_0 + v_0)\frac{dE}{dl}SnF.$$

This result is obtained by regarding the current as the sum of (1) a flow per sec., across S in one direction, of $+\alpha Nu_0(dE/dl)SnF$ coulombs, and (2) a similar flow, in the opposite direction, of $-\alpha Nv_0(dE/dl)SnF$ coulombs.

But, if Ohm's law holds, another expression for the current will be $\kappa SdE/dl$, in which κ is the conductivity of the solution, *i.e.* the reciprocal of its resistivity.

Hence, by comparison,

$$\kappa = \alpha N(u_0 + v_0)nF.$$

The physical significance of this formula is obvious, for it is merely an expression of the fact that, if we grant the ionisation hypothesis, the conductivity of a solution must be directly proportional to the concentrations of the ions, to the sum of the velocities with which they move, and to the charges which they carry.

In deducing the formula we have, for simplicity, assumed the oppositely charged ions to be of equal valency n; but it can easily be shown that the same expression holds generally.

[If the ions are of unequal valencies n_1 and n_2, the formula of the substance will be M_xA_y, in which $n_1x = n_2y = n$. For example, in ferric sulphate $Fe_2(SO_4)_3$, the value of n for the conductivity equation is 6.]

§ (6) Equivalent Conductivity.—By transposition from the conductivity equation we get

$$\kappa/nN = \alpha(u_0 + v_0)F.$$

As we have seen, n is the aggregate valency of each part of the molecule. Each gramme molecule may be said to contain n equivalents. In this sense nN represents the number of equivalents in unit volume of the solution and κ/nN is the conductivity per equivalent per c.c. It is called the "equivalent conductivity" of the solution, and is usually denoted by the symbol λ. It is a quantity of great interest in connection with the ionic theory, since its magnitude, according to that theory, depends only upon the values of the ionic velocities and of α, the "coefficient of ionisation."

§ (7) Variation of Conductivity with Concentration.—The relation between the conductivity and the concentration has been carefully examined for many electrolytes, much of this work having been carried out by Kohlrausch (see *e.g.* Kohlrausch and Holborn, *Leitvermögen der Elektrolyte*, Teubner, Leipzig, 1898). Some general results may be indicated. Solutions of inorganic acids are, as a rule, the best conductors. After these come solutions of the alkalis and finally solutions of salts. In every case the conductivity increases with the concentration at first; but the rate of increase decreases afterwards and, in the case of very soluble substances, the conductivity passes through a maximum value—usually when the solution strength is somewhere between 4 and 6 gramme equivalents per litre.

The relation between the equivalent conductivity and the concentration has also been the subject of careful study, particularly in the case of dilute solutions. For these, in every case, the equivalent conductivity increases with dilution, the rate of increase becoming very rapid in very weak solutions. If, however, the value of λ be plotted against the cube root of the concentration it is found that, in most cases, a nearly linear relationship obtains when the concentration is small. In such cases the limiting value of λ when the concentration is infinitely small would appear to be given very approximately by the equation

$$\lambda = \lambda_\infty - aN^{\frac{1}{3}},$$

where λ_∞ is the "equivalent conductivity at infinite dilution," λ being the equivalent conductivity when the concentration is N and a a constant peculiar to each electrolyte but often not varying much from one electrolyte to another. Naturally, in these very dilute solutions, the question of the purity of the solvent becomes of great importance.

§ (8) The Variation of the Equivalent Conductivity.—The fact that the equivalent conductivity increases with dilution means that $d\lambda/dN$ is negative, and hence, according to the expression for λ already given, that $\{\alpha d(u_0+v_0)/dN + (u_0+v_0)d\alpha/dN\}$ is negative. If so, one at least of the differential coefficients $d(u_0+v_0)/dN$ and $d\alpha/dN$ must be negative, *i.e.* either the ionic velocities or the coefficient of ionisation must increase as the solution becomes more dilute. The latter alternative is the more probable cause of the variation; the position with respect to the former is less certain. It is known, for example, that the temperature coefficient of the resistance of very dilute solutions is almost identical with that of the viscosity of water. This is what would be expected if the velocities of the ions determined the conductivity and were inversely proportional to the viscosity of the solvent. Under such circumstances we might expect that in dilute solutions we should have $d(u_0+v_0)/dN = 0$. On the other hand, evidence is not wanting in support of the view that the ions are "hydrated," *i.e.* that they move through the solution, not

alone, but accompanied by molecules of the solvent. It may be that the number of these attached molecules increases with dilution. In that case the velocity of the ion would diminish at the same time, *i.e.* du_0/dN or dv_0/dN, or both, would be positive. It is sometimes assumed that u_0 and v_0 are proportional to the viscosity of the solution; $d(u_0+v_0)/dN$ would then be negative.

If it be assumed that $d(u_0+v_0)/dN$ is very small in the case of dilute solutions, the negative value of $d\lambda/dN$ must, if the expression for λ is correct, be due to the negative value of $d\alpha/dN$. It is not difficult to find reasons why $d\alpha/dN$ should be negative. Of these the most direct is that based upon the "law of mass action." We assume a tendency of the molecules to break up either spontaneously through some inherent instability or in consequence of collisions with other molecules. Of the molecules taking part in such collisions with a molecule of the solute, those of the solvent would be by far the most numerous, so that the number of effective collisions per second would be practically proportional to the number of solute molecules present in each unit of volume. Hence, whether the dissociation be spontaneous or due to collisions, we should expect the amount taking place per second to be proportional to the concentration of the undissociated molecules. On the other hand, the number of recombinations per second, between separated ions, would be proportional to the product of the concentrations of the separated parts. In the steady state, if α is the coefficient of ionisation, the concentrations of the undissociated and dissociated portions will be $N(1-\alpha)$ and αN respectively. The rate of decomposition, being proportional to $N(1-\alpha)$, can be written $k_1N(1-\alpha)$. Similarly the rate of recombination, being proportional to $(\alpha N)^2$, can be written $k_2(\alpha N)^2$. These rates must be equal. Hence

$$(\alpha N)^2 = k_1N(1-\alpha)/k_2 = KN(1-\alpha),$$

where K is a "dissociation constant," depending upon the nature of the solute, and probably also upon the properties (*e.g.* the dielectric constant) of the solvent.

From this result, which may be written $\alpha^2N/(1-\alpha)=K$, and which is known as "Ostwald's dilution law," it follows that α must increase as N diminishes, *i.e.* that $d\alpha/dN$ must be negative. It remains to examine whether the observed relation between λ and N corresponds with the theoretical relation between N and α. From the expression for λ already deduced, it follows that

$$\lambda/\lambda_\infty = \alpha(u+v)/\alpha_\infty(u_\infty+v_\infty),$$

in which α_∞, the value of α at infinite dilution (N=0), must in accordance with the dilution law be equal to unity. Hence, if we assume

$$u+v=u_\infty+v_\infty,$$

we get $$\lambda/\lambda_\infty=\alpha,$$

and hence

$$(\lambda/\lambda_\infty)^2N/(1-\lambda/\lambda_\infty)=K.$$

[If we assumed

$$(u+v)/(u_\infty+v_\infty)=\eta_\infty/\eta,$$

where η_∞ and η are the coefficients of viscosity of the solvent and solution, we should get $\eta\lambda/\eta_\infty\lambda_\infty=\alpha$ with a corresponding change in the equation connecting λ and N.]

§ (9) Experimental Results.—The relation thus deduced has been tested very thoroughly. It is found to give results in accord with experiments in certain particular cases. For instance, for solutions of various organic acids and bases. These are characterised by relatively low values of α at moderate dilutions and form the class known as "weak electrolytes." But there are many electrolytes for which the relation between λ and N is not that predicted by the dilution formula. These include the solutions of most of the inorganic acids, bases, and salts. They are characterised as a class by the fact that the calculated values of α are relatively high and are known as "strong electrolytes." For these, as a rule, the value of $(\lambda/\lambda_\infty)^2N/(1-\lambda/\lambda_\infty)$, instead of being constant, is much larger when N is large than when N is small.

§ (10) The "Abnormality of Strong Electrolytes."—Many attempts have been made to find the cause of this discrepancy, and various formulae have been devised with the object of finding one which shall fit the facts more closely than the simple formula already given. As a rule, it is assumed that the equation $\alpha=\lambda/\lambda_\infty$ is probably not seriously in error. In that case the object is to explain why $(\alpha N)^2/(1-\alpha)N$, instead of remaining constant, increases as N increases. The expression $(\alpha N)^m/(1-\alpha)N$ would obviously increase less rapidly than $(\alpha N)^2/(1-)\alpha N$, as N increased, if m were less than 2. It was found (van't Hoff) that, taking $m=3/2$, this expression is approximately constant over a considerable range for many strong electrolytes.

Reverting to the original argument (§ (8)), even if the rate of ionisation depends upon the concentration of the un-ionised molecules, there is no certainty that the factor k_1 will not increase as N increases. In the absence of exact knowledge of the mechanism of ionisation it may be possible, for example, that the ionised parts of the molecules already dissociated influence the conditions of ionisation of the others. In order to allow for this possibility, an equation

$$\alpha^2N/(1-\alpha)=K+k(\alpha N),$$

where k is an additional constant, has been derived (Larmor, Partington). An empirical modification of this is

$$\alpha^2N/(1-\alpha)=K+k(\alpha N)^m,$$

which has been found (Kraus and Bray) to be applicable to solutions of strong electrolytes in many solvents other than water. An analogous equation

$$\alpha^2N/(1-\alpha)=K+k\{(1-\alpha)N\}^m$$

has also been suggested (Szyszkowski), on the ground of evidence which supports the view that the un-ionised molecules themselves exert an influence upon the ionisation.

It should be remarked that the dielectric constant of the medium, whether modified or not by the presence of the solute, may be expected to influence the degree of ionisation. For if the forces which bind the components of the molecule together are in part of electrical origin, a molecule will stand a greater chance of ionisation, under any disruptive influence, in a medium of which the dielectric constant is large than in one of which the constant is small (J. J. Thomson, Nernst). Much successful work in connection with this view has been done by Walden.

With respect to the causes of disruption it has been suggested (Perrin) that the origin of the instability of undissociated molecules is the absorption of external radiation rather than impacts with other molecules.

Returning to the equation

$$\alpha^2N/(1-\alpha)=K+k(\alpha N)^m,$$

it has been pointed out (Arrhenius) that for weak electrolytes in water k may be small enough to be negligible. For strong electrolytes, on the other hand, K may, except for extremely high dilutions, be negligible. Under such circumstances, taking $m=\frac{1}{2}$, we obtain van't Hoff's equation which agrees with experience. On the other hand, very dilute solutions of strong electrolytes would obey Ostwald's law if $k(\alpha N)^m$ were then negligible compared with K. The experimental evidence seems to agree with this view (Arrhenius, Weiland).

§ (11) Inter-ionic Forces.—Many workers have attempted to find, in the electric forces between charged ions, an explanation of the deviations of strong electrolytes from the simple dilution law. In connection with this, it is to be remembered (Arrhenius) that some weak electrolytes obey the law even when their ionic concentrations are greater than those of strong electrolytes which do not. Nevertheless a great deal of interesting work has been done from this point of view, *e.g.* by Jahn, Nernst, Sutherland, Milner, Ghosh, and others. The most recent contributions are those of Milner (*Phil. Mag.*, 1918) and Ghosh (*Chem. Soc. J.*, 1918). Each adopts the view previously taken by others (*e.g.* Sutherland), that strong electrolytes are completely ionised at all concentrations. Milner ascribes the decrease in equivalent conductivity with increasing concentration mainly to a reduction in the average mobilities of the ions in consequence of inter-ionic forces which increase the frequency of their effective association. Ghosh's work has attracted attention, partly because of the method by which he arrives at the conclusion that a certain fraction only of the ionised molecules is unrestrictedly free to move under the influence of a potential gradient, and partly because of the evidence that his theory fits the facts better than any other that has been proposed. Information with respect to these, and other contributions to the problem presented by the "abnormalities of strong electrolytes," will be found in a recent discussion of the present position of the theory of ionisation (*Faraday Soc. Trans.*, 1919, xv. pt. 1), which contains references to nearly all the important papers upon this subject.

§ (12) Average and Individual Ionic Velocities.—The conductivity equation already given (§§ (5), (6)) can be written

$$\lambda/F=\alpha(u_0+v_0)=\alpha u_0+\alpha v_0.$$

This equation might have been deduced directly in the form

$$\lambda/F=u+v,$$

where u and v are the effective velocities of the ions, *i.e.* the average velocities in cms. per sec. per volt per cm. at which the oppositely charged components of the dissolved molecules move when conduction is taking place. For, upon the hypothesis of intermittent ionisation, all the molecules take part in the conduction process, although not all at the same time, and the effective velocities which determine the current or the conductivity are the average velocities of all the molecules concerned, *i.e.* of all the molecules dissolved.

The quantities αu_0 and αv_0 of the previous argument are thus equivalent to the average velocities of the components of the N gramme molecules dissolved in each unit of volume of the solution, and could have been replaced by u and v as above.

Whichever mode of presentation be adopted, the conductivity is represented as the sum of two terms, one depending upon the cation and the other upon the anion.

If we assume that, at infinite dilution, the solute is completely ionised, every ion will be effective in current conduction at any instant. The effective velocities of the ions will then be their actual velocities. Hence ($\alpha=1$), we should have

$$\lambda_0/F=\lambda_0\times1\cdot036\times10^{-5}=u_0+v_0.$$

As an example we may take the case of the chlorides KCl, NaCl, and LiCl. For these, in round numbers, the values of λ_∞ in ohm.$^{-1}$ cm.$^{-1}$ per gramme equivalent per c.cm. are 130, 110, and 101. Whence the values of u_0+v_0 in cm. per sec. for 1 volt per cm. are approximately $1{\cdot}34\times10^{-3}$, $1{\cdot}14\times10^{-3}$, and $1{\cdot}05\times10^{-3}$. The velocities of the ions are thus of the order 1/1000th cm. per sec. under unit potential gradient; but, since (u_0+v_0) is not the same for the different salts, the velocity of an ion must depend upon its chemical constitution. Hence, although conductivity data may serve to give the sum of the ionic velocities, they are not sufficient by themselves to give the separate velocities of the different ions.

§ (13) Ionic Velocity-ratio by "Migration" Methods.—The additional experimental information necessary before single velocities could be determined was first obtained by a method due to Hittorf, who showed, in effect, how the ratio of the ionic velocities could be found.

If, when a current is passed through an electrolyte MX, the products of electrolysis M and X escape or are deposited at the electrodes, it is obvious that the total quantity of MX contained in the solution must decrease continuously. As a general rule it is found that the changes in concentration are confined for some time (diffusion being minimised as much as possible by the arrangement of the apparatus) to the regions surrounding the electrodes, *i.e.* the weakening of the solution spreads from the electrodes outwards into the solution.

What happens in such experiments can be regarded in the following way. Suppose that the current is flowing uniformly between two parallel electrodes A and C and that the electrolyte contains αN ionised molecules per unit volume. Let u be the velocity of the cations and v the velocity of the anions under the gradient causing the flow. Then across any section in the interior of the electrolyte at right angles to the current there will pass per unit area, in the unit of time, αNu cations in the direction from A towards C and αNv anions in the direction from C towards A.

The current passing per unit area will be $\alpha N(u+v)nF$, and in the unit of time, by Faraday's laws, if we consider unit area of each electrode, $\alpha N(u+v)$ cations must pass over from the electrolyte to the electrode C, and in the same way $\alpha N(u+v)$ anions must pass over into the neutral state at the electrode A.

It is obvious that into any space, bounded by two perpendicular sections of the current stream, within the interior of the solution, the number of ions of one kind which enter through one section in the unit of time will be identical with the number leaving through the other. Consequently, within such portions of the solution there will be no changes in concentration during the passage of the current.

Consider, however, an imaginary section in the immediate neighbourhood of either electrode, *e.g.* the cathode.

Across this inwards, in the unit of time, there will pass αNu cations which are in motion owing to the potential gradient. But the total number of cations leaving by the cathode in the unit of time is greater than this, namely $\alpha N(u+v)$.

Thus αNv cations must move out of solution at the cathode, along with the αNu cations brought up by the current. These must come from the cathode region. The αNv anions left unpartnered by them are carried away by the current to take the place of other anions, since, as already seen, there is a drift towards the anode, across every unit area, of αNv anions per unit of time.

In the unit of time, therefore, there must ionise, in the immediate neighbourhood of the cathode, a sufficient number of molecules to give at least αNv positively charged cations and αNv negatively charged anions. The former go out with the αNu cations brought up by the current. The latter are carried away under the influence of the potential gradient. It is thus the molecules which split up in the immediate neighbourhood of the cathode that are "lost" by the cathode region.

As a result, when $\alpha N(u+v)$ cations leave at the cathode, αNv molecules leave the portion of the solution near the cathode, and, in an exactly similar way, when $\alpha N(u+v)$ anions leave at the anode, αNu molecules leave the portion of the solution near the anode.

Hence, αNv molecules leave the cathode space and αNu molecules leave the anode space when, by electrolysis, $\alpha N(u+v)$ molecules of dissolved substance leave the solution. Thus, in this case, the ratio "cathode loss"/"anode loss" would, if measured, give the ratio v/u of the ionic velocities.

It frequently happens that, owing to chemical action, measurement of the "anode loss" is not practicable. The ratio of the ionic velocities cannot then be determined in the way just described. For example, when electrodes of some particular metal are used, and the electrolyte is a salt of that metal, the metal itself is deposited upon the cathode, but the acid radicle is not deposited at the anode. Instead, the metal of the electrode enters the solution. In this case the current is carried over from the anode to the solution by metallic ions only, just as it is from the solution to the cathode, and therefore, by Faraday's laws, the amount of metal entering at the anode must be exactly equal to that leaving at the cathode. The total quantity of salt in solution therefore remains constant.

There is now no "anode loss"; but, instead, an "anode gain" equal in amount to the "cathode loss."

Fortunately, however, the ratio of the ionic velocities can always be found without reference to what occurs at the anode. It is sufficient to compare the cathode loss of salt with the total deposit at the cathode. Thus, returning to the case considered above, the ratio of the weight of metal deposited at the cathode to the weight of metal contained in the salt molecules carried away from the cathode space is represented by the expression $\alpha N(u+v)/\alpha Nv=(u+v)/v$. Hence, if each of them is measured, the ratio $v/(u+v)$ called by Hittorf the "migration constant" for the anion or, alternatively, its "transport number," can be determined. The weight of the cathode deposit can be measured either directly or by measurement of the total quantity of electricity passed through the solution (if the electro-chemical equivalent of the metal be known) or by means of a silver voltameter in series with the cell in which the electrolysis occurs. The cathode loss is measured by comparing the salt content of the solution round the cathode at the end of the experiment with the known salt content at the beginning. In the latter measurement allowance has, in general, to be made for the change in volume accompanying dilution.

It is impossible here to enter into any detail concerning the results of measurements made in this way.

As an example of their application, however, we may take the case of the three chlorides already cited. For these in very dilute solutions the values of $v/(u+v)$, again in round numbers, are 0·5, 0·6, and 0·65 respectively. With the values of (u_0+v_0) already mentioned these give for the value of v_0, the velocity of the chlorine ion, $0{\cdot}67\times10^{-3}$, $0{\cdot}68\times10^{-3}$, and $0{\cdot}68\times10^{-3}$ cm. per sec. respectively, and for the velocities of K, Na, and Li, the values of $0{\cdot}67\times10^{-3}$, $0{\cdot}46\times10^{-3}$, and $0{\cdot}37\times10^{-3}$ respectively.

The measurements upon less dilute solutions treated in a similar way give corresponding results. Thus for solutions containing one-tenth of a gramme molecule per litre, the values of $\alpha(u_0+v_0)$ are $1{\cdot}159\times10^{-3}$, $0{\cdot}958\times10^{-3}$, and $0{\cdot}859\times10^{-3}$ respectively. The corresponding values of $v/(u+v)$ are 0·508, 0·617, and 0·69; whence the values of αv_0 work out at $0{\cdot}588\times10^{-3}$, $0{\cdot}592\times10^{-3}$, and $0{\cdot}593\times10^{-3}$ respectively.

In other cases, particularly of relatively concentrated solutions, the results obtained are not so easily interpreted as those just given. These are none the less of great value, as showing that the ions are not always of the simplest possible type. To cite one striking example from Hittorf's work, concentrated solutions of CdI_2 give values for $v/(u+v)$ which are greater than unity. This suggests that the iodine ions carry with them molecules of the undissociated salt, or perhaps that the cadmium ions carry with them molecules of the solvent. In any case, such results yield one of the many reasons for supposing that complex ions exist. The frequent variation of the value of the migration constant with the concentration of the solution is another indication of the same thing.

§ (14) Direct Determination of Ionic Velocities.—The method of finding values for the effective velocities of the ions by combination of conductivity and migration data is not the only one available, as was first pointed out by Sir Oliver Lodge (*B.A. Report*, 1886). He devised and made use of another method, subsequently extended by Whetham, Masson, Steele, and others. We can only refer to it very briefly. It is a direct method depending in its final forms upon the determination of the velocities of moving boundaries between different electrolytes in series. For instance, to take an example from Masson's work, the electrolytes in series were solutions of copper sulphate, sodium chloride, and potassium chromate, and the current was passed in the direction from the blue sulphate solution through the colourless chloride solution to the yellow chromate solution. Under these circumstances the sodium ions move in one direction, followed by the copper ions, while the chlorine ions move in the opposite direction, followed by the chromate ions. It is essential, if the sharpness of the boundaries between the solutions is to be preserved during the passage of the current, that the following ion should be slower than the ion which precedes it. This condition is satisfied in the present case, because sodium ions move faster than copper ions, and chlorine ions move faster than chromate ions. In the experiment the boundary between the blue solution and the colourless solution moves, let us say, from left to right, while that between the yellow solution and the colourless solution moves from right to left. The velocities of movement give the average velocities of the sodium and chlorine ions under the same potential gradient. This gradient can be determined from a knowledge of the strength of the current passing, of the diameter of the tube containing the salt solution, and of the conductivity of the latter. Hence it is possible to determine αu_0 and αv_0. The value of u/v, and hence of $v/(u+v)$, can of course be determined by direct comparison of the rates of movement of the two boundaries if the containing tube be of uniform bore. Steele extended the applicability of this method by showing that difference of refractive index could be used instead of colour as a means of fixing the boundaries between

the main electrolyte and the indicating solutions.

Results have been obtained in this way in excellent accord with those obtained by the method first described (cf. *e.g.* Denison and Steele, *Roy. Soc. Proc.*, 1905). In the case of the more concentrated solutions, however, there is often a considerable divergence between the value of $v/(u+v)$ found by Hittorf's method and that found by the method just described. It has been suggested (by Nernst and others) that a possible cause of this divergence is the hydration, to different degrees, of ions of different kinds (for references to some of the literature, see a paper by the present writer, *Phys. Soc. Proc.*, 1916, xxviii. 327 *et seq.*). The problem has been examined from this point of view by Washburn (*l.c.*). From his experiments with the three chlorides already mentioned he deduced, for example, that the degree of hydration increases from K to Li. This result accords with what might be expected on chemical grounds. The probability that hydration is the cause of the observed decrease in ionic velocity in the order from K to Li is increased by the fact that the atomic volumes are in the inverse order, and would lead us to anticipate that but for hydration the order of the ionic velocities would be Li > Na > K. In agreement with this, the rates of diffusion of the metals in a medium, mercury, in which hydration cannot arise are in the order Li > Na > K. Washburn shows also how, from his point of view, the different values of $v/(u+v)$, obtained by the two methods, can be reconciled.

The effect of hydration in experiments of this kind is a differential one, depending upon the relative degrees of hydration of the cation and anion. Attempts have been made (*e.g.* by Riesenfeld and Reinhold, *l.c.*) to find the degree of hydration in each case by assuming that the velocity is inversely proportional to the radius of the (spherical) ionic envelope under a given moving force. From such considerations it would appear, for example, that the H ion is unhydrated, while the K ion carries with it 22 molecules of water and the OH ion 11.

§ (15) Speculations with respect to the Actual Carriers.—Reference should perhaps be made to a method of deducing the radius of the ion, used by different investigators, which is of interest not only in connection with the previous paragraph but also in connection with the expression for the conductivity of an electrolyte derived in § (5). In finding that expression it was unnecessary to go beyond the gramme ion, *i.e.* beyond the fact that the total weight of the ions of a particular element which suffice to carry 96,500 coulombs is represented by its chemical equivalent in grammes. It was sufficient, for example, to know that 1 gramme of hydrogen ions carries approximately $0{\cdot}96\times10^5$ coulombs or $0{\cdot}96\times10^4$ electromagnetic units. We can, however, suppose that the actual carriers are charged atoms of hydrogen, and then, if the number of atoms contained in a gramme of hydrogen be known, we can deduce both the atomic mass and the atomic charge. The agreement between the various experimental estimates of the number of molecules in a gramme of hydrogen is not yet as perfect as it might be; but we may assume, provisionally, that one gramme contains about 6×10^{23} atoms. In that case the atomic charge will be $1{\cdot}6\times10^{-20}$ electromagnetic units, and the force on an ion carrying this charge in a field in which the potential gradient is 10^8 electromagnetic units (one volt) per cm. will be $1{\cdot}6\times10^{-12}$ dynes. Algebraically the mechanical force on the ion will be $f=edE/dl$, where e is the atomic charge and dE/dl is the potential gradient. The inference with respect to the behaviour of the ion under the action of this force depends upon the assumption made as to the conditions of its motion. If we assume that the motion can be likened to that of an isolated sphere moving through a viscous medium, subject to a resistance proportional to its velocity, the equation of motion will be

$$f-kv=mdv/dt,$$

where k is a constant and m is the mass of the ion. If we assume that Stokes' law applies, the value of k will be $6\pi\eta r$, where η is the coefficient of viscosity of the medium and r is the radius of the ion, assumed spherical. The solution of the equation of motion is

$$v=\frac{f}{k}\left(1-\epsilon^{-\frac{k}{m}t}\right),$$

from which it follows that the time which elapses before the velocity becomes constant is the time taken by $\epsilon^{-\frac{k}{m}t}$ to become vanishingly small. The steady velocity $(dv/dt=0)$ will be $\bar{v}=f/k$, whence

$$6\pi\eta r\bar{v}=edE/dl.$$

If we take the value of $\bar{v}$ to be $3{\cdot}2\times10^{-3}$ cm. per sec., the estimated value of u_0 for hydrogen in very dilute solution, at 18° C., and the value of η to be 0·011, the coefficient of viscosity of water at the same temperature, we get

$$\begin{aligned} r&=(1{\cdot}6\times10^{-12})/(6\pi\times{\cdot}011\times3{\cdot}2\times10^{-3})\\ &=2{\cdot}4\times10^{-9}\text{ cm.}\end{aligned}$$

Under these circumstances the value of k/m, which is equal to $6\pi\eta r/m$, would be 3×10^{14}, and hence the time taken by the ion to acquire its steady velocity within 0·1 per cent would be given by

$$1000=\epsilon^{t\times3\times10^{14}},$$

i.e. by $\quad t=2{\cdot}3\times10^{-14}$ sec. approx.

For any other ion of valency n and ionic velocity v, relative to hydrogen, the radius calculated in the above way would be

$$r = 2\cdot4 \times 10^{-9} \times n/v \text{ cm.}$$

This analysis of the phenomena, based upon the applicability of Stokes' law, is not the only one that has been put forward. Another view, for example, is that the motions of the ions are controlled by collisions with other particles and that their velocities accelerate continuously between these collisions. Under such conditions the effective velocity would be a function of the mass of the ion instead of depending only upon its size, as it would if the view above described were correct. It is obvious, however, from the experimental data, that there is no simple relation between the velocity of an ion and its mass.

It may be noted in connection with the above estimate of the time required by the ion to acquire its steady velocity that there is no difficulty, on that view, of accounting for the fact that alternating currents of high frequency give the same value as continuous currents for the resistivity of an electrolyte.

§ (16) Polarisation.—We have been concerned, so far, mainly with what takes place in the solution itself when a current is passed through an electrolyte. Thus we considered first how the current is carried through the interior of the electrolyte, and second how the phenomena which occur near the electrodes can be interpreted. We come now to the consideration of what happens at the actual surfaces of separation between the electrolyte and the electrodes.

When an electromotive force is applied between the terminals of a cell in which the electrodes are composed of some metal M, and in which the electrolyte is some salt of that metal MA, a continuous current passes, however small the applied E.M.F. may be; but with this restriction: from the moment at which the E.M.F. is applied changes in the concentration of the electrolyte around the electrodes begin to occur in the way and for the reasons already described. And if the E.M.F. is kept applied for a sufficient time these concentration changes will become considerable. Concurrently, an appreciable counter E.M.F. will arise between the cell terminals and will cause the current to diminish. Only when the concentration of the solution is kept uniform, *e.g.* by stirring, will the current remain steady while the E.M.F. is applied.

This, however, is a particular case of electrolysis. We may consider first the more general case, in which the electrodes are composed of some other metal not chemically acted upon either by the salt MA (or the acid HA) or by the products of its decomposition. Thus, suppose we take the case of an electrolytic cell in which the electrodes are of platinum and the electrolyte is dilute sulphuric acid. We shall find that the phenomena to be observed are intimately connected with the magnitude of the applied E.M.F.

Suppose the cell, connected in series with a ballistic galvanometer, to form a branch circuit, between the ends of which, a and b, an E.M.F. of any desired magnitude can be applied. So long as this E.M.F. is small, what happens is as follows: on the completion of the circuit, there is an immediate throw of the galvanometer needle; but, after the oscillation has died down, the needle comes to rest very nearly in its zero position. There is thus an initial rush of electricity through the cell, which converts it into a kind of secondary "battery" having an electromotive force equal to that applied between a and b.

If the experiment be repeated with a greater E.M.F. the initial throw is increased. The final, steady deflection becomes greater at the same time. Eventually however, with increase in the applied E.M.F. beyond a fairly definite value (which depends in general upon the nature and concentration of the electrolyte and upon the electrodes), the final deflection of the galvanometer becomes rapidly larger. The counter E.M.F. no longer keeps pace with the applied E.M.F., and at the same time visible decomposition of the electrolyte ensues.

In experiments of this kind the electrolytic cell is said to have been "polarised." The passage of electricity through it has produced a "back electromotive force of polarisation" between the electrodes.

It will be seen that the existence of this phenomenon complicates the measurement of the ohmic resistance of electrolytes. For instance, in the case just considered, when a small E.M.F. is applied, the ratio of this E.M.F. to the final current is so large as to make the apparent resistance of the electrolyte extremely high. Yet it is obvious from the initial flow that, up to a point, electricity passes through it readily enough.

The phenomenon has been studied by many observers, particularly by Kohlrausch, in connection with the measurement of resistance.

It may be assumed as a first approximation that the back E.M.F. is proportional to the total quantity of electricity which has passed through the cell. In that case the relation between the applied E.M.F. E and the current i, at any instant during the brief interval of charging, would be given by

$$E = Ri + P\int_0^\tau i\,dt,$$

where R is the true resistance of the electrolyte, τ is the time elapsed since the E.M.F. was applied, and P is a "polarisation constant" for the given cell.

It is easy to picture an electrical arrangement which would give a charging equation of this type. For, suppose we take two condensers of capacities c_1 and c_2, connected in series by a wire of resistance R, and apply a potential difference E between the unconnected plates, the equation of charging will be

$$E = Ri + \left(\frac{1}{c_1} + \frac{1}{c_2}\right)\int_0^T idt,$$

identical with the previous equation if we replace $(1/c_1 + 1/c_2)$ by P.

Hence, by analogy we may liken the process which occurs, when electricity passes through an electrolytic cell, to the charging of a pair of condensers in series. We may suppose that when q units of electricity pass round the cell circuit, $+q$ units flow into the anode A and $-q$ units into the cathode C, and that, simultaneously, anions carrying $-q$ units come up to the surface separating the electrolyte from A, while cations carrying $+q$ units come up to the surface separating the electrolyte from C. We may suppose further that these charges remain apart in condenser-like layers at the electrode surfaces, the surface densities of the charges rising until the sum of the potential differences across the two layers is equal to the applied E.M.F. In order to make the analogy complete as far as it goes, we must, however, suppose that the electrolyte-electrode condensers are not quite perfect, that their charges leak away to some extent, so that a continuous supply of electricity is necessary if these charges are to be maintained. At first the required continuous supply, represented by the steady deflection of the galvanometer, is relatively very small; but it increases with the applied E.M.F., *i.e.* with the surface densities of the charges, and becomes relatively very large when the applied E.M.F. reaches the value required to produce visible decomposition. This final stage might be likened to the discharge which occurs in ordinary condensers, *e.g.* by sparking, when the potential gradient exceeds that which the dielectric can support.

The modifications which must be made in this view of polarisation phenomena will appear later. Our immediate object is to show how the resistance of an electrolyte can be measured in spite of their existence. For this, the above preliminary sketch of the phenomena will suffice.

§ (17) The Measurement of Electrolytic Resistance.—The methods of measurement can be divided broadly into two classes: in one the effects of polarisation are avoided, in the other they are reduced to a minimum.

Comparatively few methods belong to the first class. Theoretically, the best example is that in which the circuit is wholly electrolytic and the electromotive force is supplied by electromagnetic induction (cf. Guthrie and Boys, *Phil. Mag.*, 1880); but very few measurements have been carried out in this way. Another method which may be placed in this class is that in which auxiliary or potential electrodes are used, particularly when the potential drop is measured by an electrostatic voltmeter of negligible capacity. This method has been used occasionally and measurements with it have been described, *e.g.* by Bouty (1884) and Sheldon (1888). A particular form of it, devised by the writer (1899), in which mercury electrodes (which have certain advantages) are used, is described in Watson's *Text-Book of Practical Physics* (Longmans). Further applications of the method in which both continuous and alternating currents were used have been described by Smith and Moss (*Phys. Soc. Proc.*, 1913, xxv. 133). The same method has recently been used by Newbery with the object of testing the accuracy of Kohlrausch's measurements (*Chem. Soc. J.*, 1918).

An early example of the second class was that due to Horsford in which the electrolyte was contained in a vessel of uniform cross-section between parallel electrodes, each perpendicular to its length. This vessel was connected in series with a battery and galvanometer. A measurement of the current was taken with the electrodes at a distance d_1 apart. This distance was then reduced to d_2, and at the same time known resistances were inserted to maintain the current at its original value. On the assumption that the polarisation effects remained unchanged, the added resistance was equal to that of a column of the electrolyte of length $d_1 - d_2$. This method is only reasonably accurate when the polarisation is relatively small, *e.g.* when the electrolyte is a solution of a salt of the metal of which the electrodes are made. It was improved by converting it into a bridge method with similar vessels in opposite arms, the distance d_1 between the electrodes in the one being greater than the distance d_2 between those in the other. The ratio arms being equal, the resistance required to be inserted in series with the shorter column in order to obtain a balance is equal to that of a column of length $d_1 - d_2$. (Cf., *e.g.*, Kohlrausch and Holborn, *Leitvermögen*, p. 71; Stroud and Henderson, *Phil. Mag.*, 1897, xiii. 19.)

The most widely used method of the second class is that, developed by Kohlrausch, in which the effects of polarisation are overcome by the use of alternating currents. If we assume that the polarisation arises in accordance with the equation $E = Ri + P\int idt$, the effect of alternation is easily represented. In the simplest case the applied E.M.F., instead of remaining constant, alternates in accordance with the equation $E = E_0 \sin pt$, the number of

alternations per second being given by $n=p/2\pi$. Under this condition the current through the electrolyte settles down to a value given by

$$i=E_0 \sin(pt+\theta)/R\sqrt{1+P^2/p^2R^2},$$

where $\tan\theta=P/pR$; while the corresponding values of e, the back E.M.F., are given by

$$e=-PE_0\cos(pt+\theta)/pR\sqrt{1+P^2/p^2R^2}.$$

The quantities i and e are thus always in quadrature while the phase difference between E and i depends upon the value of P/pR. If this can be made negligibly small, the phase difference between E and i and, at the same time, the existence of e can be ignored. The value of R can then be obtained by a bridge method if a suitable indicating instrument be employed.

For a given value of P/R the effects of polarisation are dependent upon the frequency of alternation n. Alternation makes the effects of polarisation non-cumulative: rapidity of alternation reduces the maximum amount. It can be seen that even if the variations of E are not simply harmonic, but only such as to ensure that the quantities of electricity passing in opposite directions in successive half-periods are nearly the same, the effects of polarisation may be overcome.

For a given value of p the effects of polarisation are dependent upon the value of P/R. To a first approximation we can assume from an earlier paragraph that P is inversely proportional to the effective area of either electrode, assuming for simplicity that the areas are equal. Hence it is relatively easy to make polarisation negligible when the electrodes are large (or when their effective areas are increased, *e.g.* by platinisation) and when the resistance of the electrolyte between them is great. Conversely, it is practically impossible to eliminate polarisation when P/R is large, and a cell for which this is true should not be used if an accurate value of R is desired. The question whether sufficient precautions have been taken can be answered by means of the expression for i already given. From this the effect of polarisation upon the resistance can be expressed by

$$R'=R(1+\tfrac{1}{2}P^2/p^2R^2),$$

where R′ is the apparent resistance. In order to attain an accuracy of 0·1 per cent, we must therefore have $\frac{1}{2}P^2/p^2R^2<1/1000$. Now if we make the approximate assumption $P=2/cA$, where A is the area of each electrode and c is the "electrode capacity" per unit area, we get $\frac{1}{2}P^2/p^2R^2=\frac{1}{2}4/c^2A^24\pi^2n^2R^2$. Hence we must have $(nAR)^2>1000/2\pi^2c^2$. If the electrodes are of mercury, copper, or platinum, c is of the order 10 microfarads per sq. cm. (more rather than less). Hence the condition for 0·1 per cent accuracy is approximately $nAR>7\times10^5$, where A is expressed in sq. cms. and R in ohms. When platinised electrodes are used the value of c appears to be increased from 25 to 50 times, and the value of nAR, necessary for 0·1 per cent accuracy, is correspondingly reduced.

In many of his measurements Kohlrausch used a small induction coil (with solid core and no condenser) as source of E.M.F. and a telephone as indicator. The conditions for a sharply defined minimum sound in the telephone were carefully examined, but cannot be discussed here. It is, however, important to observe that, in some of his standard measurements, he not only used alternating currents to avoid polarisation, but also carried out the measurements in such a way that, as in Horsford's method, any uneliminated effect appeared merely as a difference between two measurements in the final result.

In recent years the number of appliances suitable for the production and the measurement of alternating currents has greatly increased. For instance, generators capable of supplying an E.M.F. closely following a sine law and of adjustable frequency are now available, as are detectors, such as the vibration galvanometer, which can be tuned to give maximum response to a current of definite period. In consequence, new measurements have been undertaken, especially in America, in which such instruments are employed. In these measurements a double adjustment is necessary in order to balance the capacity effect in the arm containing the electrolyte, as well as the resistance. The most convenient method of balancing the capacity is by means of a variable inductance in series with the electrolyte. If the polarisation constant P were exactly equivalent to a capacity 1/C, the self induction $L=1/p^2C$ would compensate its effect and both the resistance and the capacity could be measured if L and p were known. As we have seen, however, the analogy is not exact on account of leakage. The effect of this is to alter the phase of e with respect to i so that these are not in quadrature as they would be if $e=P\int_0^\tau i\,dt$ were true. In consequence, the condition of balance is not $L=1/p^2C$ but $L=\cos\phi/p^2C'$, where C′ is greater than C, and ϕ is the amount by which the phase difference between e and i departs from $\pi/2$. Also, when the bridge is balanced, the apparent resistance of the electrolyte arm is not R, the true resistance, but $R(1+\sin\phi/C'pR)$. It will therefore appear to be a function of p if the quantity $\sin\phi/C'pR$ (which can also be written in the form $\tan\phi/C_apR$, where C_a is the apparent capacity $1/Lp^2$) is not negligible in comparison

with unity. A further reference to this method and to the literature will be found in the paper by Smith and Moss already mentioned (*Phys. Soc. Proc.*, 1913). Among later papers are those by Taylor and Curtis (*Phys. Rev.*, 1915, vi.); Taylor and Acree (*Am. Chem. Soc. J.*, 1916, xxxviii.). The effect of polarisation in this method is not, as in the first, inversely proportional to p^2; but diminishes much less rapidly as p increases. In some cases the value of ϕ is practically independent of p, and extrapolation to the case in which p is very great is easily performed by plotting the apparent resistance $R_a = R + \tan\phi/C_a p$ against $1/C_a p$. If ϕ is constant, a straight line cutting the resistance axis at the distance R from the origin will be obtained.

In connection with the measurement of resistance the double-commutator method (see, *e.g.*, Whetham, *Theory of Solution*, p. 201) deserves mention, although it is not essentially different in principle from Kohlrausch's method.

§ (18) Gas Concentration Cells.—Fresh light is thrown upon polarisation by the study of "concentration cells." One such cell, similar in construction to Grove's gas battery, contains two platinised platinum electrodes, each enclosed within a glass vessel open at the bottom. The upper parts of the vessels contain a gas, *e.g.* hydrogen, while the lower parts contain dilute acid. Each electrode lies partly in the gas and partly in the electrolyte. The vessels are arranged side by side in a wider vessel partially filled with the acid solution so that the electrolyte extends continuously from one electrode to the other. This "cell" has an E.M.F. if the pressures of the gas, p_1 and p_2, in the electrode vessels, A and B, are unequal. If p_1 exceeds p_2, the potential of B is higher than that of A. When the cell acts, gas passes through the platinised platinum into the solution at A and out of the solution at B. The masses passing in and out are equal and, for given pressures, the action is reversible, the E.M.F. required to produce the reverse charge being in the limit identical with E, the E.M.F. of the cell. Energy can be taken from the cell, at constant temperature T, by connecting it in opposition with a condenser, charged so that the potential difference between its plates is E, and allowing the capacity of the condenser to rise indefinitely slowly, *e.g.* by allowing the plates to approach against the action of the force by which they are kept apart. Concurrently the pressures p_1 and p_2 may be supposed maintained constant by means of pistons working in cylinders, one attached to each electrode vessel. Let v_1 be the volume of gas which disappears at pressure p_1 from A, and appears at volume v_2 and pressure p_2 in B, when the quantity of electricity dq flows round the circuit. The work supplied from the cell during this change is $Edq + p_2v_2 - p_1v_1$, neglecting the irreversible loss of heat, which can be made vanishingly small. The cell can be restored to its original condition by compressing isothermally the gas which has appeared round B, from v_2 and p_2 to v_1 and p_1, and then adding it to the gas round A. The work done on the gas during this process is $\int_{v_1}^{v_2} pdv$. The net work obtained from the cell during this constant temperature cycle must be zero. Hence

$$Edq + p_2v_2 - p_1v_1 - \int_{v_1}^{v_2} pdv = 0,$$

which may be written

$$Edq = \int_{p_2}^{p_1} vdp.$$

If the gas obeys the law $pv = kT$, this becomes

$$Edq = kT \log \frac{p_1}{p_2},$$

where k is a constant of which the value depends upon dq. If the gramme molecule of the gas gives rise to two gramme ions, each of valency n, then

$$\frac{k}{dq} = \frac{R}{2nF},$$

where R is the gas constant per gramme molecule. Hence

$$E = \frac{RT}{2nF} \cdot \log \frac{p_1}{p_2}.$$

This result may be taken to mean that the potential of the liquid with respect to the electrode increases with p and that E represents the difference between two "contact potential differences." This view may be expressed by the equation

$$E = ({}_S\pi_H)_{p_1} - ({}_S\pi_H)_{p_2} = \frac{RT}{2nF}(\log p_1 - \log p_2),$$

where ${}_S\pi_H$ represents the amount by which the potential of the solution exceeds that of the electrode.

If there is a value p_0 for the pressure of the gas such that $({}_S\pi_H)_{p_0} = 0$; then we could write for any pressure p the equation

$$({}_S\pi_H)_p = \frac{RT}{2nF} \log \frac{p}{p_0}.$$

Throughout it is assumed that the gaseous law, $pv/T = \text{constant}$, is obeyed.

When the gas employed in the cell is not hydrogen, but, *e.g.*, oxygen or chlorine, it gives rise to negative ions in solution and the sign of the E.M.F. is reversed. The lower pressure electrode is now the negative pole of the battery, but the value of E is obtained as

before. For this case, subject to the same simplifying assumptions, we get

$$({}_{S}\pi_{A})_{p}=\frac{RT}{2n'F}\log\frac{p_0'}{p},$$

where A represents the gas yielding the anions and the electrolyte is, *e.g.*, a solution of the acid HA.

These results can be used to improve the account given earlier of the way in which polarisation arises. For brevity we take the simplest example, electrodes of platinised platinum in a solution of HA, giving ions of unit valency. Let a polarising E.M.F. E be applied and imagine that incipient electrolysis occurs, however small E may be. The gases A and H will accumulate in and around the anode and cathode respectively. When their partial pressures have risen to p_H and p_A, the back E.M.F. e will be

$$({}_{S}\pi_{H})_{p_H}-({}_{S}\pi_{A})_{p_A}=\frac{RT}{2F}\log\frac{p_H p_A}{p_0 p_0'}.$$

The current will fall as p_H and p_A increase, and would vanish if they reached the values required to make $e=E$. They can never quite reach these values, however, for the gases will be continuously escaping, *e.g.* by diffusion and convection, and the final value of $E-e$ will be that required to allow the supply to balance the loss.

With each successive increase of E the pressures of electrolysed gas in anode and cathode will rise. A limit will be reached when p_H and p_A are each equal to the atmospheric pressure. The back E.M.F. will not increase further with increase of E and visible decomposition will ensue—the earlier stages preceding this final one in much the same way as evaporation precedes boiling.

We have taken a hypothetical case, but there is much experimental evidence, which cannot be given here, to prove its value as an indication of what occurs in general. It shows that while the simple condenser theory already described may be correct as far as it goes, it omits one essential fact. The potential difference between an electrode and a solution cannot be altered while everything else remains the same. Concomitant changes, either in the electrode or in the electrolyte, must occur at the same time. Hence the first rush of electricity, observed when an E.M.F. is applied to an electrolytic cell, represents not surface effects only but volume effects as well. This is clearly seen in the experiments described by Rothé (*Journ. de Physique*, 1904, p. 685; also *Ann. de Chim. et de Physique*, 1904) in which an oscillograph was used instead of a ballistic galvanometer and the charging current recorded photographically.

When the electrodes are not made of platinised platinum, and even then in many cases, the phenomena antecedent to gas evolution can be much less simple than we have supposed. It would appear that the complications are due in part to physical causes, such as supersaturation, and in part to chemical causes, such as the formation of compounds between the electrodes and the deposited ions. The existence of such effects, which are said to result in "overvoltage," is of considerable technical importance; but is outside the scope of the present article (see, *e.g.*, Allmand, *Applied Electrochemistry* (Arnold); Newbery, *Chem. Soc. J.*, 1916, cix. pt. 2).

§ (19) Liquid Concentration Cells.—Another aspect of polarisation, important in connection with electro-deposition, is seen in the case in which the electrolyte is a salt of the metal of which the electrodes are composed.

Here polarisation occurs because of the changes in the concentration of the electrolyte which arise when the current flows. This case is elucidated by consideration of a second type of concentration cell in which the concentration difference occurs in the electrolyte and not in the electrodes. The E.M.F. can be calculated in this case by a method analogous to that employed before.

The general arrangement of the cell is—metal M: solution of MA: less concentrated solution of MA: metal M. For simplicity, suppose that the solutions, containing N_1 and N_2 gramme molecules per c.c. respectively, are so dilute that each is completely ionised. When this cell is in action, the current flows through the electrolytes from the less concentrated solution towards the stronger, the cathode loss tending to make the latter weaker and the anode gain to make the former stronger. During the passage of dq units of electricity round the circuit, it can be seen, by the aid of § (13), that $\frac{v}{u+v}\cdot\frac{dq}{nF}=dN$ gramme cations and anions leave the solution round the electrode in the stronger solution, and that the same numbers appear in the region round the electrode in the weaker. It is necessary to find a method by which the concentrations of the solutions can be kept at their original values. For this purpose, in each case, we use a piston, operating on the electrolyte, in a cylinder of which the open end communicates with the solvent through a "semi-permeable" membrane. Through this the solvent, but not the solute, can pass. The concentration of the stronger solution is maintained by expelling solvent through one membrane; that of the weaker solution is maintained by allowing solvent to enter through the other. Work is done against the "osmotic pressure" in the former operation and by means of it in the latter. These operations correspond with those giving the

terms $p_1\ v_1$ and $p_2\ v_2$ of the calculation for the gas concentration cell. After the flow dq there is thus less of the stronger solution and more of the weaker. To restore the cell to its original condition the excess of the weaker solution, containing dN gramme molecules, is separated from the rest, and solvent is expelled from it through a semi-permeable membrane until the concentration is that of the stronger solution. To this it is then added, bringing the cell back to its initial state. The work done in this operation corresponds with the term $\int_{v_1}^{v_2} pdv$ of the earlier calculation.

It is known by experiment that the osmotic pressure of a very dilute solution containing dN gramme molecules of a salt in V c.c. is given, very nearly, by $PV = 2dN \cdot RT$. Assuming this law, the terms corresponding with $p_1\ v_1$ and $p_2\ v_2$, as above, balance out, and that corresponding with $\int_{v_1}^{v_2} pdv$ is

$$2dN \cdot RT\int_{dN/N_1}^{dN/N_2}\frac{dV}{V} = 2dN \cdot RT \log\frac{N_1}{N_2}$$

$$= \frac{2v}{u+v}\cdot\frac{dq}{nF}RT\log\frac{N_1}{N_2}.$$

For the same reason as before, this must equal Edq, where E is the E.M.F. of the cell, whence

$$E = \frac{2v}{u+v}\cdot\frac{RT}{nF}\log\frac{N_1}{N_2}.$$

The reason why $2v/(u+v)$ appears in this expression is seen when, as in the preceding case, we consider the factors of which E is composed. In the present case we have

$$E = ({}_S\pi_M)_{N_2} - ({}_S\pi_M)_{N_1} + {}_{N_1}\pi_{N_2},$$

where ${}_{N_1}\pi_{N_2}$ represents the contact potential difference between the solutions of concentrations N_1 and N_2. The latter potential difference owes its existence, in all probability, to the fact that the rates of diffusion of the ions are unequal, or, to put it in another way, to the fact that $2v/(u+v)$ is not, in general, equal to unity.

Without loss of generality in what follows we can, however, assume the electrolyte so chosen that $v = u$; in which case ${}_{N_1}\pi_{N_2}$ will be zero, and we obtain

$$E = \frac{RT}{nF}\log\frac{N_1}{N_2} = ({}_S\pi_M)_{N_2} - ({}_S\pi_M)_{N_1},$$

an equation showing how the potential difference between a metal and a solution of one of its salts depends upon the concentration of the latter.

If, as in the preceding case, there is a value N_0 of N, for which $({}_S\pi_M) = 0$, we can write

$$({}_S\pi_M)_N = \frac{RT}{nF}\log\frac{N_0}{N}.$$

This equation, like that just obtained, is, however, dependent upon the assumption that every osmotic pressure involved is related to N in the way already described. Similar calculations may be made by utilising the fact that the vapour pressure of a solution depends upon its strength (cf. Helmholtz, *Berl. Sitzber.*, 1882). The semi-permeable membrane used in this method is the surface of the solution, through which molecules of the solvent only can pass.

Such results, it will be seen, can be used without difficulty to account for the polarisation which occurs when a current passes, by electrodes of a given metal, through a solution of one of its salts.

A summary of the results of further study of polarisation, along the lines here indicated, will be found in a paper by Krüger (*Phys. Zeits.*, 1910, xi. 719), who gives also (*Zeits. f. Elektrochem.*, 1910, xvi. 533) many references to the literature.

S. W. J. S.

ELECTROLYSIS, TECHNICAL APPLICATIONS OF

I. General Introduction

This article deals with the applications of electrolysis to the extraction, production, and refining of chemical products, omitting those subjects which are of primary interest to the electrical engineer, such as (*a*) primary cells, with the attendant great possibility of the direct conversion of the chemical energy of fuels into electrical energy, (*b*) secondary cells or storage batteries, and (*c*) electrolytic alternating current rectifiers. Electro-chemical analysis is also left out, but a section is included on electroplating and electrotyping.

§ (1) Electrolytic Processes.[1]—Before proceeding further, it will be well to consider broadly the features which distinguish electrolytic from ordinary chemical processes. The most obvious one is that technical electrolytic processes all lead to the production of systems of higher chemical potential than the reacting systems, and that the increased energy content is supplied as electrical energy, not in the form of heat or as the result of a diminution in chemical energy of other added substances. The electric current never plays the part of a *catalyst*. Further, it is well known that electrical energy can be changed to chemical energy in a way which frequently approaches thermodynamic reversibility, and even under technical conditions electrolytic processes are generally characterised by a far higher conversion factor of the energy supplied into chemical energy than is the case when heat

[1] See also "Electrolysis and Electrolytic Conduction."

is used. Except, however, under very exceptional circumstances, the price of electrical energy is considerably above that of heat energy, which largely nullifies this advantage. Another feature of electrolytic processes is partly inherent, and partly arises from the necessity of keeping as low as possible the irreversible losses of the expensive electrical energy. The currents which are found economic in practice are of such magnitude as to furnish comparatively small quantities of chemical product in a given time for the size of plant used. In other words, the time-space yield of the plant is low, and as the auxiliary chemical plant is usually large, owing to the fact that, in electrolytic reactions, we are to a great extent not dealing with matter in concentrated form—*i.e.* in solid or fused state—but in aqueous solution, the first costs of the whole installation for a given annual output are liable to be high. On the other hand, the substitution of low temperature electrolysis for high temperature fuel-fired processes means a great saving in upkeep of plant. Finally, owing to the greater chemical simplicity of the reactions, electrolytic products are usually of a high degree of purity, and the same result follows from the use of electrical energy as against that of fuels. If impure raw materials are used, the impurities must either be removed beforehand or constantly eliminated during the process—otherwise disturbances will arise, electrolytic processes being more sensitive to such influences than chemical processes.

II. Current and Energy Efficiency

We have spoken above of the conversion factor of the electrical energy supplied into the chemical energy of the final product. This is termed the *energy efficiency* of a process, and is composed of two factors, the *current efficiency* and the *voltage efficiency*.

§ (2) Factors affecting Current Efficiency.—In all technical electrolyses the quantity of the desired product finally obtained falls short of the theoretical quantity calculated from Faraday's law. This is not due to a breakdown of the law, but to a variety of other reasons. Losses occur from current leaks and short circuits. Frequently two or more electrode reactions, resulting in different products, only one of which is required, take place simultaneously. Thus, in addition to chlorine, oxygen is sometimes evolved at the anode during brine electrolysis. And when an impure metal is being refined, the impurities, as well as the main constituent, will probably be dissolved at the anode, and in small quantity deposited on the cathode. More important are the losses due to secondary chemical reactions between the primary products formed at the electrodes and other substances present, *e.g.* water, or substances dissolved in the bath, perhaps the electrode material itself. Further, the primary products may be liberated under such conditions that they diffuse away rapidly from the neighbourhood of the electrode, and perhaps recombine with substances produced at the other electrode, or they may be volatile or for some reason difficult to collect. For example, in the Castner process for making sodium by electrolysis of fused caustic soda, some of the metal is lost by vaporisation, some burns away before and whilst being collected, some dissolves in the molten electrolyte and diffuses to the anode, where it combines with the oxygen being liberated there, and some reacts with the water which is simultaneously produced during the electrolysis. Lastly, either the final product or an intermediate product may be itself unstable and decompose before it can be removed or transformed into its final form. Examples are respectively furnished by sodium hydrosulphite and by the rôle played by sodium hypochlorite in the manufacture of sodium chlorate.

The ratio of the yield obtained to the theoretical yield calculated from Faraday's law is the *current efficiency*. In technical practice it nearly always varies between 40 per cent and 100 per cent.

§ (3) Factors affecting Voltage. Energy Efficiency.—The voltage taken by a technical cell is chiefly made up of three factors. Firstly and most important is the theoretical voltage necessary to bring about the change under thermodynamically reversible conditions. This is known as the *reversible decomposition voltage*. In many cases it can be closely measured by gradually increasing the potential difference across the terminals of the cell, and plotting it against the resulting current. The latter will at first increase very slowly ("diffusion" or "residual" current), but will suddenly rise when the applied voltage has reached a certain definite value, sufficient to bring about decomposition at the electrodes. This value approximates to the reversible decomposition voltage. In other cases this magnitude cannot be measured, but is calculable thermodynamically from the free energy relations of the different substances involved. In any case it is the algebraic sum of the reversible potential differences at the two electrode-electrolyte surfaces.

The second factor influencing voltage is the existence of specific irreversible effects at the electrodes. Of these, two in particular should be mentioned, viz. *overvoltage* and *passivity*. The former is met with when one of the electrode products is a gas, such as hydrogen, chlorine, or oxygen. If the potential difference electrode-electrolyte be measured at such an

electrode during the passage of current, it will be found that it differs from the reversible value, sometimes considerably, in the direction indicating increased polarisation. This difference is known as the overvoltage, and is dependent in the first instance on the specific nature of the evolved gas and of the electrode material. As would be expected from such an irreversible effect, it increases with fall of temperature and with increased current density, and often exceeds a volt in magnitude.

Passivity is frequently encountered when a metal is made the anode in an electrolyte. Such an electrode, when brought to a potential which should cause it to go into solution reversibly, does not dissolve, and an increased anodic polarisation is necessary before current will pass. In extreme cases no solution of the metal at all occurs, but another electrode process, *e.g.* gas evolution, takes place. The ferrous metals—iron, nickel, chromium, etc.—exhibit passivity in a marked degree. So also do gold and platinum. In the last case the property is a valuable one, as it enables the metal to be used as anode in brine electrolysis cells. As with overvoltage, the magnitude of the passivity polarisation depends on the specific nature of the electrode, and is affected in the same way by changes in temperature and current density. The nature of the electrolyte also has an effect. Oxidising ions, such as NO_3' and ClO_3', assist, whilst $H^{\cdot}$ ions and halogen ions diminish passivity. The causes of both overvoltage and passivity effects are still in dispute, and cannot be discussed here. Their importance in technical practice is great.

Apart from the above, the voltage of a cell is of course largely determined by the ohmic resistance of the electrolyte. This is reduced as far as practicable by bringing the electrodes near to one another and by raising the temperature, limits being set by increased liability to diffusion and chemical losses, as well as by the possibility of short circuits.

Finally, two minor factors affecting voltage must be mentioned—concentration polarisation in the electrolyte brought about by electrolysis (this is generally neutralised by effective circulation of the bath liquors) and losses in leads and terminals, depending on their resistance and on the efficiency of the contacts made.

The ratio of the reversible decomposition voltage to the cell voltage is the *voltage efficiency* of the process, and the ratio of the theoretical amount of energy required per unit of substance actually produced or recovered to the actual amount expended, *i.e.* the product of the current efficiency and the voltage efficiency, gives the *energy efficiency* of the process. Such energy efficiencies are of course lower than the corresponding current efficiencies. Thus in brine electrolysis (alkali and chlorine, chlorates, hypochlorites), they vary between 20 per cent and 70 per cent.

III. The Technical Electrolysis Bath

§ (4) General.—A technical electrolysis bath with aqueous electrolyte may absorb up to six or seven volts—seldom more. Using D.C. generators, furnishing say 200 volts, it is therefore necessary to couple up a large number of cells in series. The current taken by a single cell will be determined by the nature of the electrolysis, the most convenient dimensions of unit from other points of view, the efficiency of circulation required, the best working temperature, labour charges, etc., etc. Thus a small unit with plenty of surface for cooling is best for low temperature work. If, further, there is, as is usual, a continuous flow of electrolyte throughout the plant, a small unit, involving frequent changes of direction of flow, will mean relatively good circulation of the liquors. Technical units frequently take 1000-4000 amperes, seldom more, and often less. If they are of small capacity, it may be necessary to connect up two or more paralleled series of cells with a single generator. The disadvantage of having too many cells in series is that a mishap to one unit puts a large number out of action until it is rectified.

The bath itself is usually made of cement, concrete, slate, or lead-lined wood. Glazed earthenware and glass are also employed, whilst iron and lead are used on occasion, serving at the same time as an electrode. To avoid voltage losses, the separate cells are carefully insulated on earthenware or porcelain, and are usually mounted so that they can be inspected from underneath. The arrangement of the electrodes varies considerably. In metal production and refining, a large number of anodes are paralleled by means of a common bus-bar, and arranged

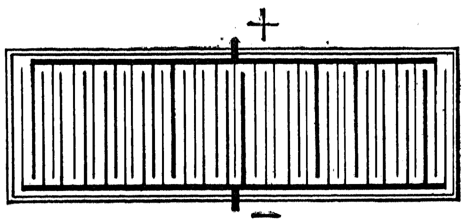

Fig. 1a.—Paralleled Electrodes.

alternately with a similar set of cathodes, thus ensuring a big surface with a corresponding large current, and, at the same time, permitting the use of a bath of convenient dimensions (*Fig.* 1a). On the other hand, in the "series" system of copper refining, the

electrodes are arranged in the bath parallel to one another in such a way that they act as *bipolar* electrodes, one side being the anode and the other the cathode, the two end electrodes being connected to the external source of current (*Fig.* 1B). In such an arrangement the current is of course small, the voltage high. And if the electrolyte resistance is not high compared with the electrode polarisation, shunt current losses will occur, owing to a fraction of the electrolysis not taking place between adjacent electrodes. Electrolytic baths for other purposes are all designed on one of these two principles (generally the former, *i.e.* high amperes, low volts), though the actual details of the arrangement adopted depend largely on the particular process concerned. The Finlay alkali-chlorine cell has a number of alternate anodes and cathodes separated by diaphragms and paralleled. Most other alkali-chlorine cells have one anode or set of anodes, with a cathode on each side or below. Certain hypochlorite and chlorate cells, also water electrolysers, have bipolar electrodes. Details will be discussed later.

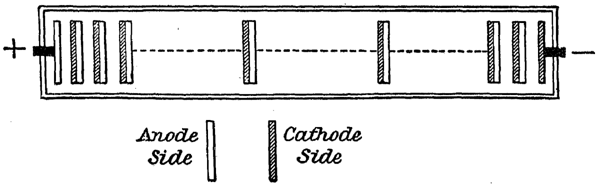

FIG. 1B.—Bipolar Electrodes.

Copper, with its high volume electrical conductivity, is the metal most frequently used for leads and bus-bars. Aluminium, which has a higher weight electrical conductivity than copper, is also employed to a considerable extent. It has the advantage of being less attacked in an atmosphere containing chlorine. Where practicable, bus-bars and electrodes are securely bolted together to avoid contact losses. If, however, the electrodes are being constantly removed and replaced, as in metal refining, they are simply suspended from the bus-bars, care being taken to secure contact between clean and plane surfaces.

§ (5) ELECTRODES.—The important points to be considered in technical electrodes, other than soluble anodes or cathodes on which metal is being deposited, are (*a*) their chemical resistivity, (*b*) their overvoltage for the gas or gases that are liable to be liberated at their surfaces. Iron, platinum, lead, mercury, and graphite are the most important cathode materials. Iron is generally used in alkaline solutions, *e.g.* in many alkali-chlorine cells. It is chemically stable, and has a low hydrogen overvoltage. Smooth platinum is used in the form of bipolar electrodes in various types of electrolytic bleach cells. It too has a low hydrogen overvoltage, though greater than that of iron. Platinised platinum at normal current densities has a practically negligible hydrogen overvoltage, but cannot be used technically, as its surface readily disintegrates. Lead is used in the Schoop water electrolyser, which employs dilute sulphuric acid as electrolyte. It has a very high hydrogen overvoltage (*e.g.* 1·2 volts at a current density of 10 amps/dm.^{2} in $2n.H_2SO_4$ at room temperature). The most commonly used cathode material when working with acid solution is, however, graphite, which is chemically stable, and has a low hydrogen overvoltage. Mercury is used as cathode in a particular class of alkali-chlorine cells. The object here is to produce a sodium or potassium amalgam, without simultaneous evolution of hydrogen, and the fact that hydrogen overvoltage at mercury is as high as, or higher than, that at lead, makes this possible. In practice a high current density is used, and 95 per cent to 99 per cent of the cathodic current in such cells is carried by the alkali metal ions.

The subject of technical anodes is of greater importance, in view of their general liability to attack by anodic chlorine or oxygen. The important anode materials used in chlorine cells are platinum, hard carbon (similar to gas carbon), graphite, and magnetic iron oxide (Fe_3O_4). Platinum is used in chlorate manufacture, in certain mercury cells, and also, as bipolar electrodes, in bleach electrolysers. It shows considerable resistance to the action of chlorine, but is slowly attacked in course of time, particularly at higher temperatures. An alloy containing 10 per cent iridium is far more resistive, and is generally employed. Under technical conditions, the chlorine overvoltage amounts to 0·7 volt in alkali-chlorine cells. Owing to the high price of the metal, and the necessity of utilising its surface to the maximum extent, platinum electrodes are frequently of net or gauze construction. The use of graphite has almost completely replaced the use of hard carbon anodes in brine electrolysis. Both materials are very resistive to chlorine. But varying quantities of oxygen are also invariably produced anodically in brine cells, and the hard carbon is far more readily attacked by this gas than is graphite. When once such anodes have started to burn away they disintegrate more or less rapidly, and foul the electrolyte. Hard carbon anodes which are partly graphitised are in use, and

have of course intermediate properties. Graphite possesses the additional advantages of having a higher electrical conductivity, and of being soft and easily machined. By means of a suitable preliminary chemical treatment, the exact nature of which is unknown, anodes can be made with a continuous life of several years before replacement is necessary. Their chlorine overvoltage value is very low. From the point of view of chemical resistivity, cast magnetite anodes are the most satisfactory, and are now coming more generally into use. They are made by fusing up decopperised iron pyrites (chiefly ferric oxide) in the electric furnace. Impurities are volatilised, and partial decomposition into ferrous oxide occurs. To the melt is added sufficient powdered ferric oxide to make a homogeneous mass of Fe_3O_4 on solidification, and the anodes are then cast in the form of hollow cylinders, closed at the bottom, and about $\frac{1}{4}''$ thick. They are coated internally with copper electrolytically, and contact thus made with a copper ring at the upper end. Their conductivity is not high, but is sufficient. Unfortunately they have a high chlorine overvoltage, greater than that at platinum.

For use with alkaline electrolytes evolving oxygen, iron or nickel can be employed. In acid solution, iron can sometimes be used, but platinum is, from a chemical point of view, more satisfactory. Lead is widely used, and electro-deposited lead and manganese peroxides, as also magnetite, have been utilised with success in certain instances. Except in the case of platinum in alkaline solution, the oxygen overvoltage values are low, and seldom exceed 0·5 volt.

§ (6) Diaphragms.—These are extensively employed in cases where it is necessary to prevent mixing of the anolyte and catholyte. To be satisfactory, they must have a low electrical resistance, and be at the same time mechanically strong and unattacked chemically. A great many substances have been tested or recommended from time to time. For use in alkaline solutions, cement and asbestos are the usual starting materials, the porosity being adjusted by suitable treatment. For use in acid solutions, diaphragms have been devised consisting of siliceous material or artificial corundum (alundum), or mixtures of the two. The porosity can be regulated by the deposition of hydrated silicic acid. Good quality canvas or linen is also used.

IV. Electrolytic Solution and Deposition of Metals

§ (7) Electro-deposition.—Before proceeding to the subject of electro-plating, a few special points in connection with the electro-deposition and anodic solution of metals must be discussed. If a solution of a metallic salt be electrolysed, using a cathode of the same metal, metal deposition should take place as soon as the cathodic polarisation exceeds the value corresponding to the equilibrium potential difference electrode-electrolyte, assuming the metal to be more readily deposited than hydrogen. In certain cases irreversible effects come into play, necessitating a considerably greater polarisation. Examples are the deposition of iron and nickel from solutions of their sulphates, the deposition of copper and zinc from solutions of their alkali double cyanides, etc. More important are the phenomena which may occur if the cathode consists of another metal which can form an alloy with the metal present in the electrolyte. In this case depolarisation will take place—the deposited metal will not exert its full electrolytic solution pressure, and can be plated out, initially at all events, at a lower polarisation than that which corresponds to its normal equilibrium value. An extreme case is the depolarising action of the mercury cathode in mercury alkali-chlorine cells, which, together with the high hydrogen overvoltage at a mercury surface, renders the formation of alkali metal amalgams possible. Other cases of alloying occur very frequently, and probably play a big part in determining whether or not, when one metal is plated out on another, the deposit will adhere well.

The physical state of a deposited metal is of great importance. It is nearly always desirable to have it in coherent form, and the electroplater in addition wants a deposit that can be polished. There are many factors that determine the form of an electro-deposit, and, by changing them, the state of aggregation, hardness, etc., of one and the same metal can undergo very considerable variations. The more concentrated the electrolyte, the more coherent and fine-grained is the deposit. A dilute electrolyte favours the formation of loose crystals. An electrolyte containing the metal in the form of a complex anion, *e.g.* double cyanides, tartrates, etc., will, as a rule, give a denser and smoother deposit than will an electrolyte containing the metal as cation. If the metal is present as cation, a slightly acid electrolyte is desirable to prevent the precipitation of basic salts. The effect of current density is somewhat complex. If it is very low, an adherent coarsely crystalline deposit is the rule. As it is raised, the deposit becomes finer in grain, harder, and brighter. If raised still higher, the concentration of metal ion in the electrolyte in the immediate neighbourhood of the electrode is depleted more rapidly than it can be regenerated by diffusion, stirring, etc., the effect being to give a non-adherent deposit.

It follows that firm deposits are favoured by good circulation of the electrolyte. The effect of temperature is again twofold. If the concentration and current density are of the right magnitude, a fine-grained hard deposit is favoured by a low temperature, a higher temperature giving bigger crystals. If, however, concentration is somewhat low, and current density somewhat high, a more adherent deposit can be got at a high temperature than at a low, owing to the increased rate of diffusion of ions into the layer of electrolyte immediately surrounding the cathode. One last point is the enormous effect often exerted on the nature of a deposit by the addition of a small quantity of some organic substance, often colloidal in nature, to the electrolyte. If the right addition agent is chosen—the action is specific for different metals—a very fine-grained and smooth deposit will result under conditions which would otherwise furnish a coarsely crystalline metal. If too much be added, the deposit becomes brittle, and contains appreciable amounts of organic matter. Examples are the addition of gelatine to a copper bath, of resorcinol to a zinc bath, and of pyrogallol to a lead tank. A discussion of the reasons for this effect would lead us too far—it suffices to say that it is undoubtedly connected with the adsorption of the addition agent on the surface of the depositing particles of the metal.

The physical state of the metal also influences its anodic behaviour. Thus a cast metal will dissolve more readily than metal that has been worked by drawing or hammering, and metal that has been electro-deposited dissolves usually less easily than other forms, though more evenly. Both cast and wrought metals are less homogeneous than electro-deposited metal, and tend, when used as anodes, to leave their less soluble parts undissolved, in the form of "slimes." "Slimes" are of course chiefly produced when anodes are used containing other metals as impurities. If these are less noble than the main constituent, they will enter solution. If more noble, they will remain undissolved. The relations may be somewhat complicated if such less noble foreign metals are dissolved in the main constituent of the anode in the form of a homogeneous alloy. In this case a metal may find its electrolytic solution pressure so decreased, and its "noble" character so enhanced, that it may not dissolve, but remain in the "slimes."

V. Electroplating and Electrotyping

§ (8) General.—Electroplating is the art of covering a metallic surface by electro-deposition with an adherent coating of some other metal, the form of the original surface being fully retained. The second metal may be deposited for decorative purposes, or because of its superior resistance to chemical and atmospheric influences. Electrotyping is the art of reproducing the form of an object by electro-deposition on a cast or negative.

As an electro-deposited metal layer must before all be firmly adherent, all articles to be electroplated are very carefully cleaned. They are first "buffed," *i.e.* all file marks, irregularities, etc., produced during manufacture are removed by suitable polishing machines. Then they are cleansed from grease by dipping into a boiling caustic alkali solution, and the last traces of rust or oxide are removed by pickling in a solution, usually acid, of composition depending on the nature of the article to be treated. From there they go to the plating bath, in some cases after a further mechanical preparation of their surface. When the acid pickling bath is inadmissible (the evolved hydrogen may dissolve in the metal and alter its mechanical properties), the oxide layer is removed by wire brushes or by sand-blasting. Electrolytic methods of cleaning have also been devised and appear to be coming into favour. The articles are made the cathodes in a solution of either acid or alkali, and both grease and scale are very efficiently removed. In some cases the connections are so arranged that the current can be switched over, the articles becoming the anodes for any desired period. Both in electrolytic cleaning and in the pickling bath, the gas evolution removes much of the scale mechanically.

As the objects in the plating vats are being continually removed and replaced, an arrangement of any considerable number of tanks in series would prove very inconvenient. They are therefore connected in parallel as far as possible, and current taken from a low voltage dynamo of high amperage. Each tank should be supplied separately with voltmeter, ammeter, and regulating resistance. When working under standard conditions, the voltmeter can be eliminated, and an ampere-hour meter conveniently used for a single tank or set of tanks. The objects under treatment are suspended by hooks from copper rods, resting on bus-bars passing round the edges of the vat. By means of an eccentric, they can be gently moved to and fro inside the bath. Additional circulation can be provided by "beaters" similarly connected up, or by blowing in air. Small objects are contained in metal baskets. The anodes, which consist when possible of a pure sample of the metal to be plated, are similarly connected up in parallel, and arranged alternately with the cathode articles. Care is taken to utilise the whole cross-section of the bath and to dispose the anodes symmetrically, in order that the cathode articles shall be evenly plated. Auxiliary anodes are placed for this purpose

in special positions when required. If necessary, the anodes are enclosed in linen or parchment bags to retain the slimes. If the electrolyte is to be heated, this is done by leaden steam coils.

The current density used varies, according to the particular process and conditions of electrolysis, between 0·1 and 2 amps/dm.^{2} The thickness of the deposit is very small—usually measured in thousandths of a mm. for cheap articles, and rarely exceeding a few tenths of a mm. At the end of the plating the articles are washed, dried, and finally polished. In some cases, particularly if comparatively thick deposits are being plated, the articles are occasionally removed from the bath during the course of the electrolysis, and the surface polished by suitable means.

§ (9) Zinc Plating.—Zinc plating (wet galvanising) is replacing hot galvanising (dipping the articles in a bath of molten zinc) to an increasing extent, for the purpose of protecting iron and steel surfaces against atmospheric influences. More resistant coatings of easily controllable thickness can be produced and there is less waste of zinc. The electrolyte is nearly always a fairly strong solution of $ZnSO_4$—say 30 grams zinc per litre—with the addition of some other salt such as Na_2SO_4 or $MgSO_4$ to increase the conductivity. A little $FeSO_4$ or alum improves the deposit, probably owing to the presence of small quantities of colloidal hydroxide, and the addition of boric acid has been recommended to regulate the acidity. An average bath will be worked at 50°, with a current density of 2 amps/dm.^{2} and will take about 3·5 volts. The current efficiency is almost 100 per cent.

§ (10) Nickel Plating.—This is of great importance, owing to the mechanical strength, chemical resistivity, and capacity for polish of the metal. The electrolyte consists of the sulphate—10 to 15 grams/litre of the metal—with the addition of a large quantity of ammonium sulphate to increase the conductivity. A little boric or citric acid confers the right acidity, which must be carefully regulated by the addition of sulphuric acid or by hanging bags containing nickel carbonate in the bath. A certain amount of acid is produced at the anodes, which do not dissolve in amounts quite corresponding to Faraday's Law, and some hydrogen is always produced at the cathodes. This must not be allowed to become too great, or the deposit will become brittle and non-adherent. Hence the need for careful regulation of the acidity. This can partly be effected by adjusting the relative numbers of cast (readily soluble) and rolled (less readily soluble) anodes. For ordinary work, the vats are run at 20°-25°. If thick deposits are required, the temperature should be raised to 70°, or special solutions used. The current density will average 0·3-0·5 amp/dm.^{2}, and the voltage 3 volts. A higher voltage is usually applied for the first few moments the articles are in the bath, until they are completely covered with a film of metal. The current efficiency approaches 95 per cent.

The above two metals are plated out from sulphate solutions. In all other important electroplating processes, viz. deposition of silver, gold, copper, and brass, a solution of the corresponding double cyanide with potassium is used, prepared by the addition of potassium cyanide to an aqueous solution of an appropriate salt. A smooth dense deposit is obtained which can readily be polished.

§ (11) Silver Plating.—This is probably the most important branch of the electroplater's art. The solutions used contain 12-15 grams/litre of metallic silver, present as $KAgCy_2$, together with a considerable excess of KCy. Owing to the action of atmospheric CO_2, gradually increasing amounts of K_2CO_3 are formed in them. Unless present in excessive quantities, this does not affect the plating qualities of the bath. When necessary, the liquors can be regenerated by the addition of $BaCy_2$, which precipitates the carbonate as insoluble $BaCO_3$. The anodes are rolled sheets of "fine" silver, and dissolve quantitatively. Their surface should be as nearly as possible equal to the surface of the cathodic articles to be plated. The electrolysis is best carried out at room temperature. Silver deposition is nearly quantitative, a current efficiency of 99 per cent being readily obtained. The most suitable current density is about 0·15 amp/dm.^{2}, at a voltage of one volt. The deposit is of a dull white colour which can be readily polished. The addition of a trace of carbon bisulphide to the bath effects a remarkable change, giving a bright shining deposit of close texture. Its action is doubtless analogous to those of other addition agents already mentioned.

§ (12) Gold Plating.—This is carried out in a bath containing 6-8 grams/litre of gold, with an excess of KCy. Depending on the class of work to be done, and the colour of the deposit required, the baths are worked at room temperature or at, say, 70°. Objects of intricate design are best plated at a high temperature, in consequence of the higher rate of diffusion of the electrolyte into the interstices of the articles. The voltage will of course depend on the temperature—at 20° four volts is about normal. The anodes are of fine gold in the form of very thin sheets, in order to obtain the maximum surface for a given weight. They exhibit passivity to a marked degree, and dissolve very slowly under normal current conditions. It is therefore necessary from time to time to add gold chloride to the electrolyte, as otherwise the deposit loses its usual rich yellow colour.

§ (13) Copper and Brass Plating.—These processes are of importance as being frequently employed in giving a preliminary coating to articles before plating with other metals which would not directly adhere to the original object. They owe their use in this connection to the marked tendency of copper to alloy formation. Thus, iron and steel articles are coated with copper or brass preparatory to silver or nickel plating, as also are Britannia metal and lead-zinc alloys before bringing them into the nickel bath. A copper bath contains about 25 grams/litre of copper as $KCuCy_2$, with 20 per cent excess KCy. The anodes are of pure sheet copper. The normal bath voltage is 3-4 volts, and cathodic current density 0·3 amp/dm.^{2}. There is considerable hydrogen evolution at the cathode surface during plating, the current efficiency rarely exceeding 50 per cent. The case of brass-plating is interesting from an electro-chemical point of view. In acid solution, the single potentials of the two metals lie far apart, and an electrolyte containing the two metals only deposits copper. In a cyanide solution, however, owing to the greater tendency to anionic complex formation of the copper, their electrode potentials can be equalised, or, with a large excess of KCy, the zinc can actually be made more noble than the copper. With the depolarising alloy effect also coming in, it becomes quite possible to deposit alloys corresponding in composition and properties to commercial brasses (*i.e.* with 20-40 per cent zinc). A suitable electrolyte contains about 12 grams/litre each of copper and zinc, present as $KCuCy_2$ and K_2ZnCy_4, with about 10 per cent KCy in excess. Anodes of rolled brass are used, corresponding in composition to the brass which is being plated out. The bath is usually worked cold, taking 4-6 volts. The current density is variable, perhaps about 0·35 amp/dm.^{2} at the cathodes, and still lower at the anodes. There is marked hydrogen evolution at the cathodes, the current efficiency averaging 50 per cent.

§ (14) Electrotyping.—Most electrotypes are of copper, sometimes coated for durability with a thin layer of iron or nickel, and are deposited from an acid copper sulphate bath, containing about 50 and 30 grams/litre of copper and free sulphuric acid respectively. The negative casts of the original are usually prepared from gutta-percha, though other materials, as plaster of Paris or a suitable wax, are sometimes used. Before putting in the bath, they are coated over with a thin layer of graphite which gives conductance, and are furnished with copper leads. Forms of fusible metal can also be used. The anodes are rolled sheets of pure electrolytic copper. The electrolysis is carried out at room temperature or somewhat above it, with a current density of about 3 amps/dm.^{2} and a voltage of one volt. When the necessary thickness of metal has been deposited, the article is taken from the bath, the negative cast detached by gently warming, and the electrotype backed with a low melting fusible alloy to give it the necessary rigidity.

Iron electrotypes are also made, for subsequent use as dies. The most suitable electrolyte is a strong $FeCl_2$ solution, containing in addition NH_4Cl or $CaCl_2$ to increase the conductivity. Great care must be paid to the exact acidity. The electrolyte should be just acid and no more, as otherwise a very brittle metal which easily rusts is produced, owing to the simultaneous formation of hydrogen at the cathode. If, on the other hand, the bath is not kept faintly acid, basic precipitates will form in the electrolyte. The anodes should be of the purest soft iron, and of area greater than that of the cathodes. A high temperature is favourable (70°-90°) and a high current density is employed—5-10 amps/dm.^{2}, or even greater if the circulation of the electrolyte is efficient.

Attention should finally be directed to the use of copper electrotypy for making seamless copper tubes of high tensile strength. The cathode negative is a revolving drum or cylinder, coated with a thin film of oil or graphite. The bath is of acid copper sulphate, similar to the one mentioned above, and is usually run at room temperatures. The anodes are electrolytic copper. In order to ensure a dense, regular, and strong deposit, the cathode is continually burnished by agate brushes, by glass beads kept suspended in the electrolyte, or other means. Ingenious methods have been proposed for making copper wire or copper sheet from the cylinders which result. Cowper-Coles recommends working with rapidly revolving cathodes and high temperatures. The increased friction allows of the use of very high current densities. The same inventor has successfully developed the production of seamless iron tubes by electrotypy.

VI. Electrolytic Extraction and Refining of Metals

§ (15) Copper Extraction.—The electrolytic refining of copper, one of the most important of the electro-chemical industries, is being dealt with in a special article of this Dictionary.[1] The extraction of the metal from its ores by electrolytic means has been the subject of much investigation, but can only recently be said to have become a commercial success. It was laid down early in this article that one of the essential factors for the success of an electrolytic process is an electrolyte of regular composition, the impurities in which can be readily kept within defined limits. And in wet processes of metal extraction these con-

[1] See "Electrolytic Refining of Copper," Vol. V.

ditions are not easily satisfied. The composition of the ore fluctuates. Such fluctuations, even when of small magnitude considered absolutely, are of particular importance with those ores which are too poor for pyro-treatment, and which are generally the ores treated by wet methods. Further, the preliminary roasting to which the ores are usually first submitted is difficult to regulate exactly. These causes lead to variations in the constitution of the electrolyte which make a controlled electrolysis very difficult, and which have led to the abandonment, after long trials, of, for example, several processes of copper extraction which promised well on the laboratory scale. The Marchese process utilised anodes cast from a copper matte containing copper, iron, lead, and sulphur in varying proportions, together with smaller quantities of other substances. The electrolyte contained copper and iron sulphates, with sulphuric acid. When a current is passed, such a sulphide anode sends its metallic constituents into solution, leaving a residue of free sulphur. At the cathode, copper is the chief metal deposited, whilst the iron remains in the electrolyte, and the lead is precipitated as insoluble sulphate. In practice, impurities accumulated in the electrolyte beyond permissible limits, the copper deposit became contaminated, the anodes disintegrated, and the voltage rose on account of the sulphur layer formed on them. Using a purer matte, the results were better, but the process never became commercially practicable. Similar reasons account for the abandonment of the ingenious Siemens-Halske and Höpfner processes. The finely-ground partly-roasted ores were treated respectively with a solution of ferric sulphate and one of $CuCl_2$ containing an excess of common salt. The copper sulphide dissolved, giving in the first case a solution containing $CuSO_4$ and $FeSO_4$, in the second case a solution of Cu_2Cl_2 dissolved in excess of salt. The purified liquors were electrolysed in a diaphragm cell containing copper cathodes and lead or carbon anodes. Metallic copper was deposited on the cathodes whilst at the anodes ferrous sulphate was oxidised to ferric sulphate and Cu_2Cl_2 to $CuCl_2$ respectively, the liquors then being utilised for leaching further quantities of ore. Expressed ionically, the two cell reactions are

$$Cu^{\cdot\cdot} + 2Fe^{\cdot\cdot} \longrightarrow 2Fe^{\cdot\cdot\cdot} + Cu$$

and $$2Cu^{\cdot} \longrightarrow Cu^{\cdot\cdot} + Cu,$$

and, in consequence of the depolarisation without gas evolution which takes place at the anodes, require considerably lower voltages than would be necessary, using pure solutions of say cupric sulphate or chloride. In spite of this advantage, the difficulty of controlling the electrolyte composition, together with diaphragm troubles, led to their abandonment. The only successful commercial processes are those in which a $CuSO_4$ solution, obtained by lixiviating the fully roasted ore with dilute H_2SO_4, followed by careful purification, is electrolysed using insoluble anodes (lead or magnetite) with oxygen evolution. The Laszczynski process may be taken as a type. The filtered electrolyte contained about 3 per cent copper as sulphate with 1 per cent free acid and much iron. The cathodes were thin copper sheets. The anodes were of lead, which soon became covered with PbO_2, and were surrounded by closely fitting thick cloth diaphragms, by which means the oxidation of the ferrous to ferric sulphate was practically eliminated. Using a current density of 0·5-1 amp/dm.^{2} and 2·2-2·5 volts, the copper could be reduced to 1 per cent with a 90-95 per cent current efficiency. The liquors, containing 4 per cent H_2SO_4, were then withdrawn from the cells and used for extraction of further portions of ore. The electrical energy consumption in such processes amounts to about 2200 K.W.H. per ton of copper produced, and their economic situation is liable to be somewhat precarious.

§ (16) Silver Refining.—Electrolytic methods in the metallurgy of silver are practically confined to silver refining. There are several different cases to consider. The crude material may consist chiefly of silver, with a small proportion of gold, and still smaller amounts of other metals, *e.g.* anode slimes from copper refining, or silver concentrates from the Parkes lead process. Or it may contain considerably larger proportions of gold, as in crude bullion. Or it may consist of scrap jewellery, plate, etc., in which case there will be high percentages of copper and of base metals. To these differences correspond well-marked differences in the methods employed. In any case, the crude material is cast and used as anodes in vats containing a mixture of various nitrates with some free HNO_3. Of the different anodic constituents, silver, copper, iron, nickel, zinc, and cadmium will dissolve, together with some of the lead, tin, and bismuth. The remainder of these last substances will enter the slimes as PbO_2 and basic salts of bismuth and tin. The slimes will also contain unattacked gold, platinum, other precious metals, and tellurium. At the cathode the only metal likely to deposit, if appreciable quantities of silver are present, is copper, and even then only under exceptional conditions—high current density, high copper concentration, and poor circulation of electrolyte. The other metals will simply accumulate and must be removed from time to time.

The Moebius process is used for refining crude silver from copper and lead refineries.

It is carried out in tanks of stoneware, divided into several compartments. Each compartment contains a number of anodes, enclosed in bag-diaphragms of canvas. They are arranged in rows alternately with rows of cathodes of "fine" silver foil, electrodes of like sign being paralleled, and the different compartments being connected in series. The anodes contain 95-98 per cent silver, 0·5-3 per cent gold, together with copper, bismuth, lead, and other metals. Interest charges lead to the use of high current densities, in order to shorten the time the silver remains in the bath. This favours copper deposition, and the copper concentration in the bath must therefore be kept below certain limits. An average electrolyte is kept at about 15-20 grams/litre and 30-40 grams/litre of silver and copper respectively. With a current density of 4·4 amps/dm.^{2} the voltage is high, about 1·5 volts. The anodes are in the bath for 24-36 hours. The silver comes down in the form of long crystals which tend to grow over towards the anodes. To avoid short circuits and to circulate the electrolyte, the cathode surfaces are continuously scraped with a wooden scraper, the crystals falling to the bottom of the vessel and being there collected. They are very pure, at least 99·9 per cent silver. The current efficiency is 94-95 per cent. A ton of refined silver requires about 420 K.W.H.

The only important modification of this process, the Balbach-Thum process, is used in the U.S.A. A shallow glazed porcelain trough, lined with graphite (the cathode), is used as the cell, and the anodes (enclosed in canvas bags) are arranged on shelves some distance above the cathode. The electrodes are further apart than in the original Moebius process, as there is no mechanical arrangement for brushing the silver from the cathode. It is merely pressed down and removed from time to time. Working with much the same current density, twice the voltage and energy expenditure are required as in the Moebius process. But there is a more complete separation of silver (the anodes are not removed until completely consumed) and the cell is of simpler construction.

With anodes which are rich in gold, such as are used at the different mints, it becomes more necessary than ever to lower interest charges, and this is effected by the use of higher current densities. Thus, at the San Francisco mint, where anodes with 30 per cent gold, 60 per cent silver, and 10 per cent base metals are employed, a modified Balbach-Thum process is used, with a high current density, and with a higher silver concentration in the electrolyte than when using anodes poor in gold. In some cases a trace of gelatine is added to the electrolyte, which furnishes the silver in coherent form.

When the percentage of copper in the crude material is very high, the process is essentially modified, the anode liquors leaving the cell and having the silver removed from them chemically before passing into the cathode compartments, where copper is deposited. For example, Dietzel employs a cell in which anolyte and catholyte are separated by a horizontally arranged canvas diaphragm. The anodes, in slab form, are below this. The anolyte is drawn off from the bottom of the cell, passes over scrap copper where the silver is deposited, and re-enters the cell by the cathode compartment, which contains the slowly rotating cylindrical cathodes, arranged above the diaphragm. Typical anodes contain 5 per cent gold, 40 per cent silver, 50 per cent copper, and 5 per cent other metals. The base metals which accumulate in the liquors must be kept down by withdrawing a part of the electrolyte at intervals and adding copper and nitric acid. With an anodic current density of 1·5 amps/dm.^{2}, a voltage of 2·5-3 volts is required.

§ (17) Gold Extraction.—Electrolytic methods are used in gold metallurgy both in extraction and in refining processes. As is known, gold is extracted from low-grade ores and from the "tailings" or "slimes" of the amalgamation process by means of a weak solution of potassium or sodium cyanide in presence of air, the metal dissolving in the form of a double salt $KAuCy_2$. From this solution it is generally removed by means of metallic zinc, the gold coming down in the form of a finely divided coloured semi-colloidal precipitate. In some mines, however, this precipitation is carried out electrolytically. The filtered liquors, carrying 3-10 grams/cubic metre of gold are passed slowly, with frequent changes of direction, through long wooden vats, containing paralleled anodes and cathodes arranged alternately. The anodes are large iron sheets, 3-4 mm. thick. As they are slowly attacked by the electrolyte, with formation of Prussian blue, they are enclosed in canvas bags. They last for years. The cathodes consist of strips of sheet lead, suspended from bus-bars of zinced iron. At the low current densities employed—about 0·4 amps/metre^2—the gold adheres to them satisfactorily. When they contain about 10 per cent of gold, which does not happen till they have been in the vats for weeks or months, they are removed, cupelled, and refined. About 85 per cent of the gold is deposited, the liquors then returning to the leaching tanks. The current efficiency is exceedingly low, perhaps 1 per cent, much hydrogen being produced. The baths take 4-5 volts. The disadvantages of the process are the slow rate of work, and the enormous plant required. On the other hand, there is a great saving in

zinc and in cyanide, and the metal is obtained in a more workable and easily purified form.

§ (18) Gold Refining.—The above process uses a cyanide electrolyte, as in electro-gilding. In the refining of gold, as now carried out at several mints and also in the big metal refineries of the U.S.A., the electrolyte is an acid $AuCl_3$ solution, consisting essentially of $HAuCl_4$ and HCl. A gold anode exhibits somewhat complex behaviour in this solution, depending on the current density, temperature, and acid concentration. At room temperature, with a small anodic polarisation, the gold goes quantitatively into solution. If the current density (and anode potential) be raised, the metal becomes passive. If the electrode be still further polarised, chlorine is evolved. The more acid present (the Cl' ions are the active agent) the less easily does the metal become passive, and the higher can the current density be raised before chlorine evolution begins. Rise of temperature, which counteracts passivity, has the same effect. For example, at 70°, with 3 per cent free HCl in the electrolyte, the limiting current density is 30 amps/dm.^{2} The metal dissolves giving a mixture of auric (trivalent) and aurous (monovalent) chlorides, the proportion of the former being the greater. With high current densities, the production of aurous salt becomes very small. If the solution contains much of it, it tends subsequently to deposit metallic gold ($3Au^{\cdot} \longrightarrow Au^{\cdot\cdot\cdot} + 2\ Au$). At the cathode the relations are also complex. With a small polarisation we get no gold deposited, but a reduction of auric to aurous salt. Further polarisation leads to discharge of a mixture of auric and aurous ions, whilst a still further increase results in the elimination of the aurous ion discharge, and in quantitative precipitation of metal from trivalent ions. At higher temperatures, particularly if the electrolyte has been used for some time, there is no noticeable reduction of trivalent to monovalent ions, and only a slight deposition of monovalent gold, nearly all the current being taken by the discharge of auric ions to metal.

In practice, typical gold anodes contain 94 per cent of gold and 5 per cent of silver, the remainder being copper, lead, platinum, etc. They are cast into thin slabs and suspended by gold wires in the electrolyte. This contains about 80-85 grams/litre of gold and 30 per cent free hydrochloric acid, a trace of gelatine being sometimes added to improve the nature of the deposit. It is circulated through a series of tanks by gravity. The cathodes are of thin gold foil, arranged alternately with the anodes, like electrodes being paralleled. The cells are of glazed porcelain, rest on sand baths, and are heated by steam pipes. The electrolysis is best carried out at 70°. This permits of the use of a current density of about 15-17 amps/dm.^{2}, and thus facilitates rapid work and low interest charges. 0·6-0·8 volt is required under these conditions. The gold, which comes down in coherent form, is deposited with a current efficiency exceeding 100 per cent, calculated on the assumption that the sole reaction is auric ion discharge. The excess is clearly due to the discharge of aurous ions.

All the constituents of the anode dissolve. The silver is immediately precipitated as insoluble chloride, and the lead by adding H_2SO_4 to the electrolyte. Copper, platinum, and palladium accumulate in the solution, the gold content of which falls. On this account the electrolyte must be continually regenerated by withdrawing a fraction and replacing it by $AuCl_3$ solution. The slimes consist chiefly of AgCl, $PbSO_4$, and gold. If the amount of AgCl is excessive, it may be necessary to lower the current density in order to avoid chlorine evolution, which normally is hardly perceptible. Wohlwill avoids this difficulty, and at the same time renders the use of still higher current densities possible by superposing on the direct current used for refining an alternating current of rather greater r.m.s. value. The way in which this acts is not clear, but its effect in practice is undoubted. Anodes of high silver content can be treated, larger current densities used, and the proportion of gold in the slimes much reduced. The cathodic current efficiency is unaffected, and the cost negligible.

§ (19) Zinc Extraction.—Owing to the ease with which zinc can be distilled, electrolytic methods are not used for refining the metal. After, however, much experimental work, and many failures, electrolytic extraction processes appear to have acquired a firm footing. We have seen that in wet galvanising a $ZnSO_4$ electrolyte is employed, fairly concentrated, and very slightly acid, and that a high current density is used. Before proceeding to the discussion of the technical extraction processes, we must consider zinc electrodeposition in further detail, as it presents several features peculiar to itself. Zinc, different from gold, silver, and copper, is far more electropositive than hydrogen, should dissolve freely in acid, and conversely should not be deposited cathodically from a solution containing appreciable quantities of $H^{\cdot}$ ions. In practice, pure zinc is unattacked by acids, and the metal can be deposited cathodically under certain conditions with excellent yields. The apparent contradiction is due to the high overvoltage necessary for hydrogen discharge at a zinc surface, higher for any ordinary metal except mercury. If metallic zinc contains traces of such metals as copper, silver, nickel, or arsenic, it will readily dissolve in acid, in consequence of the low hydrogen

overvoltage of these metals. If, further, an electrolyte contains traces of these metals—more electronegative than zinc and hence deposited first—we shall get hydrogen evolution and not zinc deposition at the cathode. We see then the importance of a pure electrolyte in zinc deposition. As further, overvoltage, like other irreversible effects, increases with rise of current density and lowering of temperature, such factors should favourably affect zinc deposition. This is borne out in practice.

Apart from the yield, the nature of the deposit is affected by the conditions of electrolysis. If proceeding favourably, one obtains a coherent, compact greyish-white metal, but often the deposit becomes spongy, voluminous, and dark coloured, a form which is difficult to handle and to melt up, which encloses electrolyte and causes short circuits, and which has a low hydrogen overvoltage. The formation of this sponge is apparently closely connected with the production of basic salt in colloidal form in the electrolyte, and hence anything tending to decrease the acidity by facilitating $H^{\cdot}$ ion discharge will also assist sponge formation. Such factors are the presence of electronegative metals in the electrolyte, a low zinc ion concentration, a low current density, and a high temperature. Taking these points into consideration, the following are the conditions which will favour zinc deposition: (*a*) high zinc concentration, say 60 grams/litre; (*b*) acid concentration not too high, but appreciable, say 0·01-0·1 n.; (*c*) complete absence of impurities less electropositive than zinc; (*d*) current density fairly high, say 1·2·5 amps/dm.^{2}; (*e*) good circulation; (*f*) low temperature.

If the current density be raised still higher, good current efficiencies can be obtained even with very high acid concentrations (150-200 grams/litre H_2SO_4). And if a small quantity of certain colloids be added to the electrolyte, the deposits are hard, bright, and satisfactory from a physical point of view. The presence of the acid increases the conductivity of the electrolyte and keeps the voltage within reasonable limits. Further, under these conditions, the deleterious effect of impurities in the electrolyte is much reduced. Such processes are now coming into use, current efficiencies of the order of 95 per cent being obtained with current densities of 20-50 amps/dm.^{2} in a sulphate electrolyte, the bath voltage being about five volts. Detailed descriptions have not been published, and the accounts apply to the older established processes. These can be divided into two classes, those using a sulphate and those using a chloride electrolyte. In the former case, the roasted ore is leached with dilute H_2SO_4, and the liquors, after purifying and almost neutralising with zinc oxide, circulated through lead-lined wooden vats and electrolysed between aluminium or zinc cathodes and lead anodes, the latter surrounded by closely fitting diaphragm bags. These anodes are not entirely satisfactory, and are best coated beforehand with a layer of PbO_2. Fe_3O_4 and electro-deposited MnO_2 have been tried with promising results. Working at 30°-35°, with a current density of 2-3 amps/dm.^{2} and a voltage of 3·5 volts, a ton of very pure zinc is obtained at an expenditure of about 3000 K.W.H. The extraction factor is considerably higher than when using the ordinary distillation processes.

Zinc chloride processes are also in operation, the electrolyte being prepared by roasting the ore with salt, or by treating the calcined ore with $CaCl_2$ solution in presence of CO_2. After careful purification, the liquors, slightly acidified with HCl, and carrying a small quantity of an addition agent, are electrolysed between graphite anodes and large revolving disc-shaped iron cathodes. Details of the plants now working are not known, but a cathodic current efficiency of 80 per cent is said to be obtained, using a current density of 3 amps/dm.^{2} and a voltage of about five volts. The losses are largely due to chlorine dissolved in the electrolyte. The metal produced is very pure. The energy expenditure amounts to about 5000 K.W.H. per ton.

§ (20) Tin Recovery.—The pyrometallurgy of this metal is very simple, and the only application of electrolysis needing mention is its use in the recovery of the metal from tin scrap, old tin cans, etc., of which it forms on the average 2 per cent by weight. Several electrolytic methods have been proposed, but only one is of importance—the Goldschmidt process—in which the scrap is made anode in a caustic soda solution, the dissolved metal being deposited on an iron cathode. The scrap is first broken up by cutting rolls, cleaned by a bath of hot NaOH, washed, and any solder removed by heating in a furnace. It is then packed loosely into iron cages which are suspended in iron tanks, the latter serving both as bath and as cathode. The electrolyte, which is kept at a strength of 8 per cent NaOH by continual regeneration, is heated to 70° by steam coils, and a current of about 80-100 amps/metre^2 of cathode passed through. The voltage is 1·5-2 volts per tank. The metal is mostly deposited in spongy form. After washing, pressing, and fusing, it is about 99 per cent pure, the remainder being chiefly lead. About 90 per cent of the tin in the scrap is thus recovered. The detinned material is sent to the steel-maker. The cathode current efficiency is perhaps 80 per cent, the deficiency being due to hydrogen discharge at the iron surface, which, as we have seen, has a low overvoltage.

The process is rendered possible by the fact that iron readily becomes passive in caustic soda solution. Otherwise it would dissolve preferentially to tin, being much more electropositive than this metal. In practice, owing to the presence of dissolved chlorides, a certain amount of solution does take place, with resulting fouling of the bath, but the chief process occurring, apart from solution of the tin, is oxygen evolution. The tin itself dissolves first as stannous ($Sn^{\cdot\cdot}$) ions. These are, however, rapidly oxidised by the oxygen to tetravalent tin ions, which are transformed in the electrolyte into sodium stannate, and the current efficiency given above is calculated on this basis.

§ (21) Nickel Extraction and Refining.—Much experimental work has been done on the extraction of nickel by electrolytic methods. The general difficulties encountered are similar to those already dealt with under copper and zinc, and it is only recently that real technical success has been achieved.

With regard to the anodic behaviour of the metal, we have already noted that it exhibits passivity phenomena to a marked degree. For every set of conditions, there is a limiting current density, above which the metal ceases to dissolve, and oxygen evolution begins. Cl' and $H^{\cdot}$ ions tend to activate the metal, and thus higher current densities are permissible in $NiCl_2$ than in $NiSO_4$ solutions, as also in acid than in neutral solutions. The differences shown by different types of anodes must also be recalled, electrolytic nickel dissolving least easily, then the rolled or worked metal, and cast metal the most easily. If the metal has been charged with hydrogen, either by treatment with acid, or by cathodic polarisation, its solution is considerably assisted. If the structure is not homogeneous, and some parts are more active than others, then it will dissolve unevenly, tend to fall to pieces, and will give slimes with high percentages of nickel.

As it is more electropositive than hydrogen, and as the hydrogen overvoltage at a nickel surface is very low, it cannot be quantitatively deposited from solutions containing much free acid. In the case of zinc we saw that by increasing the current density and thereby the hydrogen overvoltage, good current efficiencies could be got even from strongly acid solutions. In the case of nickel this is not possible, as irreversible effects, corresponding to passivity, occur during its deposition, necessitating a cathodic polarisation considerably more than the equilibrium value. This excess polarisation, like that of overvoltage, increases with the current density, and hence the effect of raising the latter is less than with zinc solutions. The same applies to lowering the temperature. A low acid concentration is therefore essential, a lower limit being set by the necessity of preventing basic salts separating out. This readily happens from neutral solutions. It stands to reason that the more electropositive metals, such as copper, must be absent from the electrolyte if a pure deposit is to be got. Iron and cobalt, if present, will be deposited, their electrochemical behaviour being very similar to that of nickel. One last point is that it is difficult to get thick deposits of nickel at room temperatures unless very low current densities are used. Otherwise the metal flakes off. This is of minor importance for the plater, but not so in winning or refining. The cause appears to be the presence of small quantities of iron in the electrolyte, deposited in slight excess at the start, and setting up strains. If the electrolyte and anode be perfectly iron free, or if the temperature be raised to 50°-60°, the difficulty disappears and high current densities can be used.

Copper and iron are the two impurities of most importance technically. If anodes are available fairly free from them, they can be used directly in a nickel bath, and the nickel plated out. At the Balbach refinery (U.S.A.) such a process, employing a nickel sulphate electrolyte, was in use for some years. The chief impurity in the anodes was carbon, which was satisfactorily separated in this way. The reason for abandoning the process was the difficulty of making homogeneous anodes. Those used were brittle, crumbled in the bath, and gave a very high percentage of slimes. In most processes, however, the copper and iron have been removed first by electrolytic and chemical means, and the purified nickel solution subsequently electrolysed, using insoluble anodes. In the Höpfner process the roasted ore was extracted with spent anode liquors (essentially a solution of $CaCl_2$, $NiCl_2$, and $CuCl_2$), and, after removing silver and iron chemically, furnished an electrolyte containing $NiCl_2$ and Cu_2Cl_2. This was electrolysed in a diaphragm cell between copper cathodes and carbon anodes. At the anodes Cu_2Cl_2 was oxidised to $CuCl_2$ the liquors then being returned to the leaching plant. In the cathode compartment copper was deposited. The last traces of this metal were removed chemically, and the resulting liquors electrolysed between sheet nickel cathodes and graphite anodes, giving chlorine and nickel of excellent quality. In the Savelsberg-Wannschaff process a matte containing nickel and iron, with only a trace of copper, is extracted with chlorine and a $CaCl_2$ solution. After purification the solution of nickel and iron chlorides is freed from iron by treatment with fresh ore whilst blowing in air, and the pure nickel solution electrolysed as above.

Using an electrolyte containing initially 100 grams/litre nickel, with a current density of 1 amp/dm.^{2} and four volts, a 93 per cent current efficiency is obtained. The product is very pure. One ton requires some 4000 K.W.H. In the Browne process anodes containing chiefly copper and nickel, with some iron and sulphur, were used in a chloride solution. They dissolved readily, copper being deposited on the cathodes. The liquors, charged with nickel, and containing also iron and some copper, were purified chemically and then electrolysed with graphite anodes as previously described. The current efficiency was about 93 per cent at 3·5 volts. The nickel was of excellent quality.

The Hybinette process successfully treats matte anodes with 65 per cent Ni, 30 per cent Cu, and 5 per cent S, arranged alternately with graphitised iron cathodes. Both anodes and cathodes are contained in canvas diaphragm bags. The electrolyte, a neutral $NiSO_4$ solution with 45 grams/litre nickel and traces of copper, is led into the cathode bags, and from there circulates through the tanks. With a current density of 1 amp/dm.^{2}, 3-4 volts are used, the liquors being heated. A product up to 99·9 per cent pure is obtained, the copper being separately recovered. About two-thirds of the anodes are consumed. The sulphur causes no difficulty.

§ (22) Iron Refining.—We have already discussed (Section V.) the conditions necessary for obtaining satisfactory electro-deposits of iron. It is only necessary to add here that, even before the war, iron was refined electrolytically on a large scale in Germany for use in transformer cores, etc., and that, during the war, this industry, owing to lack of copper, received a great impetus. Its great purity and ductility, when free from hydrogen, render it suitable for many purposes. To get the ductile material directly, electrolysis must be carried out at a high temperature.

§ (23) Lead Refining.—The extraction of lead, as of tin, is very simple and does not offer much scope for electrolytic methods. It is different with refining. In consequence of its high electro-chemical equivalent, the energy expenditure per ton of metal should be small. Further, the silver content of crude lead is an important source of this metal, its recovery by the usual refining processes is incomplete, and there are other valuable constituents, such as bismuth and antimony, which are not recovered at all. As a matter of fact, electrolytic lead refining is now well established, and a serious competitor of the older processes. Two methods are in use, one employing as electrolyte a solution of lead perchlorate, and the Betts process, using a lead fluosilicate solution. We shall deal with the latter only.

Lead is somewhat more electropositive than hydrogen. There is, however, no difficulty in depositing it from acid solution, owing to its high hydrogen overvoltage, which approaches the values given by mercury and zinc. The difficulty lies rather in the choice of a suitable electrolyte. The sulphate and the chloride are too insoluble. The nitrate is chemically attacked by metallic lead, and, further, would tend to dissolve any silver or copper present in the anode. In addition, it gives very crystalline non-coherent deposits, which form excrescent growths, causing short circuits between anode and cathode. Betts found that all these difficulties could be overcome by using lead fluosilicate, with the addition of free H_2SiF_6 to improve the conductivity. A sufficiently strong solution can be obtained, electronegative impurities, when present in normal quantities, do not dissolve at normal working current densities, and a coherent deposit, which shows no treeing effect, results. If, in addition, a trace of gelatine be added to the electrolyte, the deposit is fine and silky in texture, with no tendency to crystalline growths.

Technically, a bath with 75 grams/litre lead and 100 grams/litre free H_2SiF_6 is used, with the addition of not more than 1 gram/litre of glue or gelatine. The liquors are circulated by gravity through a series of tanks of tarred wood, each containing a number of paralleled anodes and cathodes, alternately arranged. Anodes are wedge-shaped, thicker at the top than at the bottom, and their lugs rest on the positive copper bus-bars. The cathodes are thin sheets, cast from electrolytic lead, and are suspended from copper rods. At a current density of 0·8-1 amp/dm.^{2} and a temperature of 30°-35°, the initial voltage is about 0·25 volt, rising to 0·4 volt as the anodes dissolve, owing to the increased resistance of the slimes. A very pure lead is obtained at 90 per cent current efficiency and an expenditure of 100 K.W.H. per ton. The slimes retain the form of the original anodes, of which they form a rather high proportion. Together with 10 per cent lead, they hold practically all the silver, bismuth, antimony, arsenic, tin, and copper, together with adsorbed electrolyte, and their subsequent working up is important. Zinc and iron chiefly accumulate in the electrolyte. In addition, the latter gradually loses its acidity, and the gelatine is continually consumed. Periodical regeneration is therefore necessary. The disappearance of the acid is due to slow chemical action on the lead, the same factor being chiefly responsible for the loss in current efficiency.

The chief advantages of the Betts process are the production of metal free from bismuth and antimony, the recovery of these metals, and the increased silver recovery. The process

can, moreover, be conveniently used on a small scale.

VII. Electrolysis of Brine

§ (24) General.—By passing a current through a solution of common salt, and suitably varying the conditions, a number of highly important products can be made, viz. caustic soda, chlorine, and the hypochlorite, chlorate, and perchlorate of sodium. If KCl be used, the corresponding potassium compounds result. Some of these chemicals are already made exclusively by electrolytic means, and the importance of such methods for the manufacture of the remainder continually grows.

The primary electrode reactions occurring when a brine solution is electrolysed between indifferent electrodes (platinum, graphite) are very simple. At the cathode, $H^{\cdot}$ ions are discharged and hydrogen liberated, the solution becoming alkaline. $Na^{\cdot}$ ions, owing to the very pronounced electropositive nature of the metal, are only deposited if their discharge is depolarised. At the anode Cl' ions are discharged and chlorine gas liberated. If the relations here were strictly reversible, we should get OH' ions discharged and oxygen formed. This, however, does not take place, as anodic oxygen evolution requires a very considerable overvoltage, far greater than that of chlorine. We obtain thus as primary products caustic alkali (with hydrogen as a by-product) and chlorine, and an apparatus which allows these substances to be collected and worked up separately is known as an alkali-chlorine cell. It is well known that, if brought together, they readily react, and that, according to the conditions, a hypochlorite or a chlorate will result. Both these reactions can be carried out inside the cell in which the primary products are formed, whilst, if the electrolysis be continued after the transformation of all the brine into chlorate, perchlorate will finally result.

In order to understand the principles underlying the design and construction of these types of cells, we must first discuss briefly the chemical reactions occurring between chlorine on the one hand and water or alkali on the other, and the different factors by which these reactions and their products can be modified. Chlorine, when passed into water or alkali, reacts according to the equation

$$Cl_2 + OH' \longrightarrow Cl' + HClO, \quad . \quad . \quad \text{(i.)}$$

the reaction proceeding the further the higher the temperature. About 30 per cent of the chlorine is hydrolysed in a saturated solution in water at 0°. The HClO produced is practically undissociated, but the solution reacts acid owing to the presence of $H^{\cdot}$ ions produced in equivalent quantity to the Cl' ions. If caustic alkali be used instead of water, one equivalent being present to a molecule of chlorine, the reaction is almost complete in dilute solution, though in stronger solution both chlorine and free alkali can be detected. If now more alkali be added, it will react with the HClO, and if the new addition amount in all to another equivalent the total equation will practically be

$$Cl_2 + 2OH' \longrightarrow Cl' + ClO' + H_2O \quad . \quad \text{(ii.)}$$

or

$$Cl_2 + 2NaOH \longrightarrow NaCl + NaClO + H_2O \quad \text{(iii.)}$$

the amount of free HClO in such a solution being very small. The hypochlorite solutions in this form are fairly stable. They can, however, slowly decompose, particularly on raising the temperature, in two ways, one of which (equation (x.)) is for us of minor importance. The other reaction, on the contrary, is very important, has been carefully investigated, and proceeds as follows:

$$2HClO + ClO' \longrightarrow ClO_3' + 2Cl' + 2H^{\cdot}. \quad \text{(iv.)}$$

It will be seen that the hypochlorous oxygen disappears, and that chlorate results, also that, as $H^{\cdot}$ ions are produced, which will at once regenerate HClO from the ClO' ions, the concentration of the HClO will remain practically constant throughout, only the ClO' ions disappearing. So that the net result of the reaction will be

$$3ClO' \longrightarrow ClO_3' + 2Cl'. \quad . \quad . \quad \text{(v.)}$$

If the differential reaction velocity equation for (iv.) be written, it will be clear that the concentration of the HClO is of more importance than that of the ClO' ions in determining the rate of reaction, and it is precisely this substance which is present in such low concentration in a solution prepared according to (iii.). If, however, a small extra amount of HClO be present, this means a large *relative* increase in the HClO concentration, and will greatly increase the velocity of the reaction. This can be done by adding a little HCl or a slight excess of chlorine, the HClO coming respectively from the ClO' ions or from the OH' ions of the water. Such a solution, whether at a high or a low temperature, will give chlorate far more quickly than the solution resulting from (iii.).

§ (25) Hypochlorites. (i.) *Theory.*—The above discussion has put us in a position to consider the reactions taking place in hypochlorite electrolysers or electrolytic bleach cells. In such cells, brine is electrolysed without a diaphragm between indifferent electrodes, the object being to obtain a high hypochlorite concentration at as high an

efficiency as possible. Any formation of chlorate is to be regarded as a loss. The primary products of electrolysis, one molecule of chlorine to two molecules of caustic soda, mix with one another, and reactions (i.) and (ii.) take place. The result of the passage of two faradays of electricity through the cell is, in theory,

$$NaCl + H_2O \longrightarrow NaClO + H_2. \quad . \quad \text{(vi.)}$$

At low temperatures, the chemical decomposition of such a hypochlorite solution is very slow, and it should therefore be possible to obtain a saturated solution of the same. At both anode and cathode, however, disturbing electrode reactions play a part. The ClO' ions are readily reduced at the cathode, whatever the material of the latter, to Cl' ions by nascent hydrogen.

$$2ClO' + H_2 \longrightarrow 2Cl' + H_2O. \quad . \quad \text{(vii.)}$$

As the concentration of NaClO rises, so does the rate of reduction, until finally this will tend to equal the rate of production according to (iii.), and the yield will fall to zero. In practice, this is very largely avoided by the addition of some Na_2CrO_4 to the electrolyte, its action being ascribed to the formation of a thin diaphragm of chromium chromate around the cathode, which prevents the diffusion of ClO' ions to the surface of the latter. Other addition agents are also in use technically, with equally satisfactory results.

At the anode, ClO' ion discharge will begin when its concentration in the electrolyte has reached a certain value. It takes place in a somewhat unusual manner, according to the equation

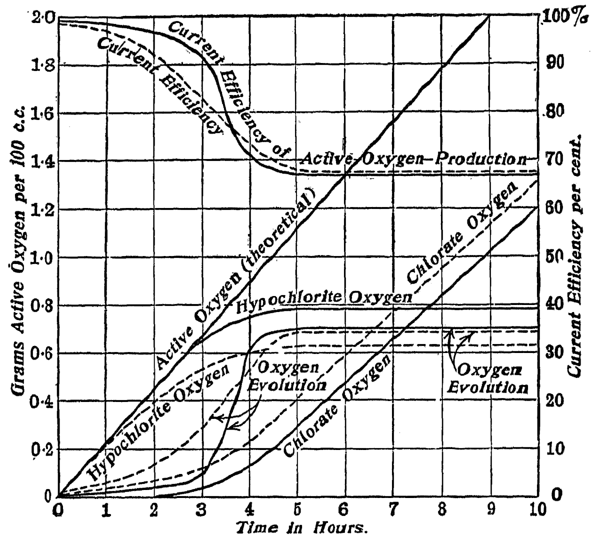

FIG. 2.

$$6ClO' + 3H_2O \longrightarrow 6H^{\cdot} + 2ClO_3' + 4Cl' + 1\tfrac{1}{2}O_2 + 6\ominus \quad \text{(viii.)}$$

the $H^{\cdot}$ ions subsequently neutralising the OH' ions produced in equivalent amount at the cathode. Unlike the cathodic reduction, it is not possible to eliminate this anionic discharge as a source of loss of hypochlorite. So, as the concentration of the latter increases, it will approach a limit at which the rate of its formation according to (iii.) becomes equal to its rate of disappearance in accordance with (viii.), assuming cathodic reduction to be negligible. The six ClO' gram-ions discharging in equation (viii.) require the passage of twelve faradays of electricity for their formation. On discharge, they furnish for the passage of six faradays, six atoms of chlorate oxygen and three atoms of molecular gaseous oxygen. At the stationary state then, we shall have a system of constant hypochlorite concentration, in which sodium chlorate is being formed in increasing concentration at 66·6 per cent current efficiency, the remaining 33·3 per cent of the current giving gaseous oxygen. The net cell equation for this complex of reactions is

$$9H_2O + 2Cl' \longrightarrow 9H_2 + 2ClO_3' + 1\tfrac{1}{2}O_2. \quad \text{(ix.)}$$

The value of the NaClO concentration at the stationary state will depend on several factors. A high NaCl concentration means a smaller anodic polarisation, and therefore a higher hypochlorite concentration before ClO' ion discharge takes place. A high current density causes efficient mixing owing to gas evolution, and prevents a local concentration of ClO' ions around the anode, followed by their premature discharge. Further, the condition of the anode exerts an influence. Cl' ion discharge takes place at a much lower potential at a platinised than at a smooth platinum anode, and this favourably affects the NaClO concentration in the same way as does a high salt content. Lastly, a low temperature is favourable. Otherwise, on cooling down from the temperature of electrolysis, there will be a re-formation of chlorine and alkali in the sense of equation (ii.) read from right to left. The influence of these factors is shown in *Fig.* 2 and the table on following page. The former exhibits the results obtained during a ten-

hours' electrolysis of a brine solution with anodes of smooth platinum (dotted curves) and platinised platinum (full curves). The conditions are otherwise identical.

Concentration of NaCl.	Temperature.	Anodic Current Density in Amps. cm.^{2}	Grams of Hypochlorite Oxygen per 100 c.c.

The most favourable electro-chemical conditions for the production of a concentrated bleach solution are therefore: (*a*) strong brine, (*b*) low temperature, (*c*) high anodic current density, (*d*) chromate in electrolyte, (*e*) platinised platinum electrodes. In practice these conditions are modified. A strong brine means a high salt consumption, as only a fraction of the dissolved chloride is converted into hypochlorite. Owing to the high current densities and voltages, much heat is produced in the cells, and even artificial cooling cannot always keep the temperature as low as is otherwise desirable. And platinised electrodes are too fragile—the surface deposit readily drops away. In practice, moreover, solutions of moderate bleaching power suffice for most purposes.

(ii.) *Technical.*—A large number of technical electrolysers have been designed, mostly using bipolar electrodes. These allow of a compact design of apparatus and also avoid the use of exposed copper connections. This is important, as traces of copper compounds (also nickel and cobalt) catalytically decompose hypochlorite solutions with oxygen evolution, a reaction which in their absence proceeds at a negligible rate.

$$2NaClO \rightarrow 2NaCl + O_2 \quad . \quad . \quad . \quad (x.)$$

They of course present the drawback of shunt current losses and consequent diminished current efficiencies, particularly serious in the present case owing to the comparatively high voltages employed. We will describe two forms only, which are typical of the remainder, and demonstrate the points brought out in the above discussion.

The Kellner cell is shown in *Figs.* 3 and 4. It consists of a long cement trough, open at the top, and divided by a series of glass walls into a number of chambers arranged terrace-wise. The brine circulates through these chambers by gravity, is cooled, and pumped back again until the required concentration has been reached. The bipolar electrodes are of platinum-iridium network, making connection under the glass separators, and kept in position by glass rods. The anode half lies very close to the bottom of the cell, the cathode half about 5 mm. above the anode. A 220-volt 60-ampere unit will have 36 such compartments. The electrolyte is 15 per cent brine with some addition to avoid cathodic reduction. The temperature of the entering liquors is about 21°. The highest concentration obtainable is about 50 grams/litre of active chlorine, at an expenditure of 9·3 K.W.H. per kilo. of chlorine. Normally the cell is worked to give a solution with 25 grams/litre of active

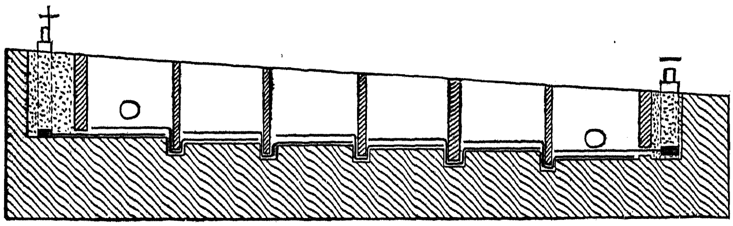

FIG. 3.—Kellner Cell (Side Elevation).

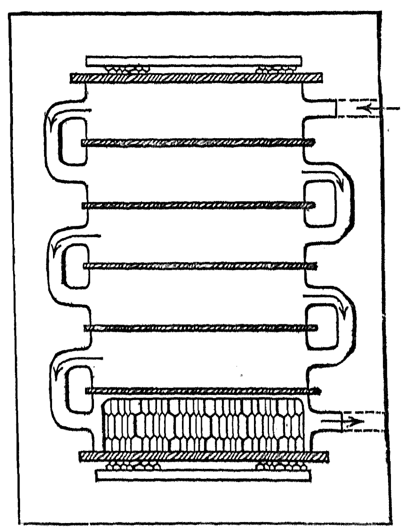

FIG. 4.—Kellner Cell (Plan).

chlorine, at an energy expenditure of 6 K.W.H., and a salt consumption of 4 to 6 kilos. per kilo.

The Haas-Oettel cell (*Figs.* 5 and 6) also uses bipolar electrodes but of carbon, not platinum. It consists of an earthenware trough, open at the top, and divided into compartments by vertical plates of hard carbon or graphite *a a a*, current being led in and out of the end plates. From each side of the trough projects out a series of open earthenware channels *d d d*, corresponding to the cell compartments and separated from one another by earthenware ribs. They serve

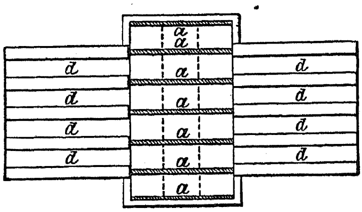

FIG. 5.—Haas and Oettel Cell (Plan).

as outlets for the liquors from the different chambers. The base of the trough contains an entrance for the brine, common to all the compartments. The electrolyser stands in an outer vessel, containing brine up to a level rather lower than that of the discharge channels. This outer tank is provided with cooling coils. When the current is switched

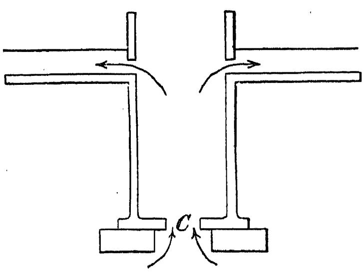

FIG. 6.—Haas and Oettel Cell (End Elevation).

on, the gas evolution discharges the liquors through the side channels into the outer tank, fresh cooled brine entering underneath. The circulation is thus effected and regulated by the electrolysis. With 17 per cent brine, one kilo. of active chlorine at a concentration of 12 grams/litre can be obtained at an expenditure of 14 kilos. of salt and 6·4 K.W.H. In spite of the lower overvoltage at the electrodes the results are seen to be much less favourable than those given by the Kellner electrolyser. This is due to the absence of any "cathode diaphragm" addition agent, and to rather high shunt current losses. The current efficiency in the case quoted is only 46 per cent. The apparatus has, however, the advantage of a far smaller first cost.

Electrolytic bleaching liquors are coming into increasing use for many kinds of fine work. They act rapidly, do not expose the fabric to acid or alkali, can readily be prepared, and their composition can be exactly and reliably regulated.

§ (26) CHLORATES. (i.) *Theory.*—We have studied the possibilities which occur when a neutral brine solution is electrolysed, and the catholyte and anolyte mixed, and have seen that chlorate can result in two ways, viz. chemically,

$$2HClO' + ClO' \longrightarrow ClO_3' + 2Cl' + 2H^{\cdot} \quad \text{(iv.)}$$

and electrochemically,

$$6ClO' + 3H_2O \longrightarrow 2ClO_3' + 4Cl' + 6H^{\cdot} + 1\tfrac{1}{2}O_2 + 6\ominus. \quad \text{(viii.)}$$

These two reactions form the basis of the two classes into which technical chlorate processes can be divided, viz. the *acid* and the *alkali* processes respectively, and before we proceed further, we must discuss the respects in which the electrolysis of a brine solution is modified if, instead of being neutral, it is acid or alkaline.

If the original solution is slightly acid, the concentration of the free HClO produced on electrolysis is, as we have seen, proportionately greatly increased. So is the rate at which reaction (iv.) proceeds. If, in addition, the electrolysis is carried out at high temperatures —70° or over—this formation of chlorate becomes very rapid, quite dwarfing the production by ClO′ ion discharge. The concentration of the latter indeed at the stationary state is very small. If, further, chromate be added to avoid any residual cathodic reduction, and a platinised platinum electrode be used, practically a 100 per cent current efficiency of chlorate oxygen should result, as no oxygen is evolved at any stage. In practice, using smooth platinum anodes, a 90 per cent current efficiency is obtained, the deficiency being due to ClO′ ion discharge.

If, on the other hand, a solution containing free alkali is used, the ClO′ ion concentration, *particularly at the anode*, is increased. Its discharge commences at a lower hypochlorite concentration *in the bulk of the solution* than is the case when using neutral brine. The more alkali added, the smaller the ClO′ ion concentration at the stationary state, until a very low figure is reached. Still more alkali results in the production of oxygen by OH′ ion discharge, and the chlorate current efficiency, never above 66 per cent, falls. *Fig.* 7 shows the dependence of hypochlorite and chlorate production on the initial alkali concentration when a given quantity of electricity is passed through 20 per cent

brine solution at 5°. Other factors which assist anionic discharge at a low anode potential by reducing the overvoltage, will also decrease the chlorate yield, lead to in-

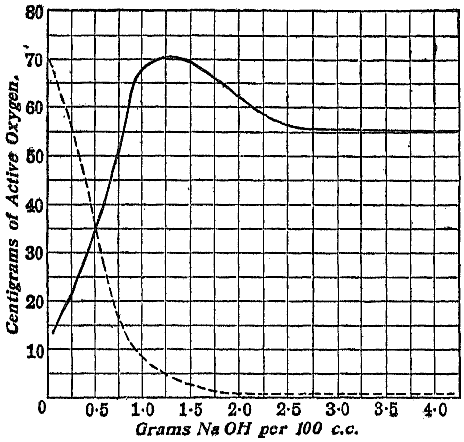

FIG. 7.

Dotted Curve—Hypochlorite: Full Curve—Chlorate.

creased OH′ ion discharge and to higher equilibrium hypochlorite concentrations. Such are the use of platinised instead of polished platinum electrodes, a low current density, and an increased temperature. These points are brought out in the following table and in *Fig.* 8.

Anode.	Anodic Current Density.	Current Evolving Oxygen.	Grams of Chlorate Oxygen.	Grams of Hypochlorite Oxygen.
	amps./cm.²	per cent.		
Platinised	0·067	75	1·049	0·087
Smooth .	0·067	58	1·639	0·0012
Smooth .	0·017	58	1·586	0·0032

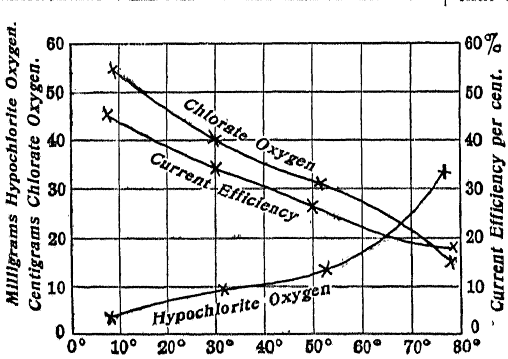

FIG. 8.

The conditions for the successful operation of the alkali process are therefore (*a*) low temperature, (*b*) a polished platinum electrode, (*c*) fairly high current density, (*d*) 1-1·5 per cent NaOH in brine, (*e*) chromate to prevent cathodic hypochlorite reduction. In practice, the alkali processes, with their maximum possible 66 per cent current efficiency, have been almost entirely discontinued, although they were the first introduced, and were used for many years.

(ii.) *Technical.*—The acid processes are usually carried out in long rectangular iron or cement cells, carefully insulated, and arranged in terraces to permit of gravity circulation. They contain a row of anodes between two rows of cathodes, like electrodes being paralleled. Such a bath will take 1000-1500 amperes. The anodes are of smooth platinum-iridium foil, the cathodes of graphite or of iron. The electrolyte contains originally 25-30 per cent KCl or NaCl and about 10 grams/litre $K_2Cr_2O_7$, and is kept at the right acidity by constant small additions of HCl. The anodic current density is 20 amps/dm.² and the temperature 70°-95°. Depending on this last factor, the voltage can vary between 4·5 and 5·5 volts. Chlorate formation proceeds very rapidly at these temperatures. The liquors are circulated until near saturation, drawn off and crystallised. With 90 per cent current efficiency and five volts, one ton of $KClO_3$ will require about 7300 K.W.H., which corresponds to a 25 per cent energy efficiency.

§ (27) PERCHLORATES.—If a brine solution which has already been converted into chlorate be further electrolysed under conditions at which the anode potential is very high, further oxidation to perchlorate takes place, the total anodic reaction being

$$ClO_3{}' + H_2O \longrightarrow ClO_4{}' + 2H^{\cdot} + 2\ominus.$$

At the cathode, $H^{\cdot}$ ions are discharged, so that the cell reaction is

$$ClO_3{}' + H_2O \longrightarrow ClO_4{}' + H_2.$$

The necessary high anode potential can be obtained by using a smooth platinum anode, a high current density, and a low temperature. The last condition also means a low electrolyte conductivity, so, in practice, the bath is frequently run at 30°-50° C., and the current density raised still further. This has the advantage of utilising the expensive platinum to the best advantage. In order to prevent direct OH′ ion discharge, involving oxygen evolution and current loss, the electrolyte is best kept slightly acid. The chlorate concentration is as high as possible in order to reduce the resistance, and consequently the very soluble $NaClO_3$ is used in practice, not $KClO_3$. Initially it

contains 600-700 grams/litre, and current is passed until conversion is almost complete. Iron cathodes are generally used. As the ClO_3' ions are readily reduced at this metal to Cl' ions, chromate is added to the electrolyte. With good circulation and an anodic current density of 45-50 amps/dm.^{2} practically complete conversion can be obtained with an 85-90 per cent current efficiency and an average voltage of six volts. The energy used is 3·2-3·6 K.W.H. per kilo perchlorate. Towards the end of the electrolysis, large quantities of ozonised oxygen are produced. There is a slight loss owing to cathodic reduction, and the final liquors contain some chloride. The electrolyte needs a regulated addition of acid throughout.

§ (28) ALKALI-CHLORINE CELLS. (i.) *Theory.*—In these cells the problem is, not how most efficiently to bring about the combination of the primary anodic and cathodic products of brine electrolysis, but how best to keep them apart, and the influence of such factors as electrode material, concentration, current density, and temperature on their exact nature must first be considered.

Normally we have seen that $H^{\cdot}$ ions, not $Na^{\cdot}$ ions, are discharged cathodically when a brine solution is electrolysed. If, however, a cathode is used which will depolarise the $Na^{\cdot}$ ion discharge by forming a sodium alloy, and which at the same time opposes a considerable overvoltage to $H^{\cdot}$ ion discharge, the reverse can take place. Mercury is such a cathode material, and is in fact used as cathode in a certain class of alkali-chlorine cells, the alkali amalgam being subsequently decomposed with water outside the cell. A high salt concentration obviously assists $Na^{\cdot}$ discharge, and is therefore favourable. So are a high current density and a low temperature, as the hydrogen overvoltage is thereby increased. With the more usual type of cell, on the other hand, we wish to reduce the hydrogen overvoltage, and from this point of view a low current density and high temperature are advantageous.

At the anode we have relations qualitatively similar to those discussed in the preceding section of this article. The liberated chlorine forms HClO with the water, and this furnishes ClO' ions, particularly if any alkali (formed at the cathode) is present. These ClO' ions can be discharged, producing ClO_3' ions and oxygen, and it has been shown that HClO can act anodically in a similar way.

$$6HClO + 3H_2O + 6\oplus \longrightarrow 2ClO_3' + 4Cl' + 12H^{\cdot} + \tfrac{3}{2}O_2.$$

There is in addition the possibility of OH' ion discharge, occurring the less easily the more acid the solution. In practice it is found that, as would be expected, the lower the concentration of the Cl' ions, the smaller the proportion of current concerned in their discharge, and the lower the chlorine current efficiency. On the other hand, the fraction of current concerned with OH' ion discharge increases with decrease in electrolyte concentration, owing to the accompanying rise in the anode potential. Finally, the concentration of hypochlorite and the fraction of current producing chlorate at first increase as the brine solution is made more dilute, pass through maximum values, and then decrease. Figures for the electrolysis of an HCl solution, which shows a similar behaviour, are given below:

Concentration of HCl.	Percentage of Current giving Chlorate Oxygen.	Percentage of Current giving Oxygen Gas.
1·0 *n*	1·04	0·9
0·33	6·54	9·7
0·1	34·62	34·4
0·033	26·50	53·6

The nature of the anode (platinum, magnetite, and graphite are used) is also important in this connection. At platinum or magnetite we have higher overvoltages for Cl' or OH' discharge than at graphite, and hence ClO' ion discharge and chlorate formation are facilitated. On the other hand, at graphite, though there is less chlorate formation, OH' ion discharge is proportionately easier, and takes a larger fraction of the current, which is augmented by the porosity of the material. Electrolysis takes place, not only at the surface of the electrode, but also inside its pores. The electrolyte there soon gets depleted of Cl' ions, and oxygen evolution commences. Not only is there a current loss, but the electrodes are attacked, with CO_2 formation and subsequent disintegration. This circumstance has in the past been very troublesome.

A rise in temperature is found experimentally somewhat to decrease chlorate formation. But on the other hand it facilitates OH' ion discharge and also (with graphite anodes) CO_2 formation. It is advantageous to have it low. The current density is determined more by the nature of the anode than by other considerations. With the expensive metal platinum it must be high on account of interest charges. With magnetite it may be low, which is favourable from the point of view of voltage. With a carbon anode which is at all porous it should be high, as the greater part of the electrolysis will then take place on the surface of the cathode, not in its pores. The better the quality of the electrode, the lower it can be.

The best conditions for getting a pure chlorine gas at high current efficiency are

therefore (*a*) non-porous anode, (*b*) strong brine, (*c*) high current density, (*d*) low temperature.

There are two main reasons which tend to cause the cathodic alkali and the anodic chlorine to mix and interact. Such mingling may be due to convection and the mixing effect of the gas evolution. This can satisfactorily be counteracted by a diaphragm between catholyte and anolyte. More important is the electrical migration of the negative OH' ions from the catholyte towards the anolyte. They will share with the Cl' ions in the transport of negative electricity in a proportion determined by their concentration and ionic mobility. The latter is nearly three times as great as for the Cl' ion, and consequently, in strongly alkaline solutions, the greater part of the negative current will be carried by the OH' ions, which will at once disappear when they reach the anode. The only way of counteracting this is by causing the electrolyte to flow steadily from the anode towards the cathode. Losses in alkali will then be determined by the amount of chlorine dissolved in the anode liquors, which is relatively small, less in a brine solution than in pure water. All modern cells, except mercury cells, are of this type, some with diaphragms, some without. We can therefore classify alkali-chlorine cells as follows:

Mercury cells.

Counter-current cells with diaphragm.

Counter-current cells without diaphragm.

(ii.) *Mercury Cells.* (*a*) *General.*—Owing to the practically complete exclusion of alkali from the anolyte of these cells, their electrochemical theory is very simple. At the mercury cathode $Na^{\cdot}$ or $K^{\cdot}$ ions are discharged, forming a dilute amalgam. In the case of sodium a 0·5 per cent amalgam can on no account be exceeded, and technically it is far lower. In order to prevent $H^{\cdot}$ ion discharge, a high cathodic current density, with high overvoltage, must be employed. This varies in practice between 5-25 amps/dm.^{2}, and is generally over 12 amps/dm.^{2}. At the anode, the potential is determined by the Cl' ion discharge. With platinum, current densities are necessarily high, and so is the overvoltage. With graphite, low current densities and voltages can be employed. The temperature of the electrolyte must not be too high, as the cathodic overvoltage would thereby be destroyed, and also appreciable chemical action would take place between the amalgam and the brine solution. In practice 50° C. is rarely exceeded. The necessary heat is supplied by the ohmic resistance of the electrolyte. The total cell voltage averages about five volts using platinum anodes, and 4·3-4·5 volts with graphite. The electrolyte, originally containing 30 per cent of dissolved salt, has only 20 per cent when it leaves the cells for re-saturation. It should be free from iron and calcium salts, and, if graphite anodes are used, from sulphates, which tend to give anodic oxygen.

The current efficiencies in these cells are of the order of 95 per cent for both alkali and chlorine, and are rather higher with platinum than with graphite anodes. The cathodic deficiency is mainly due to hydrogen evolution. This can happen either by chemical action between the solution and the amalgam, or by direct $H^{\cdot}$ ion discharge. Both processes are favoured by high temperature and by a too slow rate of removal of the amalgam from the cell. The second source of loss is also increased if the brine solution is too weak or the current density too low. The difference between cells using graphite and those using platinum electrodes is due, firstly, to the anodic production of small quantities of acid at the former, and, more important, to small particles of carbon falling on to the mercury surface, and, with their low overvoltage, facilitating $H^{\cdot}$ ion discharge and amalgam decomposition. At the anodes there is a certain amount of oxygen evolution, particularly if they are of graphite, when some CO_2 will also be formed. Lastly, directly affecting both anodic and cathodic processes, we have chemical action between dissolved chlorine and the mercury. A chloride of mercury will be formed, dissolve in the brine, and at once be decomposed, the net result being simply a current loss. Owing to these causes, the anode gases will always contain some hydrogen and oxygen. If graphite is used, the hydrogen content may amount to as much as 2-3 per cent, with the same amount of CO_2. Platinum electrodes give a far purer gas.

(*b*) *Castner Cell.*—The differences between the various mercury cells lie essentially in the means used to remove and decompose the amalgam. In the original mercury cell designed by Castner this was effected by rocking the whole cell, and decomposing the amalgam electrochemically, making it the anode in a caustic soda solution, when the sodium dissolved, and hydrogen was evolved at the iron cathode. Such an amalgam decomposition cell is a *primary* cell, furnishing current, and Castner's idea was that, by coupling it against the brine cell, the impressed voltage required for the latter would be materially reduced. His apparatus took the form of a slate box, divided into three compartments by two vertical partitions reaching nearly to the bottom of the cell (*Fig.* 9). A layer of mercury was put into the box, and by gently rocking the cell by means of an excentric, could be made to flow from one compartment to another underneath the partitions. The

two outer compartments were closed above and contained the graphite anodes, by which the positive current entered. The open middle compartment contained an iron grid cathode by which current left the cell. Brine flowed continually through the outer compartments, and water entered and caustic soda left the middle one. On passing the current, the mercury, charged with sodium, was passed by means of the rocking motion into the middle chamber, where it was denuded and returned to the brine compartments. Owing to the current efficiency in the latter being only 90-92 per cent, it was found necessary to shunt about 8-10 per cent of the current through a resistance placed in parallel with the middle compartment, as otherwise mercury went into solution there and gave a deposit of mercurous oxide. These cells required comparatively little mercury, but their small size and complicated design led finally to their abandonment.

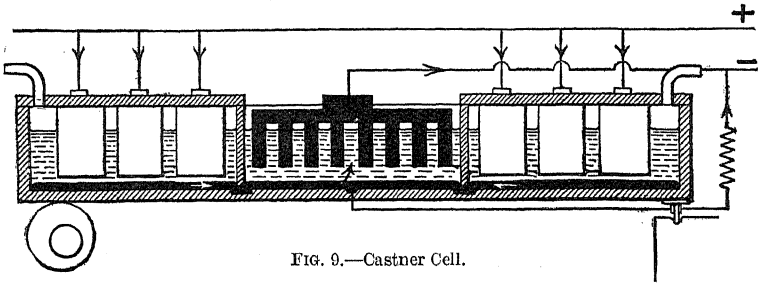

FIG. 9.—Castner Cell.

(c) *Kellner Cells.*—In the various types of Kellner cell the circulation is effected by more simple means, and no attempt is made to reduce the voltage by utilising the energy of the sodium amalgam, the latter being simply short-circuited by iron or graphite in contact with water. The Kellner-Solvay cell (*Fig.* 10) consists of a large cement trough, through which continually flow a stream of brine and a thin layer of mercury, the fresh brine entering just above the mercury. The platinum wire-net anodes are close above the anode surface. Current density and rate of flow are so chosen that the amalgam is charged to the right degree on leaving the cell. It passes by gravity into a separate adjacent trough of iron, where it is decomposed to concentrated alkali by a stream of water, the regenerated mercury returning to the cell by means of a well-wheel. The Castner-Kellner cell is similar in design, but uses graphite anodes, and the mercury is circulated by means of an Archimedean screw. The Kellner-Jaice cell (*Fig.* 11) consists of a long shallow cement trough, divided by partitions as in the original Castner rocking cell. In this case, however, the middle compartment contains the platinum anodes, carried by a series of cement hoods, whilst in the two outer compartments the amalgam is short-circuited by iron grids through which the negative current enters the cell. The circulation is effected by compressed air, applied by means of conical iron vessels dipping into mercury troughs situated at the ends of the cell, and in connection with the mercury cathodes. By alternately compressing and exhausting the air in these vessels the mercury is very efficiently driven from side to side of the cell. All these cells are simple in construction, large units can be built, and high current densities employed.

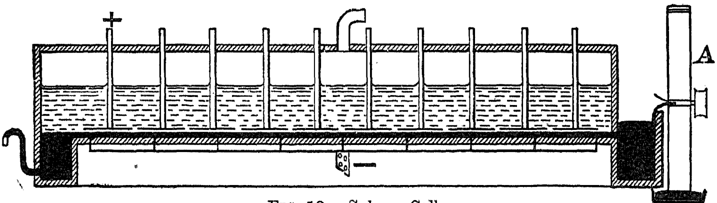

FIG. 10.—Solvay Cell.

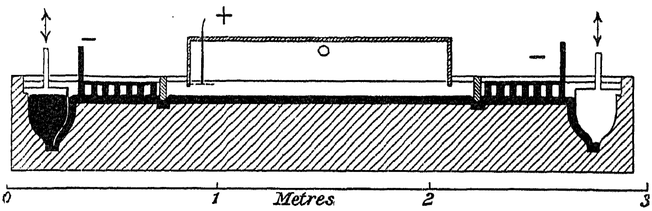

FIG. 11.—Jaice Cell.

The advantages of mercury cells are that

very concentrated and pure caustic liquors—up to 40 per cent NaOH—can be made, current efficiencies are high, and graphite anodes, when used, have a long life. On the other hand, voltages are high, and the first cost of an installation very considerable.

(iii.) *Counter-current Cells with Diaphragm.* (*a*) *General.*—In these cells, the OH′ ions formed at the cathode are prevented from reaching the anode by means of bodily moving the electrolyte towards the cathode, and at the same time mechanical mixing of anolyte and catholyte is eliminated by means of a suitable diaphragm. This permits of shortening the liquid layer between the electrodes, and hence a diminished resistance, which in practice is at least partially neutralised by the extra resistance of the diaphragm itself. More important is the fact that higher current densities can be used without mixing and that cells of compact construction can be more readily designed. The diaphragm can be arranged either horizontally, with the cathode below it, or vertically. With the former arrangement, if any alkali does happen to percolate through, there is less chance of its being lost by mixing with the bulk of the anode liquors. Further, and for the same reason, whilst the anode side of a vertical diaphragm is always in contact with an acid chlorine solution, with a horizontal diaphragm this may not be so. This is important from the point of view of durability as it is more easy to make alkali-resisting than acid-resisting diaphragms. On the other hand, a horizontal diaphragm sacrifices the compact cell construction referred to above, can less easily be changed, and, moreover, has a greater tendency to catch and filter out impurities in the brine, which in time will increase its resistance.

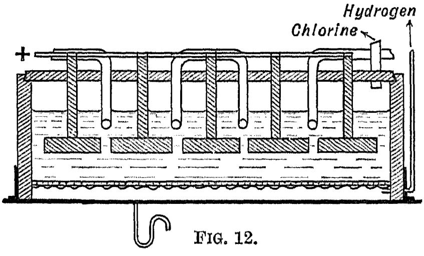

FIG. 12.

(*b*) *Billiter-Siemens Cell.* — Of the various cells with horizontal diaphragms, this is the only one needing mention, and is shown in *Fig.* 12. The active diaphragm material consists of a mixture of $BaSO_4$ and asbestos wool, spread out uniformly on a sheet of woven asbestos cloth. The whole rests on a sheet of heavy iron gauze (the cathode), in electrical connection with and supported about four inches above the bottom of a cast-iron shell, lined with chlorine-resisting brick. Such a diaphragm is of low electrical resistance, and very uniform in its permeability. The top of the cell is of cement, and carries the graphite anodes, the chlorine delivery pipe, and a number of glass U-tubes, the horizontal portions of which are arranged above the anodes, and through which hot brine solution flows in order to raise the temperature of the cell. Hydrogen and alkali are removed from the cathode compartment, the latter by means of a siphon overflow. Using concentrated purified brine, at a diaphragm current density of 4-6 amps/dm.^{2} and a working temperature of 85°, 3-4 N. alkali can be made at a current efficiency of 90-95 per cent and a bath voltage of 3·4-4 volts. The chlorine is pure, and the anodes very slowly attacked. Every few months the diaphragms must be remade and the cell cleaned.

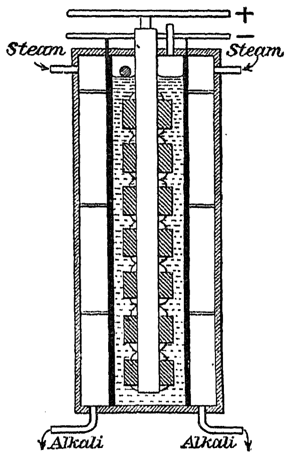

FIG. 13.—Hargreaves-Bird Cell.

(*c*) *Hargreaves-Bird Cell.* — This is the oldest of the cells with vertical diaphragms (*Fig.* 13). It consists of a large iron box, cement-lined, and divided by two cement-asbestos diaphragms into three compartments. The two outer compartments contain the cathodes in the form of an iron network in contact with and supporting the diaphragm. The inner chamber contains the carbon anodes, cemented in through the roof, which also carries the chlorine delivery pipe. Brine is led into the anode compartment, and percolates through the diaphragms to the cathodes. It is there charged with alkali, and is drawn off at the bottom. It is usual to supply steam and also CO_2 to the cathode compartments. The former heats the cell to about 85°, and lowers the voltage. The latter converts the caustic alkali into the less valuable carbonate, but also by destroying most of the OH′ ions, diminishes the losses due to their migration, and decreases the cell polarisation. A unit $10' \times 5' \times 2'$ will take about 2000 amps, and furnish 16 per cent Na_2CO_3 containing excess of salt at a current efficiency of 85-90 per cent and at a voltage of 3·5-4 volts. The diaphragms are not a good feature of the cell

design. They must be fairly dense, or else the flow of liquors would be too rapid. This means a high resistance. Secondly, the hydrostatic pressure increases from top to bottom and so also the rate of flow. If, at the top, the rate is just sufficient to counteract the migration of the OH′ ions, at the bottom it will be too great, and the resulting solution will be unnecessarily weak.

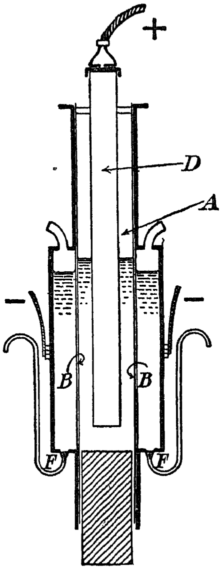

Fig. 14.—Townsend Cell.

(*d*) *Townsend Cell.*—This cell (*Figs.* 14 and 15) marks a distinct improvement on the above, both in design and performance. The central anode chamber A is of cement, and is provided with channels for entry of brine and for exit of chlorine, as also for cleaning. On either side is bolted an iron cathode chamber *b*, of which the side facing the anode compartment consists of an asbestos diaphragm B in close contact with an iron grid C. The anodes D fill up the greater part of A. The feature of the cell is that the cathode compartments are filled with kerosene oil, at a rather lower level than that of the brine in A, which is regulated by E. This has two functions.

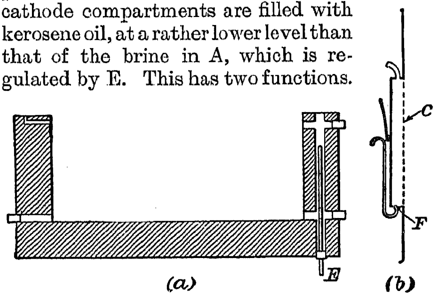

Fig. 15.—Townsend Cell.

It decreases the hydrostatic pressure difference between the two sides of the diaphragm, equalises it all the way down, and allows the diaphragm to be made of low resistance. Further, the alkaline cathodic solution does not remain in the neighbourhood of cathode or diaphragm. Owing to the surface tension effect, it at once forms spherical drops which are carried away by the hydrogen, and are finally collected at F and siphoned off. Losses owing to OH′ migration are avoided, and a high current efficiency, a strong caustic liquor almost free from chlorate, and a pure anode gas, almost free from carbonic acid, are obtained. A 2500-ampere unit measures 8′ × 3′ × 1′ and takes 15 amps/dm.^{2} at the diaphragms. 15 per cent NaOH can be made at 90-95 per cent current efficiency, and with 4-4·5 volts at the above current density. The working temperature is 50°-60°. Both diaphragms and anodes have a long life. The asbestos of the former is specially treated with a mixture of asbestos fibre, Fe_2O_3 and $Fe(HO)_3$, to ensure uniformity.

(*e*) *Nelson Cell.*—This (Fig. 16) will be described as a third typical cell. A 1000-ampere unit ($7\frac{1}{2}' \times 3' \times 1'$) consists of a rectangular steel tank, the outer cathode compartment, supporting a U-shaped perforated steel plate (the cathode), inside of which is spread

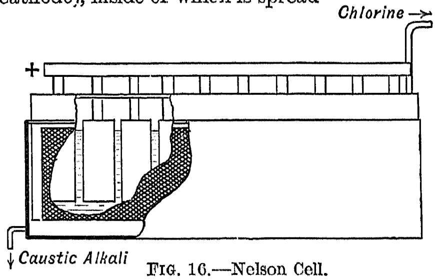

Fig. 16.—Nelson Cell.

the asbestos diaphragm. The cathode plate is closed at the ends by cement mortar blocks, and at the top by slate slabs, which in their turn carry the graphite anodes. The carefully purified brine is led into the anode compartment and percolates through the diaphragm into the cathode chamber. As in the Hargreaves-Bird cell, there is no opposing resistance to its passage. Steam is led into the outer compartment, and the caustic alkali drawn off at the bottom. 10-12 per cent NaOH is produced with a 90 per cent current efficiency and a voltage of 3·7 volts. The chlorine is 99 per cent pure. The anodes are specially treated and last for years, whilst the diaphragm has a life of 6-8 months.

(iv.) *Counter-current Cells without Diaphragm.*—Two cells only need be considered under this head—the Aussig "bell-jar" cell and the Billiter-Leykam "membrane" cell. They are so designed that the hydrogen and chlorine gas streaming away from the cathode and anode compartments respectively do not disturb the bulk of the electrolyte between the electrodes, and the rate at which the electrolyte streams towards the cathode is so chosen as just to overcome the movement of the OH′ ions with the negative current in the opposite direction. Neutralisation of the acid and chlorine from the anode by the OH′ ions will take place within a certain layer

between the electrodes. On the cathode side of this layer the solution will be alkaline, on the anode side it will contain acid and chlorine, and the maintenance of the neutral layer in a constant position is necessary if good current efficiencies and at the same time cathode liquors of a desirable alkali concentration are to be obtained.

(*a*) *Bell-jar Cell.*—The Aussig cell is shown diagrammatically in *Fig.* 17. The shallow rectangular bell jar A of sheet iron is lined with cement and carries a graphite anode which almost fills its cross-section. It further is provided with a pipe for leading off chlorine and is connected by two other tubes with the neighbouring bell jars in order to equalise the pressure. Some 25 such anode chambers are contained in a shallow cement trough. The brine enters each of them from above and is distributed evenly over the cross-section of the bell jar by means of a horizontal tube provided with a number of holes. The outer iron coatings of the bell jars serve as cathodes. All like electrodes in the one trough are connected in parallel. The caustic liquors are drawn off from the top of the trough and the "neutral" layers are formed inside and a little above the bottom level of the jars. Each bell jar takes 25-30 amperes, so the units are small. The current density is about 2 amps/dm.^{2}. 12 per cent NaOH can be made with a 90 per cent current efficiency and a bath voltage of four volts. The anodes last for years, the chlorine being very pure.

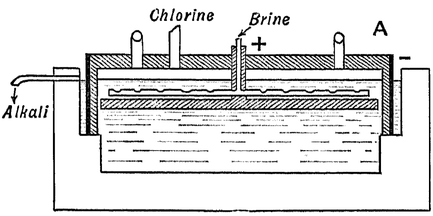

FIG. 17.—Aussig Cell.

(*b*) *Billiter-Leykam Cell.*—In this cell the above process has been modified in several ways. A large unit has only one bell jar instead of many. The distance between the electrodes is reduced by putting the cathodes beneath the anodes, disturbance of the neutral layer by hydrogen evolution being avoided by covering them with asbestos screens. These are diaphragms only in the sense that all the current must pass through them, but much of the electrolyte passes *between* adjacent cathodes and in any case the resistance of the "membrane" is very small. Finally, heat is applied by steam pipes (not shown in the diagram) and the cell is worked at 80°-90°. *Figs.* 18 and 19 explain the construction of this cell. A and B are of cement. The cathodes C are of T-iron, the asbestos tubes being braced above them by strips of non-conducting material. The most convenient current density in the bell jar is 5 amps/dm.^{2}. Making 15 per cent NaOH, a 90 per cent current efficiency at a bath voltage of 3·2 volts is obtained. The anodes have a long life and the asbestos tubes are practically unaffected by the electrolysis.

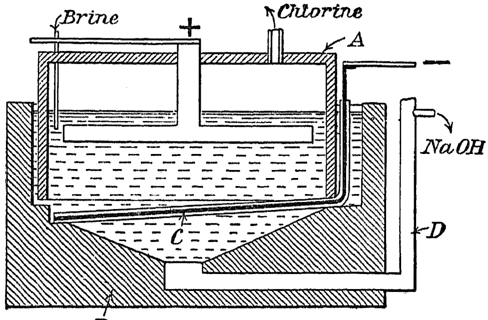

FIG. 18.—Billiter Bell-jar Cell.

It is unnecessary in both the above processes to purify the brine, and this is a very considerable advantage.

Considerations of space have made it necessary to omit various cells which, although efficient enough, have not yet found very extended use. Such are the Edser-Wildermann and Whiting mercury cells and the Allen-Moore and Finlay diaphragm cells. The important but inefficient Griesheim cell has also been omitted. The following table summarises the performances of those cells discussed. As a conventional theoretical voltage for the production of caustic soda and chlorine from brine, 2·3 volts has been taken.

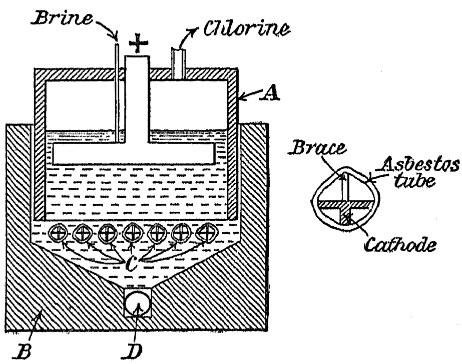

FIG. 19.—Billiter Bell-jar Cell.

VIII. Other Technical Electrolytic Processes employing Aqueous Electrolytes

The processes already dealt with are by far the most important technical applications of electrolysis of aqueous solutions, not only in respect of the substances produced, but also because of the amounts of energy utilised in their production. A few minor applications of electrolytic methods will now be discussed.

§ (29) Electrolytic Hydrogen and Oxygen.—Both these gases can be technically prepared more cheaply than by electrolysis, except where exceptionally cheap power is available. As, however, the use of the oxy-hydrogen flame has created a certain demand for the gases in the proportions in which they are liberated by the electrolysis of water, a number of technical electrolytic processes are in use. The electrolyte is usually 10-25 per cent NaOH, though 20 per cent H_2SO_4 is also employed. In the former case the conductivity is somewhat lower, but as iron electrodes can be used, whereas lead electrodes with considerably higher overvoltages must be used with the acid electrolyte, this disadvantage is more than compensated for. The gases produced are pure (97-99 per cent) and can readily be further purified. The current efficiency is nearly 100 per cent. With an alkaline electrolyte the voltages vary between two and three volts; with an acid electrolyte, between three and four volts. The theoretical decomposition voltage of water is 1·23 volts. Hence the energy efficiencies vary between 30 and 60 per cent.

The only well-known electrolyser using H_2SO_4 is that of Schoop (*Fig.* 20). In an outer lead-lined vat, containing the electrolyte, are partly immersed a number of vertical lead tubes, open at the bottom and perforated with a number of holes below and above the surface of the electrolyte, to allow of circulation of the same and to permit of the hydrogen being drawn off from the tops of the tubes. These form the electrodes, and are generally filled with fine lead wire to increase the active surface. Each is surrounded by a hood of clay or glass in order to collect the gases. Like electrodes are connected in parallel. 1000 cubic feet of hydrogen (plus 500 cubic feet of oxygen) require 230 K.W.H. With an alkaline electrolyte this is reduced to about 140 K.W.H.

Other processes employ an alkaline electrolyte. The Garuti electrolyser also uses hooded electrodes, in this case of iron, but in addition, the hoods themselves, insulated from the electrodes, are also of iron. By keeping the voltage below three volts, no decomposition occurs at their surfaces, and consequently no mixing of the gases. They are perforated near the bottom to facilitate circulation of the electrolyte. 1000 cubic feet of hydrogen require 160 K.W.H.

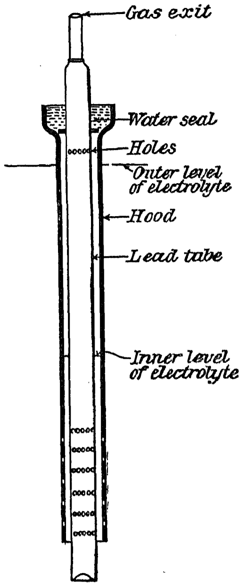

Fig. 20.
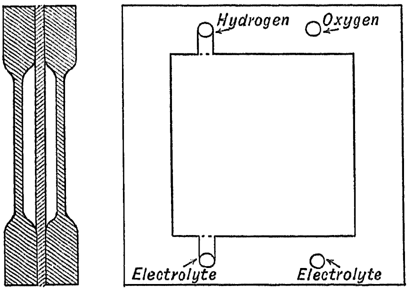
Schoop Electrolyser.

In the Schuckert apparatus, iron hoods are also used, and, in addition, unlike electrodes are separated by partitions of insulating material which extend from the top about three-quarters of the way down the cell. The resistance is correspondingly increased above that of the Garuti electrolyser, and 1000 cubic feet of hydrogen require 250 K.W.H.

The most efficient processes are probably those which make use of bipolar electrodes, the electrolysers being built up in filter-press form. In the Schmidt-Oerlikon apparatus (*Fig.* 21), designed for 110 volts, there are 40 bipolar electrodes, each taking the form of an iron plate with thickened edges or rims, so that when they are put together there

is a cavity in the middle of and between each pair of adjacent plates. This cavity is divided into two compartments, anode and



Cathode Compartment

FIG. 21.

cathode, by means of an asbestos diaphragm reinforced at the edges with rubber, which also serves to insulate the plates. By means of channels through the edges of the plates and diaphragms all like compartments are connected together for the purposes of introducing electrolyte and leading off gases. Current is led in and out of the two end plates. The voltage is low, as are also shunt current losses, and 1000 cubic feet of hydrogen require 150 K.W.H.

The electrolyser of the International Oxygen Company is very similar. By corrugating the electrodes, thereby increasing the surface, and by plating the anode sides with nickel, thereby still further reducing the overvoltage, the energy consumption is reduced to 125 K.W.H. per 1000 cubic feet of hydrogen. A unit designed for 120 volts will have 60 bipolar electrodes.

§ (30) PERMANGANATES. — Potassium permanganate is now almost exclusively made by electrolytic oxidation of the manganate. The latter is prepared by fusion of KOH and MnO_2 in presence of air.

$$MnO_2 + 2KOH + \tfrac{1}{2}O_2 \longrightarrow K_2MnO_4 + H_2O.$$

Formerly CO_2 was passed into the dissolved melt.

$$3K_2MnO_4 + 2CO_2 \longrightarrow 2K_2CO_3 + MnO_2 + 2KMnO_4.$$

It will be seen that a third of the manganese was reconverted into MnO_2, and that the alkali was turned into carbonate. In the electrolytic method no MnO_2 is formed, and caustic alkali, not carbonate, is regenerated. The anodic process is

$$MnO_4'' \longrightarrow MnO_4' + \ominus,$$

the cathodic process

$$H_2O \longrightarrow OH' + \tfrac{1}{2}H_2 + \oplus,$$

the total cell reaction therefore being

$$2K_2MnO_4 + 2H_2O \longrightarrow 2KMnO_4 + 2KOH + H_2.$$

In practice the electrolysis is carried out without a diaphragm, using sheet-iron anodes and iron-rod cathodes. The electrolyte contains 80-100 grams/litre of manganate, together with excess of alkali, and is kept at about 60°. The anodic current density is 9 amps/dm.^{2}, that at the cathode ten times as great, as cathodic reduction is thereby decreased. The voltage is 2·8-3 volts. The current efficiency falls off rapidly as conversion proceeds, owing to simultaneous cathodic reduction. With an average current efficiency of 67 per cent only one-third of the manganate is oxidised, about 0·7 K.W.H. being necessary per kilo of product. The power cost is thus negligible, which is probably the reason that the process, as technically described, is so inefficient. An improvement on the above figures has been shown by laboratory experiments to be easily possible.

In addition to the above process, permanganates have been prepared from time to time, particularly during the war, by direct treatment of ferro-manganese anodes in alkaline solution. The manganese goes into solution, whilst the iron remains undissolved. Diaphragm cells are employed to prevent reduction at the iron cathodes. Current efficiencies are poor and voltages high. One kilo of $KMnO_4$ requires about 30 K.W.H.

§ (31) CHROMIC ACID AND ANTHRAQUINONE. —The oxidation of anthracene to anthraquinone, used in alizarin manufacture, is frequently carried out by a solution containing H_2SO_4 and CrO_3, the latter being reduced in the process to $Cr_2(SO_4)_3$. Generally this is worked up and sent to tanneries, but sometimes the CrO_3 is regenerated electrolytically. The best-known process is that of Le Blanc. A cell is used divided into anode and cathode compartments by a special acid-resisting diaphragm. The electrodes are of lead. The spent liquors, containing 100 grams/litre Cr_2O_3 and 350 grams/litre of H_2SO_4, are fed into the cathode compartment, and leave by the anode compartment. At 50°, with 3·5 volts across the cell and an anodic current density of 3 amps/dm.^{2}, an 85 per cent current efficiency can be obtained, 87 per cent of the $Cr_2(SO_4)_3$ in the issuing liquors being oxidised. The process is simple, cheap, and effective. The lead anode soon becomes coated with a lead peroxide layer, and it is the latter which really effects the oxidation, being continuously regenerated electrochemically.

Chromic acid oxidises anthracene slowly compared with the rate at which its reduction product, $Cr_2(SO_{43})$, is reoxidised electrochemically. If, however, a rapid oxidising agent could be found which could also be readily regenerated anodically, the oxidation of anthracene could be carried out by suspending it in a solution of this substance as anolyte,

and passing a current. Such a substance, ceric sulphate, actually exists, and is used technically. It very rapidly and smoothly oxidises anthracene, being reduced to cerous sulphate, and the latter is readily reoxidised. The electrolyser, also acting as the anode, is a lead-lined vessel. The electrolyte is 20 per cent H_2SO_4 with 2 per cent $Ce(SO_4)_2$. The anthracene is suspended in this, and the liquors agitated and kept at 70°-100°. With an anodic current density of 5 amps/dm.^{2}, and about three volts on the bath, very pure anthraquinone is produced with practically the theoretical current efficiency.

§ (32) Persulphates.—Ammonium and potassium persulphates, which are themselves oxidising agents, and are also used to some extent for making H_2O_2, are prepared electrochemically by the oxidation at a high anode potential of the corresponding sulphates. The anode reaction is

$$2SO_4'' \longrightarrow S_2O_8'' + 2\ominus.$$

If OH′ ions are discharged, the yield will fall. From what has been already said, it is clear therefore that the first conditions for good yields are (*a*) smooth platinum anode, (*b*) high current density, (*c*) low temperature, (*d*) solution acid, or at any rate not alkaline. Further, as the S_2O_8'' ions are readily reduced, they must be kept from the cathode. In practice this is best done by the addition of a little K_2CrO_4, as in other processes. The electrolyte is a concentrated solution of $(NH_4)_2SO_4$ or $KHSO_4$. In the former case, H_2SO_4 must be continually added. With an anodic current density of 50 amps/dm.^{2}, a lead cathode, and an electrolyte kept below 15° by cooling coils, $(NH_4)_2S_2O_8$ can be made with a 70 per cent current efficiency and about seven volts across the cell. One kilo of the salt requires 2·4 K.W.H. The yield of $K_2S_2O_8$ is less good.

§ (33) Perborates.—Sodium perborate, $NaBO_34H_2O$, is a bleaching agent which has been coming into extended use during recent years. Usually it is made by the action of Na_2O_2 or H_2O_2 on $NaBO_2$, but electrolytic oxidation methods are also being employed with success. The electrolyte must be alkaline, as perborates are unstable in acid solution. Using a solution containing simply borax and NaOH, practically no perborate is produced. If, however, the NaOH be replaced by Na_2CO_3, and moderately strong solutions used, the salt can be produced with fair electro-chemical efficiencies. In practice a solution with 40 grams/litre borax and 120 grams/litre anhydrous Na_2CO_3 is electrolysed between a platinum gauze anode and a tin or aluminium cathode. The temperature should be kept below 18°, and this can be done by using a hollow cathode, and allowing water to stream through it. No diaphragm is used, but 0·1 per cent chromate is added. With an anodic current density of 100 amps/dm.^{2}, the bath takes about six volts. Either solutions of perborate or the solid salt can be prepared with satisfactory current efficiencies. The formation of perborate is probably a secondary one, sodium percarbonate being produced in the first instance.

§ (34) Iodoform.—This was formerly made by chemical interaction between iodine, alcohol, and an aqueous Na_2CO_3 solution.

$$C_2H_5OH + 8Na_2CO_3 + 5I_2 + 2H_2O \longrightarrow CHI_3 + 9NaHCO_3 + 7NaI.$$

It will be noted that 70 per cent of the expensive iodine goes to iodide and must be worked up again. Electrolytic methods avoid this loss, and are now almost exclusively used. The electrolyte consists of a solution containing alcohol, NaI and Na_2CO_3. The anode is smooth platinum and the cathode lead, surrounded by a parchment or other diaphragm. With an anodic current density of 1-2 amps/dm.^{2} and a voltage of 2-2·5 volts, very pure iodoform can be readily produced with a 90 per cent current efficiency. The successive reactions are—(*a*) electrolytic formation of alkali and hydrogen at the cathode and iodine at the anode; (*b*) partial interaction of these, giving hypoiodous acid (HIO) and sodium hypoiodite (NaIO); (*c*) substitution of the hydrogen of the alcohol by iodine, giving $CI_3 . CH_2 . OH$; (*d*) oxidation of this product by the hypoiodous acid to iodoform and CO_2.

The net result, expressed as an equation, is

$$C_2H_5 . OH + 3NaI + 3H_2O \longrightarrow Na_2CO_3 + CHI_3 + NaOH + 5H_2.$$

Fresh alcohol and NaI must be continually added, and the alkali formed neutralised by passing in a stream of CO_2.

IX. Fused Salt Electrolysis

§ (35) General.—Molten salts are good conductors of electricity, and their conduction is electrolytic. Consequently an electric current will decompose them, as it does when they are dissolved in water. There are, however, several important differences in the phenomena observed. The actual chemical decompositions brought about, owing to the absence of water and of consequent secondary reactions, are of a more simple nature than with aqueous solutions. The high temperatures used influence both current efficiency and voltage. The former tends to be adversely affected. Velocity of diffusion and of chemical reaction, as also vapour pressure, are all enormously increased, and unless anodic and cathodic products are very carefully separated from one another and from the action of the

electrolyte and the air, yields will be low. The higher the temperature the worse the yields, as has been many times shown. If the current density be increased, and therewith the rate of formation of the products at the electrodes, it is found that the current efficiency increases. This is natural, as vaporisation and diffusion losses are unlikely to increase in the same ratio. If the current density be very low and temperature high, however, the current efficiency may fall to zero. Apart from these sources of loss, there is another, peculiar to molten salt electrolysis —the so-called "metal fog" formation. A metal such as zinc or lead, if melted under a layer of one of its fused salts at a high temperature, is seen to give out dark clouds which apparently dissolve in the melted salt until a state of equilibrium has been reached. On cooling, they settle and are reabsorbed by the metal. The cause of this behaviour is to be sought in the surface energy relations between the molten salt and the molten metal. The former brings about peptisation of the latter, and produces from it a disperse phase, analogous to a dilute emulsion. Even very dark-coloured melts contain less than 0·1 per cent of metal, and quite a small quantity of an oxidising agent will destroy the colour. These phenomena will occur during fused salt electrolysis, and are a very important source of loss, as the peptised metal gets carried over to the anode, and is destroyed. It is interesting to note that the addition of certain other salts to the melt lessens or prevents "metal fog" formation, though the mechanism can hardly be the same as in the precipitation of colloids from aqueous solution. The effect of their addition is shown by a marked improvement in the current efficiency.

The voltage in fused salt electrolytic processes is affected in several ways by the high temperatures. The decomposition voltage necessary for a particular cell reaction is lower than that for the same reaction in aqueous solution at room temperature. The conductivities of the electrolytes used are higher. Further, the irreversible effects so common at the electrodes in the electrolysis of aqueous solutions practically disappear. From the point of view of voltage alone, therefore, there is much to be said in favour of high temperatures. One special effect only observed with fused salts must be noted—the "anode effect" remarked when carbon or graphite anodes are used in fused metallic halides at high temperatures. If the current density exceeds a certain value—about 4-5 amps/cm.^{2}. with hard carbon and 7-8 amps/cm.^{2} with graphite—the voltage rises very considerably and quickly, and the anode appears to glow. This is due to the electrode becoming covered with a film of gas, through which the discharge can only pass in the form of an arc. The phenomenon is general, most pronounced with fluorides, least so with iodides. It is sometimes accompanied by loss of weight of the carbon anodes, owing to formation of halides of carbon.

As far as possible fused salt baths are not externally heated, but the temperature is kept up by the current, a solidified layer of electrolyte forming next the walls. They are usually made of iron, lined if necessary with a suitable type of resistive brick. The cathode is of iron, or else a layer of the precipitated metal. With fused halides, graphite is by far the best anode material. Iron has occasional application. In the case of aluminium production hard carbon anodes are used, which burn away in the anodic oxygen.

The most important fused salt electrolytic process, viz. the production of aluminium from a solution of alumina in fused cryolite, is separately dealt with in this Dictionary. Of other processes, we shall discuss only those which are actually in technical operation, viz. the production of sodium, magnesium, and calcium, all exclusively prepared by electrolysis.

§ (36) Sodium.—The obvious raw material for the production of this metal would be common salt, were its melting-point, 800°, not so high. This in practice causes great difficulties which have not been completely overcome. By far the greater proportion of sodium is made by the electrolysis of sodium hydroxide, the melting-point of which is 327° when pure, but about 300° or a little over for the ordinary commercial products.

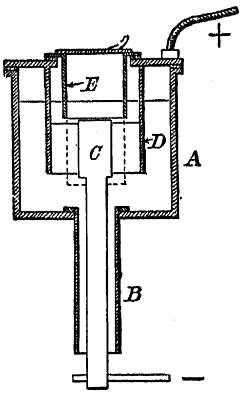


Fig. 22.—Castner Sodium Cell.

The Castner cell (*Fig.* 22) is a cast-iron pot A, embedded in brickwork to prevent loss of heat, and so dimensioned that, when working under normal conditions, it is lined with a solid layer of NaOH. The cathode C consists of an iron rod sealed into an extension B by solid NaOH. The ring-shaped nickel anode D rests on the top of the cell, from which it is suitably insulated. Between anode and cathode is hung an iron curtain E, the bottom part of which is made of gauze. Inside this curtain the sodium, lighter than the NaOH, collects, and is ladled out by perforated metal

spoons. The gauze allows of free passage of electrolyte and current between the electrodes, but prevents globules of sodium from reaching the anode. The units are of small size, take about 500 amperes at a cathodic current density of 200 amps/dm.^{2}, and absorb 4·5 volts. The working temperature is as low as the solidifying point of the alkali permits—about 315°-320° in practice. If it rises, the yield very rapidly falls off and becomes zero at 325°. The current efficiency is about 45 per cent.

The mechanism of the main process is simple. At the cathode, $Na^{\cdot}$ ions are discharged to metal. At the anode, OH' ions are liberated, giving water and oxygen. This water diffuses throughout the mass. Some of it attacks the sodium, which not only forms a "metal fog," but, as has been proved, dissolves in metallic form in the NaOH. The greater part is decomposed by electrolysis, hydrogen being produced at the cathode. The net result, therefore, of the passage of four faradays of electricity through the cell is

$$2NaOH \longrightarrow 2Na + H_2 + O_2,$$

and the maximum possible current efficiency under the cell conditions is 50 per cent. The deficiency observed from this figure in practice is due to volatilisation of the metal and to small quantities burning to form Na_2O_2. If the temperature be raised still further, so as to increase the rate of diffusion of the dissolved sodium, the yield, as has been mentioned, falls to zero. Under these circumstances the dissolved sodium ionises at the anode ($Na + \oplus \longrightarrow Na^{\cdot}$) as rapidly as it is produced at the cathode, no gas being liberated.

It is obvious that if the water liberated at the anode could be kept away from the sodium formed at the cathode, higher yields than 50 per cent would be possible. Unsuccessful attempts have been made to do this by employing cathode diaphragms, and by continuously dehydrating the NaOH by blowing air through. A series of small explosions (accounting for the use of small units) is liable to occur during the electrolysis. When it is remembered that hydrogen is liberated not only at the cathode but also around the anode (chemical action), and that metallic sodium is very reactive towards air or oxygen, this will be understood.

The decomposition voltage of pure fused NaOH is about 2·2 volts at the temperature of electrolysis. Combining this with the above figures, we have an energy efficiency of 22 per cent. One ton of sodium requires about 11,700 kilowatt hours.

§ (37) Magnesium.—This metal is made by the electrolysis of a fused mixture of $MgCl_2$ and KCl. The decomposition voltage of $MgCl_2$ in such mixtures, provided their magnesium content is not too low, and the cathodic current density not too high, is less than that of KCl. Hence, on electrolysis, pure magnesium separates, chlorine being formed at the anode.

Exact descriptions of the method used are not available. An iron pot is employed, lined under working conditions with a solidified layer of the electrolyte. This contains an iron cathode and carbon anode, separated by some sort of an anode screen or diaphragm in order to prevent access of the liberated magnesium (lighter than the electrolyte) to the anode. The best working temperature is about 700°. As magnesium fuses at 633°, it is collected in the molten state. There is some difficulty in making the small molten globules coalesce to larger ones. In practice this is overcome by the addition of some CaF_2 to the electrolyte. The current efficiency is about 75 per cent. With a cathodic current density of 30 amps/dm.^{2} the bath voltage is about six volts. The reversible decomposition voltage of the melt is about 3·2 volts, which gives us an energy efficiency of 40 per cent and an expenditure of 17·7 K.W.H. per kilo of metal.

§ (38) Calcium.—This metal is technically made on a small scale by the electrolysis of the molten chloride at 750°-800°. Metallic calcium melts at 800°, and is therefore deposited in the solid state. In order to minimise the surface of contact between the metal and the electrolyte, and thereby diminish the metal fog formation, the cathode takes the form of an iron rod which just touches the surface of the melt, and is moved upwards by a gearing at such a rate that a continuous rod of solid calcium is drawn up out of the cell. The current density at the cathode is very high, about 100 amps/dm.^{2} This causes the cell voltage also to be very considerable. Nothing is known of the actual material used for the bath, nor of the arrangements employed for preventing interaction between the metal and the anodic chlorine. The anodes are of graphite. Current efficiency and voltage, judging from laboratory scale results, are probably about 80 per cent and 25 volts respectively. With a decomposition voltage of 3·24 volts, we have an energy efficiency of 10 per cent and a consumption of 42 K.W.H. per kilo of metal.

It should finally be mentioned that similar "contact cathode" processes are also in use for the production of both sodium and magnesium, the object being to reduce the contact between the metal and the electrolyte In the former case, liquid metal results; with magnesium, a solid rod is produced.

ELECTROMAGNET, THE

An electromagnet is an arrangement for producing magnetic effects by means of an electric current flowing in a coil of wire wound round a core of iron or other magnetic material. The fact that an iron bar can be magnetised by an electric current was discovered by Arago and independently by Davy in 1820, but the electromagnet was first constructed in a practical form by William Sturgeon in 1825.

The core of an electromagnet is sometimes straight, but is more usually bent into a "horseshoe" so that its ends, or poles, are near each other. A typical form of electromagnet consists of two parallel vertical cores attached at their lower ends to a massive iron yoke. The coils are wound on bobbins which are slipped over the cores, and are so connected that the current flows in opposite directions round them. By means of pole-

pieces resting on the upper core-ends the space between the poles can be reduced to a narrow air-gap, or the space between the core-ends may be partially or completely bridged by an iron armature.

In their various applications electromagnets are used for producing magnetic flux, intense magnetic fields, attraction of small magnetic bodies, tractive force, movement of an armature or core (in "electromagnetic mechanisms"), and induced currents in a secondary circuit. We will consider these effects and the conditions favourable to their production.

§ (1) ELECTROMAGNETS FOR PRODUCING MAGNETIC FLUX.—The most important application in this class is found in the dynamo magnet, used for producing a given flux (or total induction) in an armature placed between the pole-pieces. The relation between the magnetic flux Φ in an electromagnet and the ampere-turns in the exciting coils is expressed by the equation of the magnetic circuit, viz. the magnetomotive force in a magnetic circuit is equal to the product of the flux and the magnetic reluctance of the circuit.[1] The magnetomotive force, or the line-integral of the magnetic force along any closed path, threading once through all the n turns of the exciting coils, the current in which is i amperes, is equal to $4\pi ni/10$, or approximately $1{\cdot}257 \times$ ampere-turns. The reluctance of a magnetic circuit is equal to the sum of the quotients $l/\mu s$ for the various portions of the circuit, where l is the mean length of the lines of induction in any portion, s the cross-section of that portion, and μ its magnetic permeability. The fact that an electromagnet does not usually form a perfect magnetic circuit, *i.e.* that there is magnetic leakage, so that the flux is not strictly the same in all sections of the iron and gap, may be allowed for by the introduction of leakage coefficients. These are numbers expressing the ratio of the mean flux in the various portions of the magnet to the flux in some one portion.

Thus if it be required to find the ampere-turns which will produce a flux of Φ lines in the armature, let l_1 be the mean length of the flux-path in the armature, s_1 its mean section at right angles to the lines of flux. Also let l_2, s_2; l_3, s_3; l_4, s_4; l_5, s_5, represent similar quantities for the air-gaps between the armature and the pole-pieces, for the pole-pieces, the cores, and the yoke respectively, and let q_2, q_3, q_4, q_5 represent the leakage coefficients for these portions of the magnetic circuit. Then the equation of the magnetic circuit is

$$1{\cdot}257\ ni = \Phi\left(\frac{l_1}{\mu_1 s_1} + \frac{q_2 l_2}{s_2} + \frac{q_3 l_3}{\mu_3 s_3} + \frac{q_4 l_4}{\mu_4 s_4} + \frac{q_5 l_5}{\mu_5 s_5}\right).$$

The permeability of each part of the magnetic circuit being known for the flux-density existing therein, and the leakage coefficients for the various portions of the circuit being found by experiment (for methods see S. P. Thompson's *Dynamo-electric Machinery*, 1903, chap. vi.), the ampere-turns required to produce a given flux in the armature can be calculated by the above equation. This is essentially the method suggested by J. and E. Hopkinson, and by G. Kapp, in 1886, for the calculation of the field windings of dynamos. The Hopkinsons also gave a graphical method for finding the ampere-turns, which consists in determining for each portion of the circuit a curve showing the relation between the flux and the ampere-turns required to maintain it. When these curves are obtained for all parts of the circuit they are combined by adding their abscissae, the result being a characteristic curve for the magnetic circuit, the ordinate of which represents the flux in the armature and the abscissa the ampere-turns. These methods can be easily applied to cases in which the magnetic circuit is branched, as in some forms of dynamo magnets.

Methods for determining magnetic permeability are described in Ewing's *Magnetic Induction in Iron and other Metals*, 1900, and in other works referred to below.[2] In *Fig.* 1 are shown the magnetisation curves (from data in Miles Walker's *Specification and Design of Dynamo-electric Machinery*, 1918) for specimens of four kinds of iron used in the construction of electromagnets, viz. I., cast iron; II., cast steel; III., forged ingot iron; IV., silicon steel. In these curves the abscissae represent the magnetising force H, the ordinates the magnetic induction, or flux-density, B, in C.G.S. units. Curves I.-IV. show how the flux-density increases with the magnetising force, the material being initially

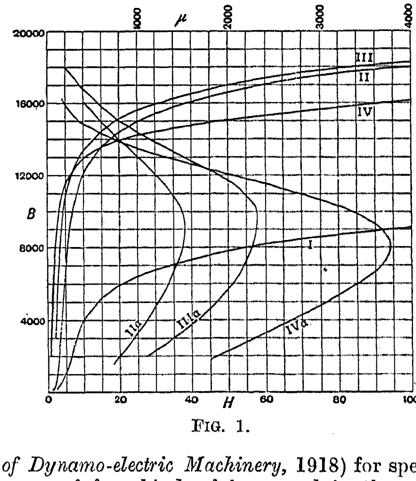

FIG. 1.

[1] See "Electromagnetic Theory," § (6).

[2] See also "Magnetic Measurements," §§ (17) *et seq.*

in the neutral unmagnetised state. The curves II.*a*, III.*a*, IV.*a* represent the permeability B/H (upper horizontal scale) for the three last-named materials at various values of B.

Cast iron is much inferior in its magnetic properties to the low-carbon steels, the maximum permeability of the specimen represented in curve I. being 410 at B = 4000. Cast iron is used for the yokes of large dynamo magnets.

Cast steel, or ingot iron, is used for the yokes and cores of electromagnets. Curve II. represents the properties of an annealed casting containing 0·2 per cent of carbon. Its maximum permeability (curve II.*a*) is 1525 at B = 9000.

Forged ingot iron is a still better (but more costly) material than cast steel for magnet cores. Curve III. is the magnetisation curve, III.*a* the permeability curve for an annealed specimen containing 0·15 per cent of carbon. Its maximum permeability is 2320 at B = 10,000.

The remarkable magnetic properties of certain iron-silicon alloys discovered by Sir Robert Hadfield are illustrated in curves IV. and IV.*a*, the magnetisation and permeability curves for a specimen containing 4·8 per cent of silicon and 0·2 per cent of carbon. The maximum permeability is about 3790 at B = 8000. The improvement in permeability at low flux-densities increases with the proportion of silicon if this proportion is between 1·8 and 4·8 per cent. At inductions over about 14,000, however, the presence of the silicon lowers the permeability. Its high permeability at low inductions, and certain other properties referred to in § (6), make alloyed steel particularly suitable for transformer cores and other magnet cores in which the flux is rapidly varying. The qualities of alloyed steel generally used for these purposes contain 3 to 4 per cent of silicon and less than 0·1 per cent of carbon.

For the laminated armature cores and pole-pieces of dynamos sheet steel (about 0·09 per cent C and 0·01 per cent Si) is preferable to alloyed steel, owing to its higher permeability at high inductions. The magnetisation curve of a good specimen of dynamo sheet steel is very slightly below curve I. (*Fig.* 1).

Considerably higher values of the maximum permeability than those shown in *Fig.* 1 have been found in carefully prepared and annealed iron-silicon alloys; values up to 12,000 are recorded by Gumlich and others. The process of melting or annealing *in vacuo* has been found to effect great increase in the maximum permeability of iron, but the amount of such improvement does not appear to have been as yet well ascertained. The iron-cobalt alloy Fe_2Co was shown by P. Weiss to have remarkably high magnetisation in strong fields, the saturation value of $(B-H)/4\pi$ at ordinary temperatures being 10 per cent higher than that of iron.

§ (2) Electromagnets for producing Intense Magnetic Fields.[1]—In the dynamo magnet no attempt is made to produce very highly concentrated magnetic fields—the average field in the air-gaps between the armature and pole-pieces does not usually exceed about 15,000 gauss (or C.G.S. units)—but for some purposes very intense fields are required, as for instance in the "isthmus" method of Ewing and Low for the examination of the magnetic properties of materials in strong fields, and in magneto-optic experiments. In these cases the pole-pieces must be so shaped as to concentrate the field as much as possible.

The form of pole-pieces giving greatest concentration was calculated by Stefan and by Ewing in 1888 on the assumption that the pole-pieces are uniformly and longitudinally magnetised, the result being that the pole-pieces should take the form of cones of semi-vertical angle 54° 44′. In practice the cones for maximum concentration should, as pointed out by Ewing, have a rather greater angle, owing to the fact that the magnetisation of the pole-pieces is not quite uniform.

As to the other parts of the magnetic circuit these should be so designed as to reduce leakage to a minimum, and therefore should have as few joints and sharp bends as possible. The exciting coils should be so placed as to produce by the direct action of the current the greatest possible field in the neighbourhood of the pole-pieces in order to magnetise them to the highest degree of saturation, and also to increase the contribution of the coil field to the total field in the gap. For it should be remembered that the field due to the magnetisation of given pole-pieces cannot be increased beyond a certain limiting value which depends upon their saturation intensity of magnetisation. The field due directly to the current is, however, proportional to the current, and it therefore becomes an increasing fraction of the total field as the current is increased.

Much attention has been given to the scientific design of electromagnets for producing intense fields by H. du Bois and by P. Weiss. In 1891 du Bois designed a large ring electromagnet, having a core of Swedish iron with coils wound nearly uniformly round its circumference, which gave a field of about 40,000 gauss in a gap 1 mm. wide and 6 mm. in diameter.

With the introduction of highly magnetic cast steel du Bois subsequently designed a less costly and more convenient form of electromagnet known as the half-ring type, which is in use in many laboratories. Further

[1] See "Magnetic Measurements," §§ (39)-(45).

improvements were introduced in a more recent design illustrated in *Fig.* 2 (from the *Zeitschrift für Instrumentenkunde*, Dec. 1911), which shows, in about $\frac{1}{15}$ the actual size, the latest type of du Bois half-ring electromagnet.

Each of the two curved cast-steel cores corresponds to about one-third of a complete

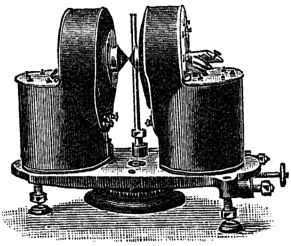

FIG. 2.

toroid; the diameter of its vertical circular section at the polar end is 93 mm., the diameter of the core increasing near the base. Conical borings, 15 cm. long and tapering 1 in 5, pierce the cores to admit a converging beam of light axially to the gap for magneto-optic experiments. For other experimental work the borings can be filled in with iron plugs, one of which is shown in *Fig.* 2. A copper tube, for water cooling, surrounds the polar end of each core.

The coils (wound for 40 amperes at 200 volts) are so arranged as to allow optical or other appliances to be brought close up to the borings. A pair of extra polar coils can be slipped over the pole-pieces so as to increase their saturation and add to the field due directly to the current.

A variety of pole-pieces are supplied with the instrument—plane for uniform fields of

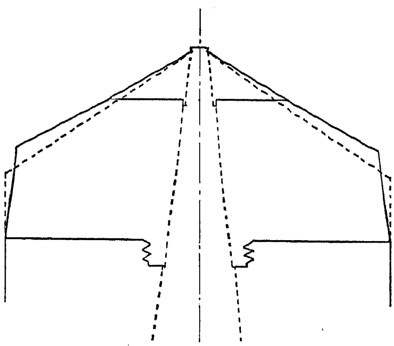

FIG. 3.

considerable extent, conical for more concentrated fields. The form of pole-piece found to give the strongest fields is illustrated in *Fig.* 3. It does not differ much from the 54° 44′ cone (represented by the broken line), but has a rather greater angle, this angle increasing slightly towards the base of the cone. Special pole-pieces are provided for various kinds of magneto-optic and other observations in strong fields.

The total weight of the magnet (large model) is 360 kilogrammes. With the extra polar coils, each of 500 turns, and the maximum current (150,000 ampere-turns in all), the field in a 1×6 mm. gap is 50,000 gauss. When the gap is reduced to $0{\cdot}5 \times 3$ mm. and the pole-pieces are provided with ferro-cobalt tips, the field is 59,000 gauss.

A still larger model of the same type, weighing 1400 kilogrammes and having a pole-base of 20 cm., gives in the $0{\cdot}5 \times 3$ mm. gap (with ferro-cobalt pole-tips) 65,000 gauss.

Without the extra polar coils the fields are about 10 per cent smaller than the above values. Polar windings have, in fact, a greater effect per ampere-turn in saturating the pole-pieces than windings situated on more distant parts of the magnetic circuit.

The du Bois magnet is also made in two smaller sizes, weighing respectively 200 and 50 kilog. and giving maximum fields of 52,000 and 40,000 gauss in a $0{\cdot}5 \times 3$ mm. gap.

Powerful electromagnets have also been recently designed by Weiss, who has adhered to the Ruhmkorff pattern of magnetic circuit having two horizontal coaxial cores supported by a massive yoke, on the ground, already referred to, that coil windings near the air-gap are more effective than those on other parts of the circuit. Weiss recommends, with a view to further improvement in the saturation of the pole-pieces, that the cross-section of the iron should gradually diminish from the distant parts towards the gap, and emphasises the importance of adequate arrangements for cooling the exciting coils. In a large electromagnet constructed on these lines in 1907 the windings of copper strip were immersed in oil cooled by water circulating in a spiral tube. The weight of this magnet was 1300 kilog., it had 3360 turns capable of carrying 60 amperes, and gave a field of 46,000 gauss in a $2 \times 3{\cdot}6$ mm. gap. The diameter of the cores was 15 cm., the length of each (excluding the pole-pieces), 52 cm. In a later and still larger model the windings were composed of copper tubing, which served to carry both the electric current and the cooling water.

With regard to the effect of a change of dimensions of an electromagnet on the field which it produces, this is governed by the principle of similarity as stated by Kelvin, viz. electromagnets of geometrically similar form give equal magnetic fields at corresponding points if their currents are proportional to their linear dimensions. In similar systems, however, the area of the cross-section of the

wire, and therefore its current-carrying capacity, is proportional to the square of the linear dimensions. A small electromagnet would thus require more windings to produce the same field at corresponding points than a large one, otherwise the current would cause excessive heating. It follows also that any further considerable increase of the field, in a gap of given dimensions, produced by increasing the size of an electromagnet of the usual type (the field of which is mainly due to the magnetism of the pole-pieces) could only be attained with an exceedingly great increase in the weight, since the weight increases as the cube, the field at the most only as the logarithm, of the linear dimensions.

The problem of producing very intense magnetic fields has been attacked in a different way by Deslandres and Perot, who increased the field due to the direct action of the current instead of that due to the magnetism of the pole-pieces. With a current of 5000 amperes flowing in a water-cooled spiral of bare silver ribbon a field of 49,900 gauss was attained even without the use of an iron core, the energy consumption in the coil being at the rate of 340 kilowatts. With an iron core a field of 63,700 gauss was reached. Doubtless still higher field intensities can be produced by such methods, the only objection to them being the cost of the heavy expenditure of energy which they involve.

§ (3) Electromagnets for attracting Small Magnetic Bodies.—It is sometimes required to exert by means of an electromagnet a force of attraction on a small magnetic body placed near it. This is the case, for example, in the torsion balance method used by Curie for measuring the magnetic susceptibility of substances at various temperatures. The same action is put to practical use in the surgical electromagnets used for extracting small particles of iron or steel from the eye or other parts of the body, and in the magnetic separators used for separating iron or iron-containing ores from other materials.

The force acting on a magnetic particle placed in a field of intensity H depends on the non-uniformity of the field; if the particle is magnetically saturated, so that its magnetism is independent of the field, the force in any direction x is proportional to dH/dx, if it is unsaturated and the susceptibility is constant the force is proportional to HdH/dx. The force on magnetic particles is directed towards the stronger, on diamagnetic particles towards the weaker, parts of the field.

For the examination of the magnetic properties of paramagnetic or diamagnetic elements du Bois recommends the arrangement indicated in *Fig.* 4. The pole axes of the electromagnet are inclined at 25° to each other, and the rather pointed pole-tips are set 3 mm. apart. At any point in the transverse axis Oy the magnetic force is parallel to Ox, its greatest value occurring at a point P within the smaller angle between the axes. The greatest value of HdH/dy is found to be at a point Q slightly to the left of the point of intersection of the axes. At this latter point Q should the specimen under examination be placed in order to experience the greatest force.

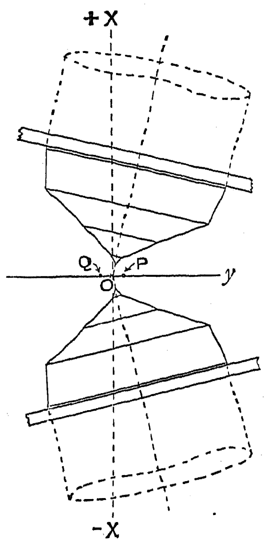

Fig. 4.

A surgical electromagnet designed by du Bois is shown in *Fig.* 5 (from the *Elektrotechnische Zeitschrift*, May 2, 1918). The "single pole" arrangement is more convenient in this case, the core of the magnet being straight but increasing in diameter towards the rear end where it expands into a wide flange. For eye applications the pole-piece takes the form of a truncated cone, which may have an axial boring to contain a small glow-lamp. The best form of pole-piece for attracting saturated or unsaturated particles was investigated by du Bois, who came to the conclusion that a cone of about 40° semi-vertical angle was suitable in both cases. A flexible extension may be attached to the pole, consisting of a bundle of very thin annealed iron wire, tapering towards the end and terminating in a suitable probe. The weight of the eye magnet is about 50 kilog.; for abdominal applications a larger model, weighing 100 kilog., is made, which is provided with a concave pole-face shaped to the surface of the body.

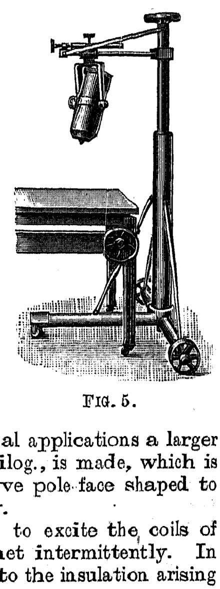

Fig. 5.

It is often desirable to excite the coils of a surgical electromagnet intermittently. In order to avoid damage to the insulation arising

from the high induced E.M.F. at "break," this should be effected by periodically shunting the magnet coil by a non-inductive resistance. The precaution of inserting a shunt should always be observed before opening the circuit of a large electromagnet.

§ (4) Electromagnets for exerting Tractive Force.—The statical tractive force exerted by an electromagnet on an armature in contact with its poles is put to a variety of practical uses, as, for example, in lifting magnets, magnetic clutches, brakes, and chucks.

The physical principle underlying this action is expressed by Maxwell's law[1] of the tractive force of magnets, that the normal traction between two plane, uniformly and normally magnetised pole-faces, separated by an infinitely narrow air-gap, is equal to $B^2A/8\pi$, where B is the flux-density and A is the area of the surface of contact. It should be observed that the above expression represents the total pull associated with all the tubes of induction that cross the area A. If, for example, we imagine a long transversely divided bar of iron to be placed in the uniform field of a very long magnetising solenoid, in which one part of the bar is fixed and the other is freely movable, the pull on the inner end of the movable part is $(B^2 - H^2)A/8\pi$, where H is the magnetic force due to the current in the solenoid. The term $H^2A/8\pi$ represents that portion of the attraction of one part of the coil on the other which is exerted across the area *A* of a plane coinciding with the section of the bar. The expression for the pull on the inner end may be written $(2\pi I^2 + IH)A$, where I is the intensity of magnetisation of the bar. In the present case the force IHA is balanced by an equal and opposite pull on the outer end of the bar, so that the force required to separate the bars reduces to $2\pi I^2A$.

If, however, the movable bar is long enough to extend well beyond the end of the coil, as in some forms of "plunger" electromagnet, the force on the outer end is much reduced, and the pull on the plunger is in this case approximately $(B^2 - H^2)A/8\pi$. This result has been experimentally verified for inductions up to 39,000 C.G.S., at which value the pull was over 700 lbs. wt. per sq. inch. A tension of over 1600 lbs. wt. per sq. inch has been observed at a higher flux-density. These observations were made in the concentrated field of a powerful electromagnet, where H is a considerable fraction of B. In ordinary circumstances H^2 is negligible in comparison with B^2, and the approximate expression for the pull reduces to $B^2A/8\pi$. This expression holds for the tractive force exerted across each pole-face of a horseshoe electromagnet on an armature attached to both its poles, if the induction across the pole-face is uniform and normal.

[1] See "Electrostatic Field," § (5).

Modern lifting magnets are generally of the bell or "iron-clad" type, circular or rectangular in form, the coil being placed round a central core, the casing forming the yoke, and the poles therefore being at the centre and the rim. The object lifted, attached at the central pole and the rim, forms the armature. *Fig.* 6 (kindly supplied by the Witton-Kramer

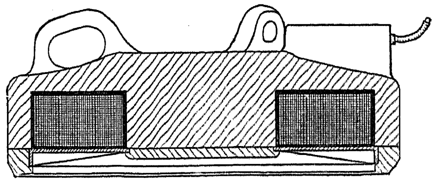

Fig. 6.

Electric Tool and Hoist Works, Birmingham) shows an axial section of a modern lifting magnet, *Fig.* 7 its manner of suspension.

The core and shell of a lifting magnet are of cast steel, the shell being usually provided with ribs which serve the purposes of strengthening the frame, reducing the reluctance of the magnetic circuit, and increasing the area of the cooling surface. The coil, generally of copper wire or ribbon—in some cases of aluminium wire insulated with a coating of oxide—is wound on a bobbin which is set in place over the core and bolted to the frame. The coil and shell are

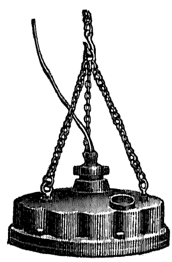

Fig. 7.

thoroughly impregnated with insulating compound *in vacuo* and covered in by a plate of phosphor bronze or manganese steel. The whole magnet is made thoroughly watertight, as it has sometimes to operate under water.

The problem of determining how the core should be shaped, and what ampere-turns should be provided in order that a magnet, constructed from a given total weight of material, should exert the greatest possible lifting force, has been considered by G. Kapp (*Principles of Electrical Engineering*, 1916, i. 195). Among the conclusions arrived at are that the best induction in the core is that corresponding to the "knee" of the magnetisation curve, *i.e.* about 17,000 or 18,000 lines per sq. cm., that in no case should the area of the pole-face be smaller than that of the core section, and that when there is a considerable non-magnetic gap between the

pole-faces and the armature it is advisable that the pole-faces should be of greater area than the section of the core.

As to the effect of a change in the size of a lifting magnet, it can be shown that in similar systems, with currents proportional to the linear dimensions so as to give the same induction, the ratio of the lifting force of a magnet to its weight is inversely proportional to the linear dimensions. Thus small magnets have a higher "load ratio" than large ones. S. P. Thompson refers to a small magnet weighing a grain and a half which could lift 2500 times its own weight.

A modern lifting magnet of the bell type, 60 inches in diameter, and weighing 3 or 4 tons, can support about five times its own weight of material. Lifting magnets are used largely in iron and steel works for loading and unloading pig iron, steel ingots, girders, plates, scrap iron, etc., also iron ore if it contains not less than about 60 per cent of iron.

Similar principles underlie the action of electromagnetic clutches and brakes. In the former the electromagnet may be contained in a pulley which runs loose on the shaft, the armature being a disc keyed to the shaft which attracts the magnet when the latter is excited. The friction between the armature and a friction plate provided on the loose pulley is sufficient to transmit power on a large scale. In magnetic brakes, such as those used on tramways, an electromagnet carried by the car is held just above the rail to which it is attracted upon excitation. The friction between the track-shoes of the magnet and the rail acts as a powerful and easily controllable brake.

Recently, magnetic chucks have come much into use in connection with shaping machines, lathes, and other workshop machines. In

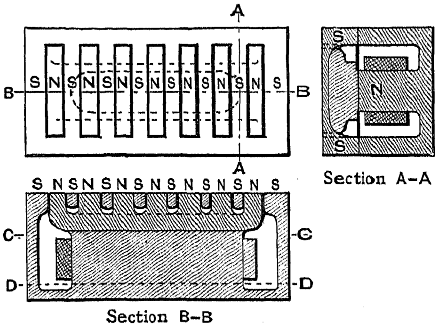

Fig. 8.

these chucks the face plate is composed of a large number of alternately positive and negative poles to which the "work" firmly adheres as an armature when the magnet is excited. *Fig.* 8 (from a paper by O. A. Kenyon in the *Electrical World*, July 5, 1919) shows diagrammatically the form of the magnetic circuit of one type of rectangular chuck. The negative poles are formed by a grid into the interstices of which project the extensions of the positive pole, these being separated from the sides of the openings by non-magnetic material. In this type the single core and coil are within the body of the chuck, and, as in the bell magnet, the casing forms part of the magnetic circuit.

§ (5) Electromagnetic Mechanisms.—There are a great many appliances (such as electric bells, indicators, relays, telephone receivers, and arc-lamp regulators) in which some required movement is produced in the armature or core of an electromagnet by varying the exciting current. In all such cases the movement which the electromagnet tends to produce is such that the magnetic reluctance of the circuit is thereby diminished. Thus in purely electromagnetic systems the air-gap between the armature and the core-ends is reduced when the magnet is excited by a current flowing in either direction, the armature (supposed held by a spring) returning to its original position when the excitation is withdrawn.

The magnitude of the attraction on the armature, represented approximately by $B^2/8\pi$ per unit area of its surface where the normal induction is B, falls off rapidly as the width of the gap increases, owing both to the reduction of flux in the whole magnetic circuit accompanying the increase of reluctance (the magnetising ampere-turns being assumed constant) and to increased magnetic leakage. Thus to obtain any considerable attractive force on the armature this must be placed very close to the ends of the magnet core. Special electrical or mechanical devices have, however, been invented for reducing the variation of the force with width of gap, so as to increase the effective range of action. Among these are the "coil and plunger" arrangement and its modifications, used in some arc-lamp regulators, in which an iron core is drawn into a coil, and in which the range of effective action is much more extended than in those mechanisms where an armature is attracted by an electromagnet having a fixed core.

Numerous attempts have been made to produce reciprocating motion of an electromagnet core by supplying intermittent or alternating current to the coil. Among these devices may be mentioned the electromagnetic hammer of Schüler—a small portable hammering machine suitable for chiselling and riveting —which is driven by an alternating E.M.F. applied to the coil through a contact breaker. The current is "on" for one period, during which the core, or hammer, delivers its blow, and "off" for the next two periods, during

which the hammer is drawn back by a spring. One of the chief difficulties in such arrangements is that of opening the circuit without causing a spark to appear at the contact breaker. This difficulty can be overcome, as pointed out by T. F. Wall, by superposing a suitable constant E.M.F. upon the alternating E.M.F. applied to the inductive coil. By this means the current and the total E.M.F. can be made to become zero simultaneously, thus allowing the circuit to be opened sparklessly.

In telephone receivers, and some relays and electric bells, the magnetic circuit is formed partly of soft iron and partly of permanently magnetised steel, the iron core, round which the coil is wound, being therefore magnetised to a certain degree by the steel magnet. In these "polarised mechanisms" the direction of displacement of the armature is reversed by reversing the exciting current, and the magnitude of the displacement of the armature for a given current (*i.e.* the sensitiveness of the arrangement) may be considerably greater than in those arrangements in which such permanent magnetisation is absent.

Assuming Maxwell's law and neglecting leakage, the pull F on the armature is represented by $B^2A/8\pi$, where B is the induction in the iron core and in the armature due mainly to the field of the permanent magnet. If a small current flows in the coil, causing a proportional change dH in the magnetising force, the change in F (upon which the displacement of the armature depends) is given by

$$\frac{dF}{dH}=\frac{A}{4\pi}B\frac{dB}{dH},$$

i.e. the sensitiveness is proportional to the product of B and dB/dH. The coefficient dB/dH is determined by the form of a small

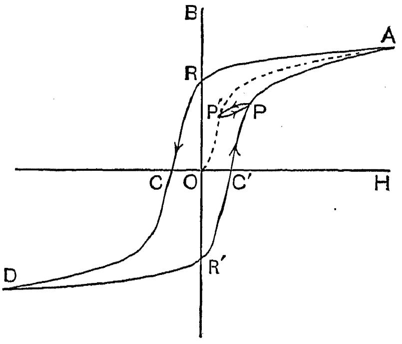

FIG. 9.

cycle (such as PP′ in *Fig.* 9) in the B, H diagram for the iron.

Measurements of dB/dH for small cycles of magnetisation superposed upon various constant values of B have been made by H. Hoffmann, who found that as the induction increases from zero the quantity BdB/dH first increases to a maximum and then diminishes, and that of the materials examined the one that possessed the highest permeability (an iron-silicon alloy) also showed the greatest maximum value of BdB/dH. In this connection reference may be made to some observations by K. W. Wagner, who found that the sensitiveness of a telephone was improved by making the cores and the diaphragm—the diaphragm here takes the place of the armature—of alloyed iron.

§ (6) ELECTROMAGNETS FOR INDUCING CURRENTS IN A SECONDARY CIRCUIT.—In transformers and induction coils an electromagnet of varying strength is employed to generate by induction electric currents in a secondary coil wound round the same core or round a part of the same magnetic circuit. The induced E.M.F. in the secondary coil, supposed to have n turns the flux through each of which is N lines, is according to Faraday's law of electromagnetic induction ndN/dt. In the transformer the flux is caused to change periodically by supplying alternating currents to the primary coil. In the induction coil the variations of flux arise from the electrical oscillations which take place in the circuits after the primary current is interrupted. In both cases electrical energy is supplied to the primary circuit, and it is desired to cause as much as possible of this energy to reappear in the secondary. It is therefore desirable to keep down as much as possible the dissipation of energy, arising from hysteresis and eddy currents, which always occurs in an iron core in which the flux is rapidly varying.

§ (7) HYSTERESIS.—If a piece of steel or other magnetic material is subject to a cyclical magnetising force, the magnetic induction corresponding to any value of the force is found to be greater as the force decreases through that value from higher values than it is as the force increases through the value from lower values. The induction appears to lag behind the force.[1] To this phenomenon Ewing gave the name of Hysteresis.

Fig. 9 shows a typical "hysteresis loop" representing a cycle of magnetic values between the limits of field and flux density represented by the points A and D. If the material be originally unmagnetised, then as the field is increased from zero to the point represented by A the induction increases along a curve from the origin lying between C′A and CA. As the force decreases from H at A to −H at D, the changes in the induction are represented by the curve ACD. If the

[1] See "Magnetic Measurements," § (1) (xii.), also "Magnetic Hysteresis."

force be now increased from $-H$ to H the induction is represented by DC′A, and these curves are repeated as the cycle continues.

OR is the residual magnetism, *i.e.* the flux-density remaining when the magnetising force has been reduced to zero, while OC is the coercive force, *i.e.* the force it is necessary to apply in a direction opposite to the original magnetising force in order to annul the residual force and demagnetise the specimen. It was shown by Warburg and by Ewing that the area of the loop representing any closed cycle of magnetisation, divided by 4π, represents the energy dissipated in the cycle per cubic centimetre of the material. The area of the loop increases with the induction limits between which it extends, being represented fairly well, when the induction alternates between moderate limits $\pm B$, by the expression proposed by Steinmetz, $hB^{1\cdot6}$. At very high inductions the index of B is smaller, at very low values greater, than 1·6.

The coefficient h is called the hysteretic constant. Its value varies with the material; in soft iron it may be 0·002, in cast iron five to eight times as great. It is very small in the iron-silicon alloys. In *Fig.* 10 (represent-

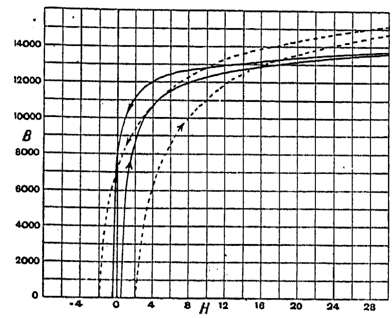

FIG. 10.

ing measurements by H. Hoffmann) the full line curve is part of a hysteresis loop for an annealed specimen of alloyed iron for which the hysteretic constant was 0·001. The broken line curve shows the hysteresis of a specimen of ordinary sheet steel for which $h = 0\cdot0024$. In a very pure specimen of alloyed sheet iron 0·5 mm. thick, containing 4·09 per cent of silicon and 0·07 per cent of carbon, annealed at 800° C. and 20 mm. of mercury pressure, Gumlich found the value 0·0006 for h. The hysteresis loss in "stalloy" sheet in very weak fields (H about 0·01 C.G.S.) was found by A. Campbell to be represented in ergs per cycle per cu. cm. by the expression $6\cdot6\ B^{2\cdot4} \times 10^{-6}$.

The eddy currents induced in the core by the changes of flux not only cause dissipation of energy but also, by their shielding action, prevent the flux changes from penetrating deeply into the core, the effective permeability of which is thus diminished. These effects are much reduced by constructing the core of thin sheets or wires parallel to the flux and insulated from one another. The theory of eddy currents in laminated or wire cores has been given by J. J. Thomson, who showed that the energy thereby dissipated per second per cubic centimetre of iron is proportional, when the quantity $\pi d\sqrt{n\mu/\sigma}$ is small, to $d^2n^2B^2/\sigma$, where d is the thickness of each sheet (or diameter of each wire), n is the frequency, B the maximum induction, and σ the specific resistance of the material. For ordinary low-frequency alternations, therefore, the eddy-current loss is smaller the higher the specific resistance of the iron. The fact that its specific resistance may be five or six times that of ordinary iron is another reason for the superiority of alloyed steel for transformer and other cores in which rapid changes of flux are taking place. In 4·8 per cent silicon steel plates 0·5 mm. thick, at a maximum induction of 10,000 C.G.S. and frequency 50, the combined hysteresis and eddy-current losses are of the order 0·5 watt per pound of the material. In ordinary sheet steel of good quality the losses in similar conditions are two or three times as great.

ELECTROMAGNETIC FORCE ON A CIRCUIT. The force is equal to $i(d\phi/dx)$ if ϕ is the magnetic flux through the circuit and i the current maintained constant during the change dx. See "Electromagnetic Theory," § (10).

ELECTROMAGNETIC THEORY

THE experimental laws of electromagnetic action are due to Faraday. It is important to establish the connection between these and the energy of the field in which the action is taking place, and to show how they follow from general mechanical principles. For this purpose an expression is required for the potential energy of the field; this we proceed to investigate.

§ (1) POTENTIAL DUE TO A SMALL MAGNET.—Consider a small magnet NOS (*Fig.* 1), of length l, with its centre at O, and having poles m and $-m$ at N and S respectively. Let P be a point at a distance r from O at which we wish to find the potential. Let OP make an angle θ with the axis SON of the magnet, and let r_1, r_2 be the distances of N and S from P. Describe a circle, with P as centre, PO as radius, cutting PN produced and PS in N′ and S′ respectively.

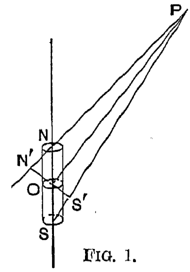

FIG. 1.

Then remembering that NS is small compared with OP, and that the angles at N′ and S′ are right angles, while N′NS and S′SN are each very approximately equal to θ, we have

$$r-r_1=\mathrm{OP}-\mathrm{ON}=\mathrm{NN'}=\frac{l}{2}\cos\theta,$$

$$r_2-r=\mathrm{OS}-\mathrm{OP}=\mathrm{SS'}=\frac{l}{2}\cos\theta.$$

Thus

$$r_1=r-\frac{l}{2}\cos\theta=r\left(1-\frac{l}{2r}\cos\theta\right),$$

$$r_2=r+\frac{l}{2}\cos\theta=r\left(1+\frac{l}{2r}\cos\theta\right).$$

Then if V be the magnetic potential at P due to the small magnet,

$$\begin{aligned}V&=\frac{m}{r_1}-\frac{m}{r_2}=\frac{m}{r}\left(\frac{1}{1-(l/2r)\cos\theta}-\frac{1}{1+(l/2r)\cos\theta}\right)\\&=\frac{ml\cos\theta}{r^2}\left(\frac{1}{1-(l^2/4r^2)\cos^2\theta}\right)\\&=\frac{\mathrm{M}\cos\theta}{r^2}, \qquad (1)\end{aligned}$$

if M be the magnetic moment of the magnet, for we may neglect $l^2\cos^2\theta/4r^2$ in the denominator in comparison with unity.

Now let δS be the area of a section of the small magnet at right angles to its axis, and imagine the poles to be due to magnetism distributed over the ends of the magnet with density σ and $-\sigma$ respectively.

Then $$m=\sigma\delta S$$

and $$V=\sigma l\frac{\delta S\cos\theta}{r^2},$$

and if $\delta\Omega$ be the small solid angle subtended at P by δS we know that

$$\delta\Omega=\frac{\delta S\cos\theta}{r^2}.$$

Hence $$V=\sigma l\delta\Omega. \qquad (2)$$

§ (2) POTENTIAL OF A MAGNETIC SHELL.—Imagine now a thin sheet of magnetic material of any form magnetised normally in such a way that the surface density of magnetisation σ is always inversely proportional to its thick-

ness, so that σl is constant over the sheet. Denote this product by ϕ.

We may consider the sheet as made up of a large number of small magnets such as NS (*Fig.* 2) each of constant moment ϕ per unit of area of the sheet, and if $\delta\Omega$ be the angle which the north end of one of these subtends at P, the potential δV due to this element of the shell is given by

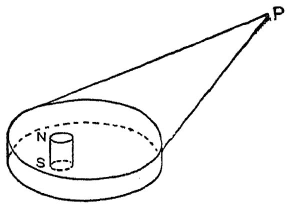

FIG. 2.

$$\delta V = \phi\delta\Omega.$$

But the potential due to the whole shell is the sum of those due to the elements. Thus for the whole shell

$$V = \phi\Omega, \quad . \quad . \quad . \quad . \quad (3)$$

where Ω is the solid angle subtended by the positive side of the shell at P.

Now imagine a magnetic pole m_1 at P, then the mutual potential energy of the shell and the pole is $\phi m_1\Omega$. Lines of magnetic induction issue from the pole, and at all points on a sphere of unit radius with its centre at the pole the induction is m_1. But the induction is measured by the number of lines which cross unit area on the surface of the sphere, thus there must be m_1 lines to each unit of area, and since there are 4π units of area on a sphere of unit radius the number of lines issuing from the pole m_1 is $4\pi m_1$. These lines are uniformly distributed, hence of the $4\pi m_1$, a number equal to $m_1\Omega$ are included within the solid angle Ω and fall within the area of the shell, passing through it in the negative direction from its north to its south side. Hence the mutual potential energy of the pole and the shell depends on the product of the strength of the shell and the number of lines of induction which cut the shell.

The potential energy is positive if the pole is on the north side of the shell; the lines of induction due to the pole cut the shell from north to south; the positive direction through the shell is from south to north, and the number of lines cutting the shell from south to north is equal in magnitude but opposite in sign to those which cut it from north to south. Hence the mutual potential energy of the pole and the shell is equal to minus the product of the strength of the shell and the number of lines of induction which cut the shell from south to north.

§ (3) Potential Energy of a Shell in a Magnetic Field.—Now consider, instead of a simple pole, any system of magnetised matter near the shell. We can treat this as made up of a series of magnetic poles—positive and negative—distributed according to definite laws, and the result just reached is true for each of these poles.

The mutual potential energy is the sum of that due to the individual poles, and the total number of lines of induction cutting the shell is also the sum of those due to the individual poles.

Hence we may write

$$\text{Mutual potential energy of shell and field} = -N\phi, \quad (4)$$

where ϕ is the strength of the shell and N the number of lines of induction due to the system which cut the shell from south to north.

Again let the second system be another shell of strength ϕ', and let N' lines of induction due to the first shell cut it. The mutual potential energy is $-N'\phi'$. Thus for the mutual potential energy of two shells we have the two expressions $-N\phi$ and $-N'\phi'$, and these must be equal. This condition is satisfied if $N = -M\phi'$ and $N' = -M\phi$, where M depends only on the relative position and form of the two shells, for then we have

$$\text{Mutual potential energy} = +M \, . \, \phi \, . \, \phi'. \quad (5)$$

M is known as the coefficient of mutual induction of the two magnetic shells.

§ (4) Equivalence of a Magnetic Shell and a Current.—Again Ampère showed [1] —following Oersted's discovery of the magnetic action of a current—that the magnetic field due to any current of strength i flowing in a small circuit was the same as that due to a small magnet with its axis normal to the plane of the circuit, provided the moment of the magnet is equal to $i\delta S$, where dS is the area of the small circuit.

If we look upon the magnet as a portion of a shell of strength ϕ, bounded by the circuit carrying the current, then its moment is $\phi\delta S$. Hence $\phi = i$.

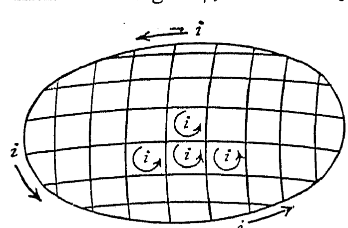

FIG. 3.

Consider now a finite shell as in *Fig.* 3 with its north side uppermost.

Draw a series of lines across the shell,

[1] The real proof of this lies in the fact that it leads to results which are fully verified by experiment.

dividing it into a number of elementary areas, and imagine a current i to circulate as shown round the boundaries of each of these elements. The potential due to each of these current elements is, we have just seen, equal to that of the corresponding shell element if ϕ, the strength of the shell, is equal to i. But a little consideration shows that except at the boundary of the whole shell there are two equal and opposite currents in each of the elementary arcs on its surface. Thus except at the boundary the effects of currents in contiguous elements are mutually destructive. Moreover, the elements of current in the boundary constitute a continuous current i circulating round the boundary of the shell. Thus the magnetic potential due to a shell of strength ϕ and a current of strength i circulating round its boundary are equal provided $i=\phi$.

Hence the mutual potential energy of two circuits carrying currents i, i' may be written Mii', where M depends solely on the geometrical relations of the circuits, and is known as the coefficient of mutual induction between them.

§ (5) Electromagnetic Energy of the Field.—Again, if during a time dt the current i increases by an amount di while i' remains constant, the mutual potential energy increases by $Mi'(di/dt)$, and Mi' is the number of lines of induction due to the second circuit which thread the first.

But lines of induction due to the first circuit also thread that circuit, and these are proportional to the current in that circuit. Denoting them by Li, we see that the rate of increase in energy due to an increase of current in the circuit is $Li(di/dt)$, and the total energy due to the growth of i from zero to its final value is given by $\int Li(di/dt)$ or $\frac{1}{2}Li^2$.

The quantity L is known as the coefficient of self-induction of the circuit.

Thus if we have two circuits of self-inductions L and L′ and mutual induction M carrying currents i, i', the electromagnetic energy of the system is

$$\tfrac{1}{2}Li^2 + Mii' + \tfrac{1}{2}L'i'^2. \qquad (6)$$

We have thus established the identity of the magnetic fields due to a magnetic shell and a current; it should be noted, however, that this identity does not extend to the interior of the shell.

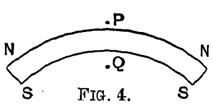

Fig. 4.

§ (6) Work done in circling a Current.—Again let P and Q be two points close together but on opposite sides of the shell shown in section in *Fig.* 4, and let Ω be the solid angle which the positive side of the shell subtends at P. Then the angle subtended by the shell at Q is $4\pi-\Omega$. If ϕ be the strength of the shell the potential at P is $\phi\Omega$, and that at Q is $-\phi(4\pi-\Omega)$.

Hence the work done in taking a unit pole by any path not cutting the shell from Q to P is $\phi\Omega+\phi(4\pi-\Omega)$ or $4\pi\phi$.

If we replace the shell by a current i circulating round the boundary the work done in making a complete circuit round the current is $4\pi i$; if the pole compass the current n times we find that work done in circling n times round a current i

$$=4n\pi i. \qquad (7)$$

In this expression the current is measured in C.G.S. units if it be equal to I amperes.

Then $\qquad I=10i$

and the work is

$$\frac{4\pi}{10}nI=\frac{4 \text{ Ampere turns}}{10}. \text{ Units of work.} \quad (8)$$

§ (8) Relation between the Direction of the Current and the Magnetisation of the Shell.—We can determine this relation thus:

Let the current flow (*Fig.* 5) in the anticlockwise direction round the circuit supposed to lie in a horizontal plane. Then, experiment shows that a north pole when near the plane of the circuit will tend to move upwards when within the area of the circuit, downwards if outside that area; the lines of induction due to the current run downwards outside the circuit, upwards within it; the upper face of the equivalent shell is a north face, while the lower face is south.

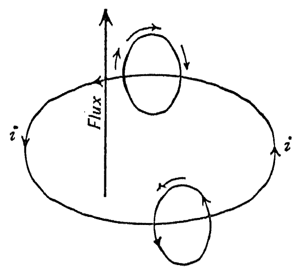

Fig. 5.

Again, as we have seen, the mutual potential energy of a circuit carrying a current i and a pole m is $-m\Omega i$, that of the circuit when in a magnetic field is $-i\Phi$, where Φ is the total flux passing through the circuit in the direction from south to north. Now it is a general rule that any system of bodies free to move under their mutual reactions set themselves so as to make the potential energy of the system a minimum; this will apply to the circuit, which will if free set itself so that $-i\Phi$ is a minimum, *i.e.* so that Φ is a maximum, and the circuit will then embrace the maximum number of lines of induction which will traverse it from its south face to its north.

The direction of the field and the direction of the current will be related as shown in *Fig.* 5.

§ (9) ELECTROMAGNETIC FORCE ON AN ELEMENT OF THE CIRCUIT.—Moreover, if we imagine the conductor to be flexible, it will alter in shape so as to include as many lines of force as possible; if, for example, the field be uniform the conductor would take the form of a circle, for with a given perimeter a circle includes the maximum area.

We can find the force on an element of the wire ds in the following way:

Consider an element PQ (ds), *Fig.* 6, and let it be displaced a distance PP′ ($=dx$) parallel to itself in a direction making an angle α with PQ—we may imagine PP′, QQ′ to be conducting rails on which P and Q slide, thus maintaining the circuit complete—Let the direction of B, the magnetic field at PQ, make an angle θ with the normal to PP′Q′R.

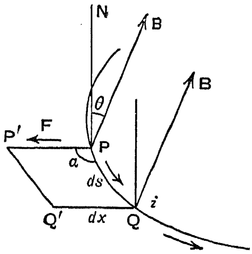

FIG. 6.

The area of PP′Q′Q is $dxds$ sin α, and the total induction through this area is

$$B \cos\theta \sin\alpha dxds.$$

The increase in potential energy is then

$$-Bi\cos\theta\sin\alpha dxds.$$

But if F is the force on ds in the direction PP′ then Fdx is the work done, and this must be equal to the decrease in potential energy.

Hence $Fdx = B\cos\theta\sin\alpha \times idxds$

or $$F = B\cos\theta\sin\alpha \times ids. \quad . \quad . \quad (9)$$

F is clearly a maximum if $\theta = 0$ and $\alpha = \pi/2$, for then $\cos\theta\sin\alpha$ is unity. Thus the resultant force $\overline{F}$ is at right angles both to the element of current and also to the magnetic field, and we then have

$$\overline{F} = Bids, \quad . \quad . \quad . \quad (10)$$

or on each element of the current there is a force per unit of length equal to the product of the current and the magnetic induction.

The relations between the directions of the three quantities involved, the current, the magnetic field, and the force, are as shown in *Fig.* 7.

These relations are perhaps most easily remembered thus: Let the direction of the magnetic field B be vertically upwards, and let the current i be flowing in a horizontal wire at right angles to the field; on one side of the wire the field due to the current is in the same direction as B, on the other side it is opposite to that of B; the effect of the current is to strengthen the field on one side and to weaken it on the other. Then the electromagnetic force is at right angles both to the field and the current and tends to move the wire from the side where the field is strong to that on which it is weak.

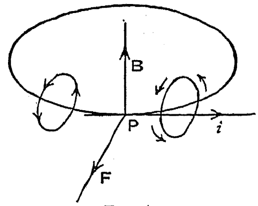

FIG. 7.

§ (10) ELECTROMAGNETIC FORCE ON A CIRCUIT.—We can find an expression for the electromagnetic force on a complete circuit carrying a current thus: We have seen that we can represent the potential energy of the circuit in a magnetic field by the expression $-\Phi i$. Now let some displacement of the circuit denoted by δx take place, and let X be the force resisting this displacement, then the work done is $X\delta x$ and the increase in potential energy is $-\delta(\Phi i)$. If the work is done at the expense of the energy we must have

$$X\delta x - \delta(\Phi i) = 0$$

or $$X = \frac{d(\Phi i)}{dx} = i\frac{d\Phi}{dx}, \quad . \quad . \quad (11)$$

if i is maintained constant.

§ (11) ELECTROMAGNETIC INDUCTION.—So far we have considered the mechanical forces on a conductor in a magnetic field; electromotive forces also are set up if the circuit is moved in the field or the amount of magnetic induction linked with it made to vary in any way.

Let the motion be such that the flux through the circuit is increased by $d\Phi$; the work done by the electromagnetic forces is $i\delta\Phi$, and if this occurs in time δt the energy used in heating the circuit of resistance R is $Ri^2\delta t$; both these supplies of energy come from the battery or other source of the current, and if E be the E.M.F. the whole amount supplied is $Ei\delta t$.

Thus $$Ei\delta t = Ri^2\delta t + i\delta\Phi,$$

and ultimately we find

$$i = \frac{1}{R}\left\{E - \frac{d\Phi}{dt}\right\}. \quad . \quad . \quad (12)$$

Thus whenever the flux through the circuit varies an electromotive force is set up which is measured by the rate of decrease of the flux.

If the current, the induction, and the electro-

magnetic force be related as in *Fig.* 7 the induced E.M.F. will be as shown in the opposite direction to the primary current as in *Fig.* 8.

If, for example, we consider the case when the field is due to a current i' in a second coil

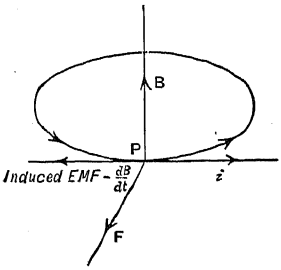

FIG. 8.

we have for the value of Φ the quantity $Li+Mi'$, and if L and M can be treated as constants

$$\frac{d\Phi}{dt}=L\frac{di}{dt}+M\frac{di'}{dt},$$

so that the equation connecting the electromotive force and the current is

$$L\frac{di}{dt}+M\frac{di'}{dt}+Ri=E. \quad . \quad . \quad (13)$$

We must, of course, know how both E and i' vary with the time before we can solve this; if we have a second circuit in which i' is flowing under an E.M.F. E′ we have

$$L'\frac{di'}{dt}+M\frac{di}{dt}+R'i'=E', \quad . \quad (14)$$

and if E and E′ are both known functions of the time we can solve these two equations.

§ (12) FARADAY'S LAWS OF ELECTROMAGNETISM.[1]—The two results we have obtained, giving respectively the electromagnetic force on a conductor and the electromotive force set up in it when the flux linked with it is varied, contain the theory of Faraday's discovery of electromagnetic induction, the laws to which they lead may be put into various forms; they are made use of in the design of electric generators and motors in transformers and in all kinds of electric machinery. We may state the laws thus:

(i.) A closed circuit carrying a current when free to move in a field of magnetic flux sets itself so that the number of lines of magnetic induction through the circuit is the greatest possible.

From this it follows that—

(i.*a*) A conductor carrying a current i placed in a field of magnetic induction B in a direction at right angles to that of the field experiences a force of Bi dynes per unit length in a direction at right angles to both the current and the field.

(ii.) If there is any variation in the magnetic flux linked with a closed circuit an E.M.F. is induced round the circuit which is equal to the rate of decrease of the flux.

And this leads to—

(ii.*a*) A conductor moving in a magnetic field with velocity v at right angles to the lines of magnetic induction of the field has induced in it an E.M.F. equal to $-Bv$ per unit of length.

The various quantities occurring in these statements must, of course, be measured in some consistent system of units,[2] *e.g.* either the C.G.S. system or the ohm-ampere-volt system of practical units.

§ (13) THE MAGNETIC FORCE WITHIN A SOLENOID.—Consider now a circuit like that shown in *Fig.* 9 in which the conductor carrying a current i is wound uniformly round the surface of a ring in such a way as to form a spiral enclosing the whole ring, and let the axis of the ring be a circle of circumference l; let there be n turns of wire on the ring. Then, as we have just seen, the work done in carrying a unit pole once round the axis of the ring, and thus threading all the coils of the solenoid, is given by the expression $4\pi ni$. But it is clear from the symmetry that the magnetic intensity H is the same at all points of the axis of the ring, while the length of the path is l; thus the work is also equal to Hl.

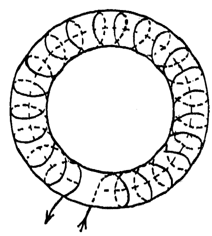

FIG. 9.

Hence $$Hl=4\pi ni$$

and $$H=4\pi\frac{ni}{l}. \quad . \quad . \quad . \quad (15)$$

But n/l is the number of turns per unit length of the axis, and ni/l is the number of current turns per unit of length.

Hence $H=4\pi\times$number of current turns per unit length of the axis of the coil.

In this expression the current is measured in C.G.S. units; if we measure it in amperes, then since 1 ampere$=10^{-1}$ C.G.S. units, we have for the value of H in terms of the Gauss

$$H=\frac{4\pi}{10}\times\text{ampere turns per unit length.} \quad (16)$$

In this form the result is strictly true.

Now let us suppose the ring to be of very large diameter, its cross-section remaining unaltered, so large that we may treat a

[1] See "Dynamo Electric Machinery," § (1); "Transformers," § (7).

[2] See "Units of Electrical Measurement," §§ (2), (21).

limited portion of the axis as though it were straight. The field near the centre of this straight portion will be mainly due to the coils in its immediate neighbourhood and will not be seriously modified if we suppose the more distant parts of the ring removed. If we do this we have a straight coil of wire or solenoid, the length of which is considerable in proportion to the radius of its cross-section. The magnetic intensity within the central portion of such a coil is then still given by the same expression

$$H=\frac{4\pi}{10}\text{ ampere turns per unit length.} \quad (17)$$

Electrometer: an instrument for measuring differences of electric potential. See "Alternating Current Instruments," § (18).

Use of, for the measurement of small currents at radio frequencies. See "Radio-frequency Measurements," § (18) (vi.).

Use of as a Wattmeter. See "Alternating Current Instruments," § (20).

Vibration, an alternating voltage-detecting instrument suitable in cases where the circuits have high impedances. See "Inductance, The Measurement of," §§ (36)-(37).

Electromotive Force. The energy required to convey a unit of positive electricity from one point to another measures the electromotive force between the two.

In electrostatics E.M.F. is measured by the potential difference between the points.

When a steady current i is flowing in a conductor the E.M.F. is measured by the product of its strength and the resistance R of the conductor,

or $$E=Ri.$$

If the current is variable an E.M.F. is produced equal to $-L\,di/dt$, L being the coefficient of self induction of the circuit in which the current i is flowing, while in a neighbouring conductor there is experienced an E.M.F. equal to $-M(di/dt)$, where M is the coefficient of mutual inductance between the two conductors.

The practical unit of E.M.F. is the volt. One volt exists in a conductor when one watt is expended in the passage of one ampere. See "Units of Electrical Measurement," §§ (7), (8), (21); "Electrical Measurement, Systems of," § (37).

ELECTRON THEORY AND SPECTRUM ANALYSIS

In recent years the results of experimental research on the properties of electrons have accumulated with startling rapidity. As knowledge grows, the importance of the part played by the electron in the mechanics of the world becomes ever clearer.

It helps to a right appreciation of the position

as regards the electron if we observe its strong resemblance to the older state of things when first the atomic theory of matter was clearly defined. Just as chemistry has grown and prospered on its recognition of the unit of matter, so electrical science has already begun a new life, and to all seeming a most vigorous one, based on the understanding of nature's unit of electricity. There are many different atoms of matter; nearly a hundred are distinguishable by their different chemical reactions; but the number of different kinds of electrical atoms is very much more limited. We have for some years been clear as to the existence of the electron, nature's unit of negative electricity. More recently the work of Rutherford and of Aston indicates that the nucleus of the hydrogen atom is to be regarded as the positive counterpart.

The first suggestion of the atomic character of electric charge came, it is well known, from observation of the laws of electrolysis. Since the movement of atoms or atom clusters or ions across the electrolytic cell was accompanied by a simultaneous transfer of electricity, in which each ion, of whatever nature, bore always the same charge or at least a simple multiple of it, there was a clear indication that this division of electricity into parcels of constant magnitude implied the existence of some natural unit charge. No progress, however, was made or could be made so long as the charge could only be observed as an attachment to an ion: it was not even clear that it could ever have a separate existence. In the long series of researches which finally led to the isolation of the electron and the determination of its properties, there were certain that marked definite stages in the forward movement. Crookes examined the electric discharge in bulbs exhausted to a high degree by the new air pumps which he had succeeded in making; and he observed the so-called cathode rays, streaming away from the negative electrode. He showed that they possessed the properties to be expected from a stream of particles projected across the bulb, and carrying negative electricity with them; for, on the one hand, they could heat up bodies on which they fell, and on the other, they were deflected in crossing a magnetic field. Crookes spoke of a fourth state of matter and defended his view against the opposing hypothesis, held largely on the Continent, that the stream consisted of electromagnetic waves in some form or other. Hertz showed that the rays could pass through thin sheets of matter such as aluminium leaf, and Lenard took advantage of this to coax them outside the bulb and display their effects in the air outside.

In the later years of the last century came the great experiments of Wiechert, J. J. Thomson, and many other well-known observers, who weighed the electron and measured its charge, and showed that there was only the one electron, though it was to be found everywhere and in every body. Since then, the measurements of these quantities have been repeated many times with increasing skill and understanding. They have reached their present high-water mark perhaps in the experiments of Millikan at Chicago, who gives for the value of the charge in electromagnetic units $e=1{\cdot}591\times10^{-20}$, the mass being $0{\cdot}900\times10^{-27}$ gramme or 1/1850 of the mass of the hydrogen atom.

So we arrive finally at an accurate comparison of these unique and fundamental units of nature with the units which we ourselves have chosen for our convenience, and without, of course, any consideration of the former. We infer from experiments, such as those of Kaufmann and Bucherer, that the energy of the moving electron may be considered to exist wholly in the form of electro-magnetic energy such as is necessarily present when an electrical charge is in motion; and that its mass is in this way perfectly accounted for. But this conclusion sets a limit to the size of the electron and we must assume that its radius, if its form is spherical, is very small compared with the radius of any atom. Also as the velocity of the electron approaches that of light, its mass increases; imperceptibly at first, but at the end very rapidly.

Why, we may well ask, have these measurements of charge and mass never been made before? The electron is everywhere: the transfer of electricity from place to place consists always in the transfer of electrons. The electric current is a hurrying stream of electrons: all our electrical machinery concerns itself with setting them in motion, giving them energy, and again withdrawing it. In the processes of electrolysis the electrons are handed to and fro. Everywhere they fill the stage: why have we not noticed hitherto their qualities, which so far can be expressed so simply?

The answer is that we have never, until recently, been able to make them move fast enough in spaces sufficiently empty of air or other gases. It is only when an electron has a sufficient speed that it can escape absorption in the atoms which it must be continually meeting. Unless an electron has a speed exceeding about a three-hundredth of the velocity of light, that is to say, such a speed as it acquires in falling through a potential of a few volts, it sticks to the next atom it runs up against: even with 10 times that speed it can only move a fraction of a millimetre through air at ordinary pressure before it loses its velocity and, therefore, its power

of going through the atoms. When Crookes first saw the cathode-ray stream in full course, it was because he had reduced the number of gas molecules in his bulb to such an extent that an electron could fly in a straight line from end to end of the bulb without going through more than a hundred atoms or so, and the induction coil had given it quite enough speed to do that without turning out of its course, no matter what sort of atoms they were. Incidentally, since atoms can be traversed in this way, we naturally think of an atom as a very empty affair.

Electrons flying still faster than in the discharge tube are found to constitute a part of the radiation from radioactive substances. Some of the β-rays have velocities nearly equal to that of light, and can pass through millions of atoms before their energy is spent. In open air a β-ray may have a course of metres in length, though it is generally broken, by encounters with traversed atoms, into a path full of corners and irregularities.

It is speed which gives separate existence to the moving electron, and speed which also betrays its presence to us. For, on its way, the electron here and there chips away another electron from an atom which it is crossing and leaves behind it a separation of electricities which may subsequently influence chemical action as in the case of the phosphorescent screen or photographic plate, or provide a current for the ionisation chamber. We do not know exactly how this removal of electrons is effected, nor why some atoms part with electrons more easily than others so that the flying electron loses less energy as it goes through: there is much that is obscure in the whole process. But it gives us a ready means of observation, without which indeed our knowledge of the electron would be far less than it is.

These electrons which are so made manifest by speed form but a minute fraction of the whole number in existence. They are to be found in every body, and in every atom of every body. They form one of the elements of construction of the atom; and it is one of the most immediate aims of present research to find in what way they are built into atomic structure. In every atom there are certain electrons of which one can be removed at the cost of an amount of energy of the order of 10^{-11} ergs. The potential through which an electron must fall so that it acquires this energy is of the order of a few volts. There are other electrons within the atom which are intrinsically far more difficult to remove. On the other hand, some atoms, for example those of a metal in the solid or liquid condition, have each one or more electrons which are little more than hangers on, and are indeed removed with very little trouble. A block of pure metal is full of such loosely bound electrons, so that if an electric potential difference is maintained across the block an electron flow or electric current is produced. The metal "conducts."

At sufficiently high temperatures all bodies become conductors; we must imagine that the violent thermal agitation shakes electrons free from their ties to the atoms even when at low temperature the bonds ordinarily remain unbroken. At high temperature, too, the electrons acquire high velocities as they move to and fro with their proper share of heat energy. At the surface of the hot body the electrons may break away; and hence the "thermionic emission" investigated by O. W. Richardson. So copious is this supply of electrons at the surface of a hot body that if the latter is made negative in potential relative to its surroundings there is a current discharge which may sometimes be measurable in amperes.

There is the most remarkable connection between moving electrons and electromagnetic waves. The one, it seems, can always call up the other; and the action obeys certain precise numerical laws.

Let us take as an example the production of X-rays in a Coolidge bulb. A plentiful supply of electrons is provided at the cathode by heating a fine spiral of tungsten wire to a high temperature. A high potential difference between cathode and target is provided by some appropriate means, and the electrons are hurled at the target, each possessing an amount of energy equal to the product of the electron charge and the applied potential. Where the electrons strike, some of their energy is converted into electromagnetic waves of very high frequency, the so-called X-rays. Let the energy supplied to each electron be measured—not an easy matter with the usual arrangements, but very easily done if, as in certain experiments of Duane and Hunt at Harvard University, the potential is derived from a great storage battery of 40,000 volts. Further, let the X-ray radiation that issues from the target be analysed by the X-ray spectrometer. It is found that the frequencies of the emitted rays may have a wide range of values, but that the upper limit of the frequencies is always proportional to the energy of the electron and, therefore, to the potential imposed on the tube. The ratio remains the same no matter what is the intensity of the electron discharge, and no matter what the nature of the target. This ratio of electron energy to maximum frequency is a number which has turned up in previous cases where the emission of radiation energy has been measured: it is known as Planck's constant and is denoted by "h." Its value is $6{\cdot}55 \times 10^{-27}$. Although the constant has

been met with before, there is probably no instance where the transformation of energy which it governs is so simply displayed or so easily measured as in the case just described.

In certain measurements made by Duane and illustrated in *Fig.* 1, the X-ray spectrometer was set to observe the presence of a

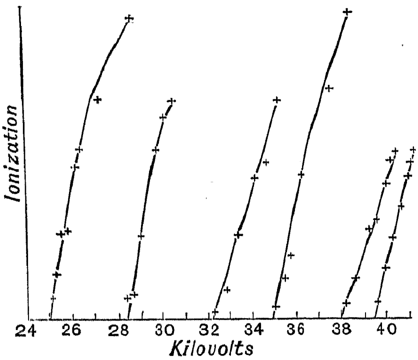

FIG. 1.

Each curve shows the rise of intensity of X-rays of one particular wave-length as the volts on the bulb are increased. The wave-lengths are (left to right) 0·488, 0·424, 0·377, 0·345, 0·318, 0·308, all in Ångström units (10^{-8} cm.). (From Duane and Hunt, *Physical Review*, 1915, p. 166.)

certain frequency as soon as it appeared. The potential on the tube was then increased by degrees. The rays of the given frequency appeared as soon as the energy supplied to the electron was equal to the frequency multiplied by h. As the potential was increased still further these rays increased in intensity, as the *figure* shows. The product of a frequency and the constant "h" is known as the quantum energy of that frequency.

It is to be observed that the production of X-rays is no aggregate of individual efforts by separate electrons: each electron produces its own train of X-rays when it strikes the target. There is no sign of any combined action, as indeed is evident from the fact that the intensity of the cathode-ray stream is without influence on the frequencies of the X-rays produced.

The crucial point is that when the energy of an electron is handed over in whole or in part, the frequency of the X-ray waves that take over the energy is determined by the quantity of energy handed over. This explains why there is a limit to the frequency of the X-rays: it is because there are some electrons, though only a fraction of the whole number, which give up all their energy to the formation of X-rays at the moment of striking, before they have lost energy in collisions. The rest of the rays, all those which have lesser frequencies, will come from electrons that have lost speed in this way, or possibly transfer only part of their energy. The atom of the target is playing the part of a transformer, and does not determine the frequency, so far as these effects are concerned.

This remarkable effect is reciprocal. Just as the swiftly moving electrons excite X-rays, so X-rays when they strike any substance lose their energy, which now appears as the energy of moving electrons. And, again, the same variation is found in the result and the same limit to that variation. Among the electrons so set in motion, if examined as soon as possible after their motion has begun, occurs every variety of energy-content up to a certain critical value which is equal to the frequency of the X-rays multiplied by the same constant h. It is to be observed that it is impossible to measure all the electron velocities as soon as they exist, because some of the motions begin in the body of the substance into which the X-rays have penetrated, and speed is lost on the way out. Again, therefore, there is nothing against the hypothesis that the energy of every electron set going by waves of given frequency is originally the same, and is determined by the standard condition already given.

Not only in the case of X-rays are these effects observed, but also in the case of light. The only difference is that the frequencies of light vibrations are some 10,000 times less than those of X-rays, and the electron energies are correspondingly smaller. When the light waves produce the electrons we have what is known as the photo-electric effect. The production of light by electrons has been much studied recently in experiments to find "resonance-potentials," that is to say, the magnitudes of potentials which must act on electrons so as to give them enough energy to excite certain radiation from atoms on which they fall.

Exactly how this strange transfer of energy from one form to another takes place is not known: the question is full of puzzles. The magnitudes involved are hard to realise; it helps to alter their scale of presentment. Suppose that the target of the X-ray bulb were magnified in size until it was as great as the moon's disc, that is to say, about a hundred million times. The atoms would then be spheres a centimetre or so in diameter. But the electrons would still be invisible to the naked eye. The distance from earth to moon would correspond roughly to the distance that ordinarily separates the bulb from an observer or his apparatus. The enlarged electrons are now shot at the moon with a certain velocity: in every second each square yard or square foot or square inch, it does not matter which, receives an electron. A radiation now starts away from the moon which immediately manifests itself (there is

no other manifestation whatever) by causing electrons to spring out of bodies on which it falls. They leap out from the earth, here one and there one; from each square mile of sea or land, one a second or thereabouts. They may have various speeds; but none exceed, though some may just reach, the velocity of the original electrons that were fired at the moon. That, reduced again to normal size, is the process that goes on in and about the X-ray bulb: which is part of a universal natural process going on wherever radiation, electron or wave, falls on matter, and which is clearly one of the most important and most fundamental operations in the material world.

Keeping these results in mind it is possible to appreciate a very remarkable development of electron theory which has been made in the last few years. Spectrum analysis has long been occupied with the extraordinary complications of the light radiation emitted by the various atoms. As a result it appears that the frequencies of the lines in a spectrum often display curious and exact numerical relations, in the form generally involving differences of frequencies of similar lines or groups of lines. For instance, the famous Balmer equation:

$$\text{Frequency} = \nu = \mathrm{N}\left(\frac{1}{n^2_1} - \frac{1}{n^2_2}\right),$$

where $\mathrm{N} = 3{\cdot}290 \times 10^{15}$,

gives the frequencies of series of lines in the hydrogen spectrum. When n_1 is put equal to 2, and n_2 to 3, 4, 5 in succession, the series of values for ν represent the frequencies of the lines in the visible spectrum. If $n_1 = 3$ and $n_2 = 4, 5, 6 \ldots$, in succession, the frequencies are those of lines in the infra-red (Paschen), and if $n_1 = 1$, $n_2 = 2, 3, 4 \ldots$, the frequencies correspond to those recently shown by Lyman to exist in the ultra-violet.

Now there is nothing in the older conception of the origin of radiation within the atom to give a clue as to why differences of frequencies should come into these empirical though most useful formulae. Our imagination has pictured to us vibrating systems, mechanical or electric, and waves arising therefrom. But no connection between masses or electricities gives in any simple way equations involving the addition or subtraction of frequencies. It is reasonable, therefore, to abandon preconceptions as to the origin of those lines which are found in the light spectrum and to suppose that here also they arise in the same fashion as in the cases considered above. Suppose that the energy of an emission of radiation is derived from the energy of an electron. It may be the only way in which radiation ever does arise, but it is not necessary to suppose so much at present. It is sufficient to carry into the atom the whole process which in X-rays and the photo-electric effect are observed to take place in part outside. Suppose that within the atom there are certain positions or conditions in which electrons *may* be, each postulating a certain energy associated with the electron; and suppose that sometimes an electron slips from one position to another of lower energy, and that the difference in energies is transformed into wave radiation according to the same law as before, *i.e.* energy transferred $= h \times$ frequency. Let the energy in these states be $\mathrm{N}h/1^2$; $\mathrm{N}h/2^2$; $\mathrm{N}h/3^2$; etc., and so on. Then all the series yielded by the Balmer formula are accounted for at the same time.

What may these states be? Why not, as Bohr suggests, so many different orbits in which electrons can move round the central positive nucleus in the atom, the nucleus whose existence has been established by Rutherford? At one time, if the existence of these orbits had been assumed, they would have been connected with the direct emission of radiation; and the frequency of that radiation with the number of revolutions in a second. But now it is assumed these orbits persist without radiation, and that radiation arises when the electron steps from one orbit to another; moreover, the frequency of the issuing radiation is determined by the simple rule: frequency is equal to change of electron energy divided by h. There is no more in this than supposing a process to exist in one place which is already known to exist in another.

It is a very remarkable fact[1] that the number N is equal to $2\pi^2 me^4/h^3$ within small errors of experiment. Spectrum measurements show that N is equal to $3{\cdot}29033 \times 10^{15}$ and $2\pi^2 me^4/h^3$ is equal, taking the most recent determination of m, e and h, to $3{\cdot}289 \times 10^{15}$.

Imagine an electron revolving in a circle about the positive nucleus of the hydrogen atom with kinetic energy $2\pi^2 me^4/n^2h^2 = \mathrm{N}h/n^2$. Its velocity, v, $= 2\pi e^2/hn$; the radius, r, of the circular orbit is found by putting $mv^2/r = e^2/r^2$, and is equal to $n^2h^2/4\pi^2 me^2$. The angular momentum is $mvr = nh/2\pi$. If the electron changes its orbit from $n = n_2$ to $n = n_1$, where n_2 is greater than n_1, its kinetic energy in the new orbit is *greater* than in the old by $\mathrm{N}h(1/n^2_1 - 1/n^2_2)$. But an amount of potential energy has been set free equal to $e^2(1/r_1 - 1/r_2)$, and this is equal to twice the change in kinetic energy, as is easily seen by substituting for the r's their values as found above. Consequently the right amount of energy is available for radiation.

It is possible, therefore, following Bohr, to define the necessary separate states as those of motion in circular orbits in which the

[1] See "Quantum Theory" and "Radiation Theory," Vol. IV.

angular momentum is an integral multiple of $h/2\pi$. The simplicity of these expressions is very attractive. But the matter is far from ending here. During the last few years Bohr and Sommerfeld have led an inquiry into the possibilities of this theory which has furnished very remarkable results. These are due to a slight modification in the original conception. The different circular orbits which Bohr first pictured have become groups of orbits fixed by laws which are somewhat arbitrary, but not without foundation. A group contains a limited number of orbits in which the electrons may move, and each group corresponds to one of the original circular orbits. Some of the orbits in each group are elliptical. It appears that the energy of the electron would be the same in all the orbits of any one group were it not that when an electron moves in an ellipse its velocity is not always the same. Now a fast-moving electron shows a variation in mass when its speed alters, and this does affect slightly the energy of the orbit. Consequently, the electron that steps from an orbit belonging to one group to an orbit belonging to another group may part with an amount of energy which is not always exactly the same. The frequency of the consequent radiation may, therefore, have two or more values differing slightly from each other; the single spectrum line is doubled or trebled. This is what Sommerfeld calls the "fine structure" of the lines.

Now there is far more than mere speculation in this. The formula which Sommerfeld gives as the result of an analysis which is as reasonable as can be expected does more than account for known effects; it has predicted the existence of numerous lines, and even their intensities, and the predictions have been verified by experiment in the most remarkable way.[1]

The interchange of energy between wave and electron has recently been examined from a new point of view with very interesting results. It is well known that every atom can be stimulated under proper conditions to the excitement of X-rays characteristic of the atom. For instance, tin atoms can be made to emit a certain series of "lines" known as the K series, provided that the incident and exciting radiation is, if a wave, of shorter wave-length than 0·421 Ångstrom units; or, if an electron, of the corresponding quantum energy.

The actual measure of the "critical quantum energy" of the wave or the kinetic energy of the electron is

$$6{\cdot}55 \times 10^{-27} \times 3 \times 10^{10} \div 0{\cdot}421 \times 10^{-8} = 4{\cdot}67 \times 10^{-8} \text{ ergs.}$$

When the quantum energy of the exciting radiation exceeds this amount the whole K series is excited: the quantum energies of the principal members of the series are 4·55 and 4·02, the unit being 10^{-8} ergs.

Tin, like other atoms, has other characteristic radiations; in particular, there are certain so-called L series whose quantum energies are about one-eighth of those of the K series; and again, there are M series of still smaller energy, and no doubt others amongst which quanta of visible light are included. It is sufficient for present description to assume that the L series have on the average a critical quantum energy 0·65 and the M series 0·12.

Two questions now arise: (1) If the critical energy 4·67 represents, as is natural to assume, an energy given up by the incident radiation to the atom, what becomes of the balance when the radiation 4·55 or alternatively 4·02 is excited in the atom? (2) If the energy of the exciting radiation exceeds 4·67, what becomes of the excess?

The answer to the first question appears to be supplied by the observation that $4{\cdot}67 - 4{\cdot}55 = 0{\cdot}12$ (M) and $4{\cdot}67 - 4{\cdot}02 = 0{\cdot}65$ (L).

It seems to be the general rule, verified carefully by Duane,[2] that the difference between two critical quanta is equal to a wave quantum.

An answer to the second question is given by de Broglie,[3] whose experimental results agree with the hypothesis that the excess of the incident quantum energy over the critical quantum energy appears subsequently as the energy of a high speed electron. De Broglie examined (with other similar cases) the magnetic spectrum of the electron radiation arising from the incidence of rays characteristic of tungsten upon a tin radiator. The two principal incident radiations had quantum energies 10·62 and 9·40: they were, in fact, the K lines of tungsten. In the magnetic spectrum were found five groups of electrons: one of these had a maximum energy 5·9, which is equal to $10{\cdot}62 - 4{\cdot}67$ within experimental error: the maximum energy of the other was 4·7, which is very nearly $9{\cdot}40 - 4{\cdot}67$.

In this case, then, the difference between the energies of the exciting quantum and of the critical quantum is equal to the maximum energy of a group of electrons which is found in the magnetic spectrum.

Three other groups of electrons were found by de Broglie on his plates. Their maximum energies were 4·4, 3·9, and 3·4. These were to be expected, since the characteristic rays of tin 4·55 and 4·02 were present, having been excited by the tungsten rays of superior quantum energy; and in further sequence to the rule just stated there ought to be electron groups having respectively maximum energies equal to $4{\cdot}55 - 0{\cdot}12 = 4{\cdot}43$,

4·55 – 0·65 = 3·90, 4·02 – 0·12 = 3·90, and 4·02 – 0·65 = 3·37.

Parallel results in the case of γ-rays have been obtained by C. D. Ellis under the direction of Rutherford. They are described in the *Proceedings of the Royal Society*, June 1921.

W. H. B.

ELECTRONS AND THE DISCHARGE TUBE

§ (1) ELECTRIC DISCHARGE THROUGH GASES AT LOW PRESSURE.—When an electric discharge is passed through a gas at a fairly low pressure, say below 6 mm. of mercury, some very beautiful and interesting phenomena are to be observed. The effects can be studied by sealing two electrodes, generally of aluminium, in a glass vessel which is gradually exhausted by means of a vacuum pump. If the electrodes are raised to a sufficiently high potential difference, either by means of a small induction coil or a battery of 1000 volts, and the pressure of the gas is gradually reduced, an electric discharge will eventually take place accompanied by luminosity in various portions of the gas. Tubes specially constructed to exhibit these phenomena are known as Geissler tubes, and the discharges themselves are sometimes referred to as Geissler discharges.

The appearances presented by the discharge, and the gas pressure and potential difference necessary to excite them, depend not only on the nature of the gas, but also on the shape and size of the discharge tube, the current passing through it, and to a smaller extent the nature of the electrodes. The simplest form of Geissler tube, and therefore the form most suited for studying the phenomena, consists of a simple cylindrical glass tube fitted with a pair of plane parallel electrodes, the electrodes being sufficiently large to cover the whole cross-section of the tube. A tube of from 2 to 3 cm. in diameter is convenient (though very much wider ones have been used by some observers), and if the tube is to be excited by a 1000-volt battery the distance between the electrodes should not exceed 10 or 12 centimetres. The longer the tube the greater the potential difference necessary to produce the discharge.

With a simple discharge tube of this kind the appearances presented by the discharge may be divided into four main types, which change gradually from one to another as the conditions are varied. The most important factor in determining the appearance of the discharge is the pressure and nature of the gas in the tube, but the exact pressures at which the changes take place depend also on the shape and size of the discharge tube and the current passing through it. An increase in the potential applied to the tube will generally produce an effect on the discharge similar to that which would be produced by a further reduction of the gas pressure. The following description refers to air enclosed in a discharge tube 3 centimetres in diameter, and having plane parallel electrodes 22 centimetres apart. The numerical data are due to Townsend.[1]

As the pressure of the air in the tube is gradually reduced, say to 4 or 5 millimetres of mercury, a discharge passes between the electrodes accompanied by luminosity in the gas. If the potential difference across the tube is not much greater than that required to maintain a current through it, the luminosity is at first confined to the surface of the electrodes (*Fig.* 1),[2] each of which is

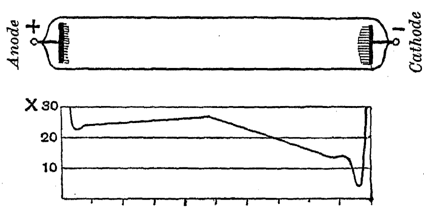

FIG. 1.

seen to be covered by a luminous glow. As the pressure is still further reduced these glows extend outwards into the tube, especially that at the positive electrode, which, at pressures of between 1 and 2 millimetres, will be found to occupy the greater part of the length of the tube. The colour of the two glows is quite distinct. In air the positive column is orange red and the negative blue. The positive column when examined spectroscopically gives the characteristic spectrum of the gas in the tube, and this portion of the discharge is therefore employed in spectroscopic work. The two luminous portions of the gas are separated by a non-luminous portion known as the Faraday dark space.

When it first makes its appearance the positive column is a uniformly luminous column of light. As, however, the pressure is still further reduced to about 0·5 millimetre of mercury it tends to break up into striae, the striation taking place more readily if the applied potential difference is small. The tendency to break into striae increases as the pressure is reduced until, at a pressure of about ·25 millimetre, the column is completely striated for a large range of currents. The luminous striae are button-shaped in appearance with their convex sides facing the cathode. They are spaced at regular intervals, their number and distance apart depending on the

[1] Townsend, *Electricity in Gases*, p. 398.

[2] The lower part of the diagram gives the electric intensity in the tube measured in volts per cm. See § (3).

size of the discharge tube and the current passing through it. The striae are more widely separated in a wide than in a narrow tube.

Somewhere about this stage it will be noticed that the negative glow is beginning to extend outwards into the tube, driving the positive column backwards towards the anode. As soon as the phenomena at the negative end of the tube have become sufficiently well developed it will be seen that the glow consists of two portions separated by a dark interval known as the Crookes dark space. The portion immediately around the surface of the cathode is known as the cathode glow. The other portion, lying between the two dark spaces, is known as the negative glow. The typical appearance of the discharge at this stage is indicated diagrammatically in *Fig.* 2.

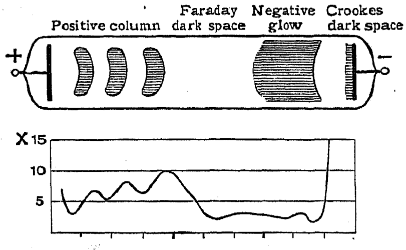

FIG. 2.

If the tube is still further exhausted the Crookes dark space increases rapidly in length at the expense of the positive column, which is soon represented merely by a glow (known as the anode glow) on the surface of the anode. The anode glow generally persists over some considerable range of gaseous pressures, but finally disappears, leaving only the negative glow and the glow on the surface of the cathode (*Fig.* 3). The pressure at which these

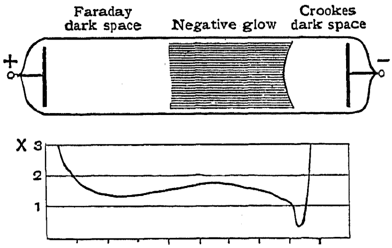

FIG. 3.

changes occur depends mainly on the distance between the electrodes. It is found that the length of tube occupied by the Crookes dark space and negative column is independent of the distance between the electrodes. At a pressure of ·1 millimetre in air the Crookes dark space is about 1·5 centimetres wide and the negative glow about 10 or 12 centimetres long. Thus if the distance between the electrodes is less than from 11·5 to 13·5 centimetres the negative glow will reach the anode and there will be no positive column. If the pressure is still further reduced, the Crookes dark space continues to extend, driving the negative glow before it. The cathode glow also disappears, the whole of the gas eventually becoming non-luminous. At this stage, which is employed in X-ray tubes, the discharge is entirely dark, save for the vivid fluorescence excited on the walls of the discharge tube itself. If the exhaustion is pushed to extreme limits the tube ceases to conduct.

§ (2) POTENTIAL NECESSARY TO PRODUCE THE DISCHARGE.—The potential necessary to initiate a discharge is not a very definite quantity, owing, possibly, to electrification on the inner walls of the discharge tube, and a considerably larger voltage may be required to excite the discharge than that necessary to maintain it when once excited. The latter voltage depends mainly on the nature and pressure of the gas and the distance apart of the electrodes, but it also depends on the diameter of the tube, being greater for a narrow than for a wide tube. It also depends to some extent on the nature of the electrodes. The following figures, due to Townsend,[1] give the potential difference in volts necessary to maintain a current of 10^{-2} amperes between aluminium electrodes 11·5 centimetres apart in rarefied air at a pressure p:

p in mm. of Mercury.	v in Volts.	p in mm. of Mercury.	v in Volts.
4	650	·40	530
2·84	620	·29	590
1·65	500	·24	630
1·04	470	·17	740
·66	490	·13	800

The discharge tube in this example was 3 centimetres in diameter. There is therefore a definite pressure of gas at which the discharge takes place most easily. Either increasing or decreasing the pressure from this critical value increases the potential difference necessary to maintain the discharge.

If the potential is increased beyond the minimum necessary to maintain a discharge, the current through the tube increases. At the higher pressures a very slight increase in the voltage of only 1 per cent or 2 per cent may be sufficient to more than treble the current produced. This sensitiveness, however, becomes less marked as the pressure becomes lower.

§ (3) DISTRIBUTION OF ELECTRIC INTENSITY IN THE DISCHARGE.—The distribution of the

[1] Townsend, *Electricity in Gases*, p. 396.

electric intensity in various parts of the discharge has been investigated by many observers, including Hittorf,[1] Graham,[2] H. A. Wilson,[3] J. J. Thomson,[4] and Aston.[5] The method employed by the earlier observers was to insert in the tube a small subsidiary electrode consisting of a fine-pointed platinum wire connected to an electrometer. Assuming that there is an adequate supply of charged ions in the neighbourhood, any difference of potential between the point and the surrounding space will set up an electric field either towards or away from the point, and ions of the appropriate sign will thus be driven up to the wire until the difference of potential is neutralised. The potential of the wire will then be the same as that of the surrounding gas.

The accuracy of the method obviously depends on there being a sufficient supply of both positive and negative ions in the gas around the wire. Let us suppose, for example, that only negative ions are present, as is practically the case near the anode. The negative ions will collide with the wire, giving it a negative charge, and will continue to do so until the potential of the wire is so far below that of the surrounding gas that the resulting field is sufficiently strong to prevent any further negative ions reaching it. As the number of positive ions present is too small to neutralise the charge on the wire, the latter will thus acquire a potential which may be considerably lower than that in any part of the surrounding space before the introduction of the wire. Hence at points close to either electrode the results obtained by this method are almost certainly misleading. In the main part of the discharge they are probably sufficiently near the truth.

In applying the method it is desirable to use two exploring points situated at some small fixed distance apart, say 1 millimetre. Since the distance apart of the points is fixed, the difference of potential between the points will be directly proportional to the electric intensity in the portion of the discharge between the points. This method was employed by Graham (*loc. cit.*) and H. A. Wilson (*loc. cit.*). The two test points *e* and *f* (*Fig.* 4) were sealed into the walls of the discharge tube, while the main electrodes A and C between which the discharge was taking place were mounted on a movable frame which could be controlled magnetically from outside the tube. In this way the position of the test wires could be made to coincide with any desired part of the discharge.

[5] F. W. Aston, *Proc. Roy. Soc.* A, 1911, lxxxiv. 526; *ibid.* A, 1912, lxxxvii. 437.

An ingenious method, which would appear to be free from the uncertainties introduced by the test wire, was devised by Sir J. J. Thomson (*loc. cit.*), and is based on the fact

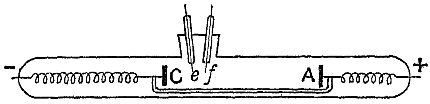

FIG. 4.

that a beam of cathode rays (see later, § (8)) is deflected by an electric field, the deflexion being directly proportional to the intensity of the field. A beam of cathode rays is generated in a side tube placed at right angles to the main discharge, and the rays, after crossing the main discharge, are received on a fluorescent screen placed in another side tube directly opposite to the first. The deflexion of the cathode rays from their normal position will then be a measure of the electric intensity in the portion of the discharge through which they have passed. This method was subsequently adopted by Aston (*loc. cit.*). Except in the vicinity of the electrodes, the results obtained by the two methods are in good agreement.

Starting at the cathode, it is found that the intensity of the electric field in the actual vicinity of the cathode itself is very high, much higher, in fact, than in any other part of the discharge. The intensity decreases rapidly as we pass through the Crookes dark space until on reaching the negative end of the negative glow its value is almost inappreciable. Aston (*loc. cit.*), who has made a special investigation of this part of the discharge, finds that the force at a point in the Crookes dark space is directly proportional to the distance of the point from the negative edge of the negative glow.

The electric intensity rises slightly in passing along the negative glow, falls again in the Faraday dark space, increasing once more as the positive column is approached. When the positive column is uniform the field in the column is also uniform. If, however, the column is striated the striations are accompanied by local variations in the intensity, the latter being a maximum at positions of maximum brightness. The intensity of the field in the positive glow decreases with the pressure. According to most observers, there is a small but rapid increase of potential, with corresponding increase in the field, in the direct vicinity of the anode.

The phenomena are, of course, modified if any parts of the discharge are not present. Graham's results for discharges of different types are given in *Figs.* 1-3, immediately below the diagrams illustrating the appearances of the discharge.

§ (4) Cathode Fall of Potential.—Since the field in the neighbourhood of the cathode, and through the greater part of the Crookes dark space, is much greater than that in any other part of the discharge, it is obvious that the difference of potential between the cathode and a point in the negative glow will in general be a very large fraction of the whole difference of potential across the tube. It is known as the cathode fall of potential. The cathode fall of potential is independent of the pressure of the gas in the tube, and also of the current density of the discharge if the latter is not too great. It is found that when the current through the tube is small the cathode glow only occupies the central part of the cathode, the area occupied by the glow increasing as the current is increased. As long as the cathode is not completely covered by the glow the cathode fall of potential remains constant,[1] and may be known as the normal cathode fall. If, however, after the glow has completely covered the electrode, the current is still further increased, the cathode fall increases with the current.

A considerable number of determinations of the normal cathode fall of potential have been made, and the results of the various observers have been summarised by Mey.[2] The fall of potential depends upon the nature of the gas. Using platinum electrodes, it is about 340 volts in air, 300 volts in hydrogen, 167 volts in argon, and 470 volts in water vapour. The value for a given gas is very nearly the same for electrodes of any of the less electropositive elements, such as platinum, silver, copper, or iron, but is considerably reduced when the electrodes are of magnesium, sodium, or potassium. With electrodes of the latter metal the normal cathode fall in hydrogen is reduced to 172 volts, and in argon to 69 volts. This is probably due to the great facility with which these metals emit electrons under the action of the radiations from the discharge.

§ (5) Conductivity in Various Parts of the Discharge.—The conductivity of various parts of the discharge has been investigated by H. A. Wilson [3] by measuring the current passing between two small platinum plates placed on opposite sides of the discharge, and parallel to its direction; a small potential difference (that of a single Clark cell) being maintained between the plates. For potential differences of this order it was found that the current was directly proportional to the applied potential difference, thus showing that the number of free ions in the main discharge was not appreciably affected by the field between the plates. Under such circumstances it can be shown that the current between the plates is proportional to $k_1n_1 + k_2n_2$, where n_1, n_2 are the numbers of positive and negative ions per unit volume, and k_1, k_2 their respective mobilities.

The matter has recently been re-investigated by van der Pol[4] by an ingenious method not involving the use of subsidiary electrodes. If stationary waves are induced in a pair of parallel wires, which have been adjusted to be in tune with the generator employed, the current in this Lecher system will reach a stationary condition in which the energy supplied by the generator is exactly balanced by the energy dissipated in the system. If, now, a conductor is introduced anywhere in the space between the wires, currents will be induced in the conductor and the rate of dissipation of the energy in the system will be increased. If the energy is supplied at a constant rate the current in the wires will therefore decrease, and the decrease in current affords a measure of the conductivity of the conductor. By bringing different parts of the discharge tube in turn into the plane of the wires the conductivity of the different parts of the discharge can be investigated.

The results obtained by the two methods, while agreeing in the main, exhibit some minor discrepancies. The conductivity and therefore the number of ions per unit volume is very small in the Crookes dark space (*Fig.* 5),

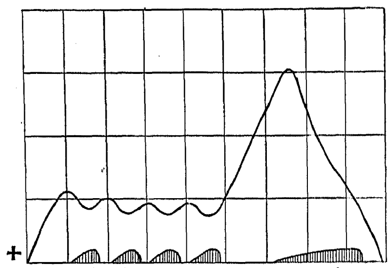

Fig. 5.

increases rapidly in passing along the negative glow, and attains a maximum value in the neighbourhood of the junction of the negative glow with the Faraday dark space. It decreases as the positive column is approached, and then, if the positive column is uniform, remains constant until the anode is approached, when it again decreases. If, however, the positive column is striated, variations in the conductivity are found corresponding with each of the striae. According to H. A. Wilson the maximum conductivity occurs at the brightest part of each striation; according to van der Pol the brightest part of the striation is a place of minimum conductivity. This is in

accordance with J. J. Thomson's observation that the field is most intense in the bright parts. Assuming that the velocity of the ions increases with the field, they should be removed more rapidly from places where the field is strong, and hence the number of free ions and the conductivity should be less in such regions. It is possible that in Wilson's experiments the radiations emitted by the luminous portions of the gas caused an actual emission of electrons from the surfaces of his test electrodes, thus increasing the apparent conductivity at these points. According to van der Pol, for a given current through the discharge tube the conductivity of the positive column increases as the pressure of the gas is decreased.

§ (6) The Crookes Dark Space.—The length of the Crookes dark space has been investigated by numerous observers, including Ebert[1] and Aston.[2] When the current through the tube is so small that the cathode glow does not cover the whole surface of the cathode the length occupied by the dark space depends only on the nature and pressure of the residual gas. According to J. J. Thomson,[3] Ebert's results show that under these circumstances the thickness d of the Crookes dark space may be expressed in the form $d=a+b/p$, where p is the pressure and a and b are constants. This may also be written in the form $d=a+\beta . \lambda$, where λ is the mean free path of an electron in the gas. The dark space, as measured from a distance a in front of the cathode, would thus be directly proportional to the mean free path in the gas. The distance a is of the order of ·25 millimetre.

When the current is sufficiently large to cause the negative glow to cover the cathode completely the phenomena are complicated by the action of the walls of the vessel. Under these circumstances Aston (*loc. cit.*) found that the length d of the Crookes dark space could be expressed by the formula

$$d=\frac{A}{p}+\frac{B}{\sqrt{I}},$$

where p is the pressure, I the current density, and A and B are constants for a given gas. Under the same circumstances the cathode fall of potential V is given by the formula

$$V=E+\frac{F\sqrt{I}}{p},$$

where E and F are constants for a given gas.

§ (7) General Theory of the Discharge.—Assuming that the discharge is conveyed across the tube by the motion of gaseous ions, then, in the absence of any external ionising agent, these ions must be produced from the molecules of the residual gas in the tube by the action of the ions already present. It is known that if a sufficiently strong electric field is applied to an ion, especially in a gas at low pressure, the ion acquires sufficient energy to ionise a neutral molecule with which it may collide. This ionisation by collision takes place more readily with negatively than with positively charged ions. It is obvious that for a continuous discharge to take place both the positive and the negative ions must be able to produce fresh ions by collisions at any rate in certain parts of the discharge. At low pressures such as those employed in the Geissler discharge the negative ion exists for the most part in the free or electronic condition. The positive ion, on the other hand, consists of a charged molecule or atom of the gas in the tube. The mobility of the negative ions will therefore be much greater than that of the positive.

Let us suppose that a discharge is passing through the tube and that conditions have become steady. We have seen that the electric field reaches its maximum value in the immediate neighbourhood of the cathode. The positive ions will therefore attain their maximum velocity, and hence their maximum power of producing fresh ions by collisions in this region. J. J. Thomson considers that the results of Ebert (*loc. cit.*) on the thickness of the Crookes dark space suggest that the negative ions are mainly produced in the region of gas lying about ·25 mm. in front of the cathode. On the other hand, the fact that the cathode fall of potential depends somewhat on the metal employed for the cathode would suggest that electrons may also be emitted by the cathode itself under the action of the rapidly moving positive ions. In either case the negative ions are produced within a region very close to the cathode, probably entirely within the cathode glow. Owing to the very strong field in this region the negative ions, which at this pressure consist of free electrons, will move away from the cathode with very high velocities, forming the cathode rays, which will be dealt with later. Both negative and positive ions will be rapidly removed from the space in front of the cathode, thus accounting for the small conductivity of this region, but the negative, being much more mobile than the positive, will be removed more quickly. There will thus be an excess of positive ions in the Crookes dark space. This accumulation of positive electricity in the neighbourhood of the negatively charged cathode accounts for the very large values of the electric field in this region.

The negative ions move from the cathode with sufficient velocity to enable them to

[3] Thomson, *Conduction through Gases*, 1906.

produce fresh ions by collision. The probability of a collision will, however, not be very great until the ion has moved through a distance comparable with its mean free path in the gas. If we assume that the luminosity of the gas is associated with ionisation the Crookes dark space will represent the distance fallen through by the negative ions before collision with the molecules of the residual gas, that is to say it should be comparable with the mean free path of an electron. This is at any rate approximately the case, and the supposition is further supported by Sir J. J. Thomson's interpretation of Ebert's results.

The positive space charge in the Crookes dark space obviously reduces the field on the positive side of the space, which, therefore, falls to a very small value, in accordance with the experimental determinations. The negative ions formed in the negative glow do not acquire sufficient energy to produce fresh ions by collision. Ionisation, therefore, ceases as soon as the cathode rays have exhausted their original impetus, and we have the beginning of the Faraday dark space. The positive ions formed in the negative glow are attracted to the cathode and thus maintain the supply of negative ions.

The current across the Faraday dark space is conveyed mainly by negative ions drawn from the negative glow. There is thus an accumulation of negative electricity in this region which gradually increases the electric field until finally it attains a sufficiently high value to cause fresh ionisation by collision. This point marks the beginning of the positive column. If the field remains constant, ionisation by collision will occur throughout the rest of the tube with the production of a uniform column of light. The striations, when formed, are probably due to a repetition in a modified form of the phenomena at the negative end of the tube.

The mathematical treatment of the theory of the discharge tube presents great difficulties, owing largely to the disturbing effects of the walls of the discharge tube. These certainly exercise an important effect in determining the nature of the discharge, but very little is known about the exact part which they play. Theories have been advanced by J. J. Thomson [1] and Townsend,[2] but the questions raised cannot be regarded as yet settled.

The hypothesis that the discharge is maintained by the action of positive ions approaching the cathode from the negative glow is, however, demonstrated quite readily by experiments such as those of Villard.[3] In these experiments a metal diaphragm (*Fig.* 6) pierced with two small holes, *a*, *a*, was placed at a distance of 1·5 centimetres in front of the cathode C, which consisted of a large plane disc, and the tube was then gradually exhausted. As long as the Crookes dark space did not extend to the diaphragm the current flowed from the whole surface of the cathode as shown by the fact that the whole of its surface was covered by the negative glow. As soon, however, as the dark space had expanded so as to reach the diaphragm, and the negative glow ceased to occupy any part of the region between the diaphragm and the cathode, the luminosity was found to be confined to two spots, *b*, *b*, immediately opposite the two holes in the diaphragm. The position of these luminous spots could be deflected by placing a positively charged electrode in the dark space, the direction of the deflexion indicating that the particles producing the luminous spots carried a positive charge. The existence of these positive particles can be demonstrated by using a perforated cathode. The presence of particles passing through the perforation is evinced by the appearance of luminous streamers behind the cathode. They form, in fact, the well-known Kanahlstrahlen, or Positive rays. Recent experiments by Aston,[4] in which the charges conveyed by the particles were collected in a Faraday cylinder, suggest that about half the current in the tube is conveyed to the cathode by these positively charged particles.

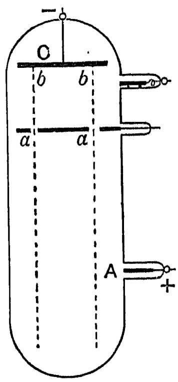

FIG. 6.

§ (8) THE CATHODE RAYS.—When the pressure in the discharge tube is very low the appearances presented are quite different from those of the Geissler discharges. The gas as a whole is non-luminous, except for the cathode glow, which also vanishes if the vacuum is high. At the same time a beam of light may be seen proceeding normally from the cathode, and penetrating to a greater or shorter distance along the tube as the pressure is comparatively low or high. At low pressures the beam may reach the further boundary to the tube, in which case it excites a vivid fluorescence on the portions on which it falls. The colour of this fluorescence depends on the nature of the substance on which the rays impinge. In ordinary German glass the fluorescence is bright green, possibly due to traces of manganese. With lithium glass the

fluorescence is blue, as is also the case with many samples of English glass.

These phenomena were first noticed by Hittorf.[1] The name cathode rays was given to them by Wiedemann. The discovery gave rise to much controversy, some holding that the rays consisted of vibrations in the ether, either transverse, as in the case of ordinary light, or longitudinal. Crookes, to whom many of the early experiments on the rays are due, suggested that they consisted of electrified particles of some very attenuated form of matter, projected with high velocities by the electric forces near the surface of the cathode.[2] This view is now universally accepted. The evidence in favour of this hypothesis will be gathered from the following summary of the properties of the rays.

An inspection of the trajectory of the rays, when the pressure is adjusted so as to make their path readily visible, shows that they travel in straight lines, proceeding normally from the surface of the cathode. If the cathode is plane, the beam is parallel and can be limited to a very narrow pencil, if desired, by placing a solid obstacle pierced with a small hole in front of the cathode. If the cathode is concave, the rays come to a focus at some point along the axis. Owing to the action of the strong electric field through which the rays are travelling, this focus is somewhat further from the cathode than its geometrical centre of curvature.

The cathode rays are deflected by a magnetic field, a discovery first made by Crookes. The direction of the deflexion is that which would occur in a flexible conductor coinciding with the path of the rays and carrying an electric current from the anode to the cathode. That the rays exert a pressure was proved by Crookes by placing a little windmill with mica vanes inside the discharge tube so that the rays impinged excentrically upon the vanes. On exciting the tube the mill revolved.

In order to explain the magnetic deflexion on the assumption that the rays consist of particles it is necessary to assume that the particles are negatively charged. The early experiments of Crookes and others to detect this charge were inconclusive, and sometimes gave quite unexpected results. This has been shown to be due to the very intense ionisation produced by the rays in the residual gas in the tube, and to the large emission of electrons which they produce when they impinge on a solid obstacle. The matter was placed beyond all doubt by the experiments of Perrin,[3] who passed the rays from a plane cathode C (*Fig.* 7) through a small aperture *a*, into a Faraday cylinder F connected to an electrometer. When the tube was excited so that the cathode rays entered the cylinder the latter acquired a negative charge of very

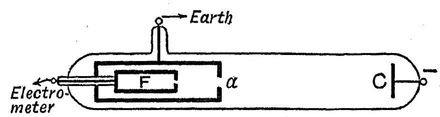

FIG. 7.

considerable amount. Using an induction coil to excite the discharge, the negative charge gained by the cylinder often reached as much as 100 electrostatic units for each interruption of the coil. If the rays were deflected by a magnet so that they did not strike the aperture of the chamber the cylinder remained uncharged. The experiments were repeated by J. J. Thomson in a slightly modified form with similar results.[4] These experiments were generally accepted as proving that the cathode rays consist of negatively charged particles.

The deflexion of the cathode beam by an electrostatic field, which is a necessary consequence of the hypothesis that they consist of negatively charged particles, had been indicated by experiments of Goldstein in 1876, and later by Perrin (*loc. cit.*), in which a subsidiary electrode which could be raised to a high potential was introduced into the path of the cathode stream. A negative charge repelled and a positive charge attracted the cathode beam, but very high potentials were required to produce an appreciable effect. Sir J. J. Thomson, however, by passing a narrow beam of the rays between a pair of parallel plate electrodes in a discharge tube at very low pressure was able to obtain a perceptible deflexion with a difference of potential of only two volts, thus placing the matter beyond all doubt. The difficulty experienced in obtaining the electrostatic deflexion is due to the fact that the rays produce intense ionisation in the residual gas of the discharge tube, and thus render it partially conducting. The rays are therefore screened to a considerable extent from external electric forces. This effect only becomes negligible when the pressure is very low.

The conductivity produced in a gas by the passage of the cathode rays was demonstrated by Lenard,[5] who allowed the rays to fall on a small aperture in the wall of the discharge tube covered with a very thin sheet of aluminium. The rays penetrate the aluminium leaf, passing into the air, which they also penetrate to a distance of some 8 or 10 centimetres. These Lenard rays, as they

are called, produce very considerable ionisation in the gas through which they pass.

§ (9) Determination of the Ratio e/m for the Cathode Rays.—A measurement of the magnetic deflexion of the rays throws important light on the nature of the particles constituting the rays. The deviation produced in the path of a particle of mass m and charge e projected with a velocity v in a uniform magnetic field of strength H was calculated by J. J. Thomson.[1] He showed that such a particle would be acted upon by a mechanical force of $\mathrm{H}ev \sin \theta$, where θ is the angle between the velocity of the particle and the direction of the field, the direction of this force being at right angles to these two directions. For if dt be the time taken by the particle to traverse a distance ds, its effect is that of a current i where $e = i\delta t$, while $v = ds/dt$. Thus

$$\mathrm{H}ev \sin \theta = \mathrm{H}idt \sin \theta \frac{ds}{dt} = \mathrm{H}i \sin \theta \,.\, ds,$$

and this is the mechanical force[2] on the current element ids. The path of the particle, therefore, would in general be a spiral with its axis parallel to the lines of force, the radius of curvature ρ being given by the equation

$$\rho = \frac{mv}{e\mathrm{H} \sin \theta},$$

where θ is the angle between the direction of projection of the particle and the field. If the velocity of the particle remains constant the path is therefore a helix wound on a circular cylinder with its axis parallel to the field and of radius r given by

$$r = \rho \sin^2 \theta = \frac{mv \sin \theta}{e\mathrm{H}}.$$

If the particle is projected at right angles to the field, the helix contracts into a circle of radius $r = mv/e\mathrm{H}$. If the field is not uniform the particles will describe spirals of varying amplitudes about the lines of the magnetic field.

These equations obviously afford a method of determining the ratio of the charge to the mass on a cathode particle, if the velocity of the particles can be determined. Determinations of the ratio e/m for the cathode particles were made independently and almost simultaneously in 1897 by J. J. Thomson,[3] Kaufmann,[4] and Wiechert.[5] The experiments differ principally in the methods employed to estimate the velocity of the rays.

§ (10) Thomson's Method of determining e/m.—In Thomson's experiments the velocity v of the rays was determined by balancing the magnetic against the electrostatic deflexion of the rays. If a uniform electrostatic field of strength X is applied at right angles to the magnetic field and coterminous with it, and the cathode rays are directed across the fields in a direction at right angles to both, the electric force acting on the particle will be $\mathrm{X}e$ in the direction of the electric field, and the magnetic force will be $\mathrm{H}ev$ at right angles to the magnetic field, that is in the same direction as the electric force. If the two forces are adjusted so that they are equal and act in opposite directions the resultant force upon the particles will be nil, and the beam will be undeflected. Under these circumstances we have, obviously,

$$\mathrm{X}e = \mathrm{H}ev,$$
$$v = \mathrm{X}/\mathrm{H},$$

which determines the velocity v, since X and H can be measured.

The apparatus (*Fig.* 8) consists of a plane cathode E and an anode placed in a small

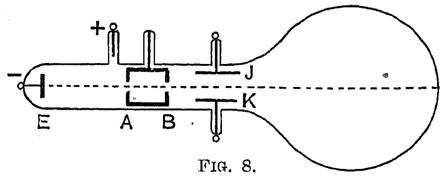

Fig. 8.

side tube to avoid interference with the rays. The cathode rays are limited to a narrow pencil by means of a pair of brass stops A and B pierced with a narrow slit. On emerging from the second stop the beam passes between two parallel plates J and K which can be charged to a difference of potential by a battery of cells. The magnetic field is applied by a small electromagnet, not shown in the figure, at right angles to the line joining the plates J, K. The strength of the two fields is adjusted until the position of the fluorescent spot produced where the beam strikes the further wall of the tube is unaffected by the joint action of the fields. The ratio X/H then gives the velocity of the rays. The electric field is removed, and the deflexion produced by the magnetic field alone is measured. From this and the dimensions of the apparatus the radius of curvature of the rays in the field can be calculated, thus giving a value for e/m. The value obtained by Thomson for this ratio was $1{\cdot}17 \times 10^7$ electromagnetic units per gm. This result is too low, probably owing to the screening action of the residual gas on the electric field. The ratio e/m was found to be constant, and independent of the nature and pressure of the gas in the tube. The velocity

[5] Wiechert, *ibid.*, Beiblatter, 1897, xxi. 443.

of the rays increased as the potential difference across the tube was increased.

§ (11) KAUFMANN'S METHOD OF DETERMINING e/m.—In Kaufmann's experiments (*loc. cit.*) a narrow pencil of rays from a plane cathode (*Fig.* 9) was passed through a small perforation in the anode of the tube, and it was assumed that the energy of the particles on passing through the hole was equal to that due to a free fall through the whole difference of potential V, between the anode and cathode. This assumption implies that the effect of the collisions between the rays and the molecules of the residual gas in the tube is negligible. This was apparently the case in Kaufmann's experiments. Thus we may write $\frac{1}{2}mv^2 = Ve$ or $v = \sqrt{2Ve/m}$. Combining this result with the magnetic deflexion of the rays we have two equations for determining e/m and v. In Kaufmann's apparatus the whole path of the rays from the aperture to the fluorescent screen was placed in a nearly uniform magnetic field produced by two coaxial solenoids. The actual distribution of the field was subsequently determined and corrections applied. Kaufmann's value for e/m was $1{\cdot}77 \times 10^7$, which is very near the mean of the most recent observations.

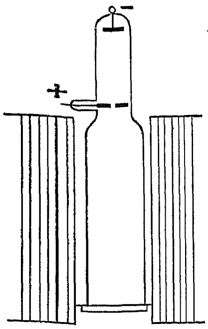

FIG. 9.

§ (12) WIECHERT'S DETERMINATION OF THE VELOCITY OF THE CATHODE RAYS.—The importance of Wiechert's experiments (*loc. cit.*) lies in the fact that the velocity of the rays was measured by direct experiment, as opposed to the indirect method of Thomson, and the assumption of Kaufmann. He found that the velocity of the cathode rays at the pressures he employed was of the order of one-tenth of that of light. His method consisted of comparing the time taken by the rays to cover a distance of about 20 centimetres with the period of the discharge of a condenser. The apparatus employed is indicated diagrammatically in *Fig.* 10. The cathode rays from the cathode C fall normally on a small hole in a screen A, and thence through a hole in a second screen A′ to a narrow fluorescent plate S. If a small magnet M is placed near the cathode the rays can be deflected so as to fall upon the solid part of the screen A, and the fluorescent screen will then be dark. A circuit *opqr* is placed near CA so that the magnetic field produced by a current passing round it is in the same direction as that due to the magnet. If a condenser of suitable capacity is now discharged round this circuit, a rapidly alternating magnetic field will be produced which will set the beam of rays swinging like a pendulum. If the oscillations are sufficiently large the rays will, in the course of their oscillations, fall intermittently upon the aperture in A, and the screen S will fluoresce. The fields are adjusted so

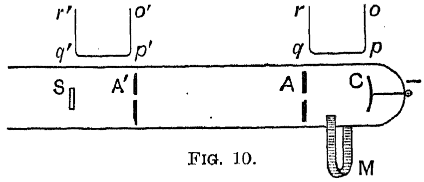

FIG. 10.

that the rays fall upon the aperture at the extreme end of their excursion.

A second circuit $o'p'q'r'$ is placed in the neighbourhood of A′S and connected in series with the circuit *opqr*. This will deflect the rays which pass through A′ exactly in the same manner as rays between C and A are deflected by *opqr*. The rays which emerge from A have been deflected to the maximum extent. If these rays reach A′ instantaneously they will again be deflected to the samé extent as between C and A, and will thus be thrown off the screen which will remain dark. If, however, the time taken by the rays to pass from A to A′ is such that the current has changed in phase by one-quarter period, there will be no current in $o'p'q'r'$ when the rays reach A′. For the moment there will be no magnetic field in the space, and the rays will pass through and reach the screen.

Thus the screen will be luminous if the time taken for the rays to describe the distance AS is equal to one quarter of the period of the condenser discharge. The latter can easily be determined experimentally, and thus the velocity of the cathode rays can be calculated.

The method is not susceptible of great accuracy, but the experiments are important, as providing a direct corroboration of the values obtained for the velocity of the cathode rays by less direct methods, and thus proving that their velocity is not that of light.

§ (13) THE MAGNETIC SPECTRUM.—The velocity of the cathode particles depends on the difference of potential between the ends of the tube and thus varies with the conditions of the experiment. Kaufmann's experiments may be regarded as proving that the maximum energy of the particles in the tube is equal to that which would be acquired if the particles fell freely through the full difference of potential between the electrodes. If, as is generally the case, the tube is excited by an induction coil, the cathode rays are far from being homogeneous, since the potential difference between the terminals of a coil is not constant.

The cathode beam will therefore contain particles having velocities corresponding to varying potentials between the minimum necessary to excite the discharge up to the maximum supplied by the coil. When a magnetic field is applied, the single spot of fluorescence produced by the undeflected beam will be drawn out into a band at right angles to the field, each point of which corresponds to rays of definite velocity. The effect is known as a magnetic spectrum, and the method is often employed to isolate a beam of cathode rays of definite uniform velocity.

The magnetic spectrum is generally not uniform, but consists of several bright lines, separated by more or less dark intervals. According to Strutt [1] the number and dispersion of these lines depend upon the peculiarities of the induction coil used to excite the tube. If a large electrostatic machine or a battery of cells is employed the rays are homogeneous and the spectrum reduces to a single line.

§ (14) NATURE OF THE CATHODE PARTICLES—THE ELECTRON.—The ratio e/m for the cathode particles is constant, being independent both of the nature and pressure of the gas in the tube and the nature of the electrodes. The most recent determinations of the ratio by different observers give values which do not differ by more than 1 per cent, and lie in most cases between $1 \cdot 76 \times 10^7$ and $1 \cdot 77 \times 10^7$ electromagnetic units per gram. The nature of the cathode particles is therefore independent of their mode of production, and of the nature of the substances from which they are produced. These particles are now known as ELECTRONS. They must obviously be present in all kinds of matter.

Since a charge of one electromagnetic unit in passing through a liquid electrolyte liberates $1 \cdot 0357 \times 10^{-4}$ grams of hydrogen, the ratio of the charge to the mass of a hydrogen atom in solution is $\cdot 96 \times 10^4$ electromagnetic units per gram. This is only about $\frac{1}{1850}$ of the value obtained for the cathode particles. If we assume that the charge is the same in the two cases the mass of the electron must be only $\frac{1}{1850}$ that of the hydrogen atom, the lightest particle hitherto known. There is now ample evidence in support of the assumption that the charges carried by an electron, and by a monovalent negative ion in solution are identical, perhaps the most direct being that supplied by the experiments of Rutherford [2] on the α-particles. We are therefore driven to the conclusion that the electron has a mass only $\frac{1}{1850}$ of that of the hydiogen atom.

§ (15) OTHER SOURCES OF ELECTRONS.—Electrons can be liberated in other ways than by the discharge in high vacua. If a metallic wire is raised to incandescence and charged to a small negative potential a very considerable emission of negative electricity takes place from the wire, which increases rapidly with increase in temperature. This emission can be shown to be due to the wire giving off negatively charged particles. The effect is enormously increased if the wire is coated with certain oxides, notably those of calcium and barium, in which case the emission of negative electricity may amount to several amperes per square centimetre of the surface. A platinum strip having a speck of barium or calcium oxide on its surface, and raised to incandescence by the current from a battery, forms a very convenient point source of electrons, and is known as a Wehnelt cathode. Cathodes coated with barium oxide are employed in the thermionic valves which are now employed so extensively in wireless telegraphy. A full account of the phenomena is given by O. W. Richardson,[3] to whom much of our knowledge of the subject is due. The negative particles emitted by hot bodies are often referred to as thermions.

Negative particles are also given off when a clean metal surface is illuminated by ultraviolet light. These are spoken of as photoelectrons. The effect is particularly well marked in the case of the alkali metals; so much so, in fact, that in the case of rubidium it has been actually employed to detect small quantities of light radiation. A well-constructed rubidium cell will easily detect the light radiation from a single candle at a distance of three miles, and is thus hardly inferior in sensitiveness to the human eye. This photo-emission takes place, though to a much smaller degree, with all metals, and also with non-metals if the wave-length of the illumination employed is sufficiently small.

Negative electricity in a corpuscular form is also given off when X-rays fall upon any material obstacle, and when the α-particles from radioactive substances, or the positive rays in a discharge tube, are stopped. The value of e/m for all these particles is identical with that obtained for the particles in the cathode rays. In other words, the negative emission consists in every case of electrons, which differ from each other only in the velocity with which they are emitted.

§ (16) DETERMINATION OF e/m FOR PHOTO-ELECTRONS AND THERMIONS.—The velocity of emission of the photo-electrons is very small compared with that of the cathode rays, corresponding generally to a fall through a potential difference of a few volts, that is to say it is of the order of 10^8 cm./sec. The velocity of the thermions is even less. As,

[1] R. J. Strutt, *Phil. Mag.*, 1899, xlviii. 478.

[2] Rutherford and Geiger, *Proc. Roy. Soc.* A, 1908, lxxxi. 141.

[3] O. W. Richardson, "Emission of Electricity from Hot Bodies," 1921. See also article "Thermionics."

however, they are all negatively charged, their velocity can be increased to any desired value by applying a suitable electrostatic field. Thus if the ordinary cathode in Kaufmann's experiment is replaced by a Wehnelt cathode the value of e/m for the electrons emitted can be determined in exactly the same way as for the ordinary cathode rays, by measuring the deflexion produced in a uniform magnetic field. Since the electrons are emitted with practically negligible velocities, the velocity attained by the electrons is due entirely to the field between the electrodes and can be calculated from the applied difference of potential. The value of e/m for the photo-electrons can be determined in a similar way, using a cathode of some suitable metal, illuminated by ultra-violet light.

The ratio can also be determined by a somewhat different method due to J. J. Thomson,[1] and applicable to all cases in which the initial velocity of the particles is small. A uniform electric field X is established between two plane parallel plates, and a uniform magnetic field H is applied at right angles to the electric field and, therefore, parallel to the plates. If the negative plate is now caused to emit electrons, say by illuminating it with ultra-violet light, these electrons, being negatively charged, will begin to move away from the plate with increasing velocity. As soon, however, as they have acquired a velocity they will be deflected by the magnetic field in a plane at right angles to the lines of the magnetic field, and will thus eventually return to the plate from which they started. It can easily be shown that, under these circumstances, the path of the particles is a cycloid, the curve traced out by a point on the circumference of a circle when the latter rolls along a straight line. The particles, therefore, cannot penetrate to more than a certain distance, equal to the diameter of this circle, from the negative plate. This maximum distance can be shown to equal $2X/H^2 . m/e$ where X and H are the electric and magnetic fields. If the distance apart of the plates is greater than this value no charge will reach the positive plate. If the distance is less than this critical value the whole of the negative electricity emitted by the negative plate will be conveyed to the other. The fields are adjusted until the positive electrode just begins to receive a negative charge. The value of e/m is then given by the equation

$$\frac{e}{m}=\frac{2X}{H^2d},$$

where d is the distance between the plates.

The same principle can be applied to the case of the thermionic emission. In this case the negative electrode takes the form of a straight incandescent wire, the positive electrode being a cool concentric cylinder. The magnetic field is applied at right angles to the electrostatic field, and parallel to the electrodes. The value of e/m is then given by the equation

$$\frac{e}{m}=\frac{2V}{H^2d^2},$$

where V is the difference of potential between the electrodes and d their distance apart.

§ (17) Recent Determinations of e/m for Electrons from Different Sources.—The table on the following page gives the values obtained for e/m for electrons from different sources by recent observers.

The close agreement between the values is remarkable and leaves no doubt as to the identity of electrons from different sources. The most generally accepted value is that given by Bucherer for the slow moving β-particles from radium. These experiments are dealt with later. The values calculated from the Zeeman effect for the ratio e/m for the negative particles emitting the bright lines in the spectrum of an element are also included in the table for comparison.

§ (18) The Nature of the Electron.—The question immediately presents itself as to what is the nature of these particles, which are so much lighter than the lightest known atom, and which can be produced in so many different ways from matter of every kind. The question has now been satisfactorily answered: the electron consists simply of a highly concentrated electrical charge, quite unassociated with anything which can be called matter in the ordinary sense of the word. In other words, it has been shown that the whole mass of the electron is due to the charge which it carries.

The fact that a moving charge will act as if it possessed inertia was first demonstrated by J. J. Thomson.[2] It can be shown that a point charge of strength e moving with a velocity v is equivalent to a current element ids coinciding with the path of the particle, and of strength given by the equation $ids=ev$. The moving particle will thus produce a magnetic field in its vicinity equal to $ev \sin\theta/r^2$, where r is the distance of the point considered from the charged particle, and θ the angle made by the line joining the two with the direction of the velocity. Now the energy in a magnetic field of strength H is $\mu H^2/8\pi$ per unit volume where μ is the magnetic permeability. Hence if du is a small element of volume in the neighbourhood of the point considered the magnetic energy in this element of volume will be $\mu(ev\sin\theta/r^2)^2\,du/8\pi$.

The total magnetic energy in the space around the charged particle can be obtained by integrating this quantity throughout the whole of the field, from the surface of the particle to infinity. If the charge is supposed to act as if it were concentrated at the centre of a small sphere of radius a in air, for which $\mu=1$, it can easily be shown that the total magnetic energy in the space is equal to $\frac{1}{3}e^2v^2/a$.

For $\qquad du=r^2 \sin \theta dr d\theta d\phi.$

Thus the energy

$$=\frac{1}{8\pi}\cdot e^2\cdot v^2\cdot \int_a^a\int_v^\pi\int_v^{2\pi}\frac{\sin^3\theta}{r^2}dr d\theta d\phi,$$

and this when integrated gives the value above.

This magnetic energy is due to the fact that the charged particle is moving with a velocity v. It must therefore be given to the particle when the latter is set in motion. Thus if the particle has a mechanical mass M when uncharged, the work done in giving it a velocity v when it carries a charge e is obviously

$$\tfrac{1}{2}\mathrm{M}v^2+\tfrac{1}{3}\frac{e^2}{a}v^2=\tfrac{1}{2}\left(\mathrm{M}+\tfrac{2}{3}\frac{e^2}{a}\right)v^2.$$

The particle thus behaves as if its mass had been increased by $\frac{2}{3}e^2/a$. This may be called the electromagnetic mass of the particle. Thus even if M is zero the particle will behave as if it had a mass $\frac{2}{3}e^2/a$ owing to the fact that it carries a charge e.

Other assumptions as to the distribution of the charge on the electron give values differing from that of Thomson only by a numerical factor. Abraham,[1] on the assumption that the charge was distributed on the surface of a perfectly conducting sphere of radius a obtained the value $1/6\pi e^2/a$. The large values obtained for e/m for the electron compared with that for the hydrogen atom made it probable that at any rate part of its mass might be due to the charge which it carried.

A very close analogy to electromagnetic mass is to be found in hydrodynamics. When any body is moving through a fluid it sets the surrounding fluid in motion, and when the body is moving with a uniform velocity, this fluid motion travels along with the body as if it were rigidly attached to it. In order to set the body in motion with a definite velocity we have, therefore, to supply energy not only to the body itself, but also to the fluid. The body, in fact, behaves as if its mass had been increased by some fraction of the mass of fluid which it sets in motion.

The actual mass of an electron can be determined by experiments to be described later. As, however, we have no means of measuring the radius a of the electron, we cannot immediately determine whether the charge e is sufficient to account for the whole of the mass. The question has, however, been settled in another way.

It can be shown from electromagnetic theory that the expression obtained for the electromagnetic mass of a charged particle is only valid if the velocity of the particle is small compared with that of light, in practice if it is less than one-tenth that of light. If the velocity approximates to that of light the distribution of the electric field around the particle is altered in such a way as to increase the electromagnetic energy in the field, and thus the electromagnetic mass of the particle.

[1] Abraham, *Ann. der Phys.*, 1903, iv. 10, p. 105.

The electromagnetic mass is, therefore, not a constant, but increases rapidly as the velocity approaches that of light. The analysis is complicated, but an interesting illustration of the principles involved has been given by J. J. Thomson, founded on the hydrodynamic analogy already discussed. If the body moving through a fluid is unsymmetrical the apparent mass depends on the direction in which the body is moving. Thus a long thin circular cylinder moving through a fluid in a direction at right angles to its length has its mass increased by that of a volume of fluid equal to the volume of the cylinder. If the cylinder is moving in the direction of its axis the additional mass is comparatively negligible. It can also be shown that the cylinder will always tend to turn so that its axis is at right angles to the direction of motion, that is to say in such a way as to make the additional mass as large as possible.

Suppose, now, that the field of electric force round the charged particle is mapped out by a series of Faraday tubes, each of which is regarded as a long thin cylinder. When the particle is at rest the field is uniform and the tubes will be uniformly distributed. If we regard this system of Faraday tubes moving through space as equivalent to a similar system of cylinders moving through a fluid, the tubes which are directed parallel to the direction of motion will contribute practically nothing to the additional or electromagnetic mass, while those at right angles to this direction will contribute the maximum amount.

Now in a mechanical system such as that we have imagined the cylinders which were moving end on would be in unstable equilibrium, and if free to move would turn into the equatorial plane, where their effect on the apparent mass would be the greatest. On this analogy we should expect the Faraday tubes to tend to crowd together in a plane at right angles to the direction of motion of the particle; that is to say, the field would be strengthened in this plane and weakened in the direction of motion. This is what actually occurs. The mutual repulsion of neighbouring Faraday tubes, however, tends to maintain a uniform distribution, and it is only when the velocity is comparable with that of light that the distribution is seriously affected. When such velocities are attained the hydrodynamic analogy would lead us to expect that the electromagnetic mass would increase.

The theoretical relation between the electromagnetic mass and the velocity depends on the assumptions made as to the behaviour of the electron. The problem was attacked from two different standpoints by Abraham (*loc. cit.*) and Lorentz.[1] The former assumed that the electron was rigid, its dimensions being the same at all velocities. Lorentz, however, assumed that the electron contracted in the direction of motion in accordance with the hypothesis put forward by Fitzgerald[2] to account for the results of the Michelson-Morley experiment. On either hypothesis the electromagnetic mass of a particle for accelerations at right angles to the direction of motion differs from that for accelerations along the line of motion. The former is known as the transverse mass, the latter as the longitudinal mass. The two coincide when the velocity of the particle is small compared with the velocity of light. In determinations of e/m by measurements on the magnetic and electric deflexions it is obviously the transverse mass with which we are concerned, as the forces are applied at right angles to the direction of motion of the particles.

According to Lorentz's hypothesis the transverse mass m_t is given by the equation

$$m_t = \frac{m_0}{(1-\beta^2)^{\frac{1}{2}}},$$

where m_0 is the electromagnetic mass of the charged particle for velocities, small compared with that of light, and β is the ratio of the velocity of the particle to the velocity of light. The longitudinal mass m_l is given by the relation

$$m_l = \frac{m_0}{(1-\beta^2)^{\frac{3}{2}}}.$$

The same expressions can also be deduced very simply on the Principle of Relativity. The relations on the hypothesis of the rigid electron are far more complicated, the expression obtained by Abraham for the transverse mass being of the form

$$m_t = \frac{3m_0}{\beta^2}\left[\frac{1+\beta^2}{2\beta}\log\frac{1+\beta}{1-\beta} - 1\right].$$

§ (19) Experimental Determinations of the Variation of the Mass of an Electron with the Velocity.—The experiments on the value of e/m for the cathode rays were made at speeds too small to produce any sensible effect on the electromagnetic mass. The β-rays from radioactive substances, however, furnish a source of electrons moving with much higher velocities than those usually obtained in the discharge tube, approaching in fact in some cases within about 2 per cent of the velocity of light. The value of e/m for these particles was investigated by Kaufmann,[3] by the method of magnetic and electrostatic deflexions. The two fields were applied in the same direction (instead of at right angles to each other as in Thomson's experiments on the cathode rays), and the deflexions produced by the two fields were thus at right angles to each other. The displacement of the rays from their undeflected

[1] Lorentz, *Theory of Electrons*, p. 210.

[2] Fitzgerald, *Nature*, June 16, 1892.

[3] Kaufmann, *Gottingen Nach.*, 1901.

position in a direction parallel to the fields measured the electrostatic deflexion, while the deflexion at right angles to this gave the magnetic deflexion. The two deflexions could thus be measured simultaneously. On making the experiments it was found that the single spot, given by the undeflected beam of rays, was drawn out into a continuous line, thus indicating that the value of e/m was a continuous function of the velocity. Kaufmann found that the effective mass of the particles increased with the velocity. For the slowest particles the value obtained for e/m ($1{\cdot}77 \times 10^7$) agreed with that for the cathode rays. The ratio, however, diminished to $1{\cdot}31 \times 10^7$ with a velocity of $2{\cdot}36 \times 10^{10}$, and to $\cdot 63 \times 10^7$ when the velocity was $2{\cdot}83 \times 10^{10}$ cm./sec.

If the whole mass of the electron is electromagnetic it should vary with the velocity in accordance with one or other of the relations given in the preceding section. If any portion of the mass is mechanical, this portion would be constant and the variation should be less rapid than that given by the formulae. Kaufmann considered that his results agreed more closely with the formula of Abraham than with that of Lorentz, but it is doubtful whether his experiments were sufficiently accurate to distinguish between the two theories. On either assumption it was clear that practically the whole of the mass of the β-particle was of electrical origin.

The question was definitely settled by the experiments of Bucherer [1] by a very ingenious method. The source of β-radiation, a small speck of radium fluoride R (*Fig.* 11), was

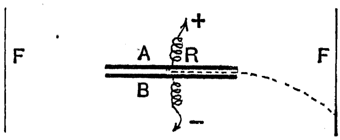

FIG. 11.

placed at the centre of a pair of plane parallel circular plates A, B, which could be charged to a suitable difference of potential. A uniform magnetic field was applied at right angles to the electric field, that is parallel to the plates, and extending over the whole of the path of the particles. The plates were placed so close together that only particles travelling parallel to their surface could escape from between them. These particles on emerging from the plates were acted upon only by the magnetic field, and after moving a certain distance were received upon a photographic film F, F, which was bent into a cylinder coaxial with the plates.

It is obvious from the arrangement of the apparatus that particles will only be able to escape from the space between the plates if the electric and magnetic forces upon them are exactly equal and opposite. Otherwise they will be deflected by whichever of the fields is the stronger, and will strike one or other of the plates. The electric force upon all the particles is the same and is equal to Xe where X is the field. The mechanical force due to the magnetic field, however, depends on the direction of projection of the particles, being given by H$ev \sin\theta$, where H is the magnetic field, v the velocity of the particle, and θ the angle between the direction in which the rays are travelling and the field. Thus the particles emerging from the plates at an angle θ with the direction of the magnetic field will have a velocity given by

$$Xe = Hev \sin\theta.$$

Hence the particles escaping from the plates along any given radius all have the same velocity, which can be calculated when the angle between the radius and the direction of the magnetic field is known. After leaving the plates the particles are deflected by the magnetic field. The magnetic field is reversed during the experiment and the distance between the two traces thus obtained on the photographic film at any point is twice the deviation experienced by the particles travelling in this direction. From this measured deviation the value of e/m for the corresponding particles can be determined. Thus v and e/m are known for all the particles emitted by the source.

Bucherer found that his results agreed very closely with the theoretical values given by the formula of Lorentz, the maximum discrepancy being less than 1 per cent. The agreement with the formula of Abraham was much less satisfactory. The values of m_v/m_0 as calculated from the Lorentz formula are given in the table, where m_v is the transverse electromagnetic mass at a velocity v, m_0 the value for slowly moving electrons, and β the ratio of the velocity of the particle to the velocity of light. The value of e/m_0 as deduced from Bucherer's experiments is $1{\cdot}763 \times 10^7$ e.m.u. per gm. These experiments have been accepted as proving the validity of the Lorentz formula, and the assumption that the whole mass of the electron is electromagnetic in origin.

§ (20) DETERMINATION OF THE CHARGE ON AN ELECTRON.—It has been shown in the preceding section that the electron consists simply of a discrete negative charge, dissociated from anything which can be called matter. It may be described as an atom of electricity, since all electrons have the same charge, which is also the same as that carried by a monovalent ion in solution. There is no evidence of the existence of any charge smaller than that of the electron, while all charges sufficiently small to be compared directly with that of the electron are found to be exact multiples of this charge. The determination of the magnitude of this electronic, or "atomic" charge is therefore of some importance.

The earliest determinations were based on the discovery of C. T. R. Wilson,[1] that a charged ion was capable of serving as a nucleus for the condensation of vapour in a supersaturated space.

It had been shown by Aitken,[2] that the clouds which form in a gas which is supersaturated with water vapour are produced by the condensation of the vapour around small dust particles or other nuclei already présent in the gas. If these nuclei are removed by filtering the gas through cotton-wool, a very considerable degree of supersaturation may exist in the space without the formation of any drops. If, however, the pressure of aqueous vapour exceeds about eight times its saturation pressure for the temperature of the experiment a fine drizzle sets in, even in the absence of all nuclei.

Wilson showed that, in a dust-free space, condensation could be produced on charged ions when the supersaturation was appreciably less than this eight-fold value. The method consisted in making a very rapid expansion in air contained in a closed space saturated with water vapour. The rapid expansion of the gas causes an adiabatic cooling of the space, the lowest temperature reached being given by the relation[3]

$$\log_e \frac{\theta_1}{\theta_2} = (\gamma - 1) \log_e \frac{v_2}{v_1},$$

where θ_1, v_1 and θ_2, v_2 are the temperatures and volumes of the gas before and after expansion, and γ is the ratio of the specific heats of the gas. The saturated pressure of aqueous vapour at the temperatures θ_1 and θ_2 could be obtained from tables, and hence the degree of supersaturation could be calculated.

In this way Wilson showed that in an ordinary dust-free space no cloud was formed with values of v_2/v_1 less than 1·375. If, however, the gas was ionised by passing a beam of X-rays through it, a dense cloud was formed with an expansion of only 1·26, thus showing that fresh nuclei capable of condensing the water vapour were formed in the gas by the action of the rays If these nuclei are charged ions they should be removable by an electric field. This was found to be the case. The negative ions were found to be more efficient in producing condensation than the positive. If only positive ions were present condensation did not commence until an expansion of 1·30 was reached. Between the limits 1·26 and 1·30 condensation took place only on the negative ions.

These results can readily be applied to determine the charge on a single ion. The small drops making up the cloud fall under the action of gravity with a uniform limiting velocity v given by Stokes' law for the fall of a small sphere through a viscous fluid.[4] If r is the radius of the drop, η the viscosity of the air, ρ the density of the drop, and g the acceleration due to gravity

$$v = \frac{2}{9} \frac{g\rho r^2}{\eta}.$$

This velocity can be determined by observing the rate at which the surface of the cloud settles down, and the value of r can thus be calculated. Knowing the radius of the drop, the mass of a single drop can be calculated. If M is the mass of water vapour saturating the vessel at the initial temperature, and M′ the mass required to saturate it at the lower temperature, the mass of water condensed in the cloud is M − M′. This, when divided by the mass of a single drop, gives us the number of drops in the cloud. The total charge brought down by the cloud can be measured by allowing the cloud to settle on a horizontal surface connected to an electrometer. The total charge divided by the number of drops in the cloud gives the charge on each nucleus, that is, on each negative ion. The experiment was first performed by J. J. Thomson,[5] who showed that the value of the charge was independent of the mode of production of the ions, the same result being obtained for the ions produced by a beam of X-rays as for the ions set free from a metal plate illuminated by ultra-violet light. The latter are, however, emitted as electrons. The method therefore gives us the value of the electronic, or "atomic" charge.

The method was subsequently improved by H. A. Wilson.[6] The clouds were formed in the space between a pair of horizontal plates at a distance of about one centimetre apart, and the radius of the drops determined

[6] H. A. Wilson, *ibid.*, 1903, v. 429.

by the application of Stokes' law. An electric field X was then applied between the plates so as to attract the drops towards the upper electrode, the expansion being adjusted so that the drops were all negatively charged. The electric force Xe thus acts in the opposite direction to gravity, and by properly adjusting the value of X the cloud can be made to remain stationary, neither rising nor falling. Under these circumstances the electric force must be equal to that of gravity, that is,

$$Xe = mg.$$

The mass m is calculated from the radius of the drop, and so e can be determined. Both forms of the experiment are subject to the difficulty that the drops begin to evaporate as soon as they are formed, since the gas after expansion rapidly warms up again by conduction and radiation from the walls of the vessel. This defect has been overcome in more recent experiments, due to Millikan.

§ (21) MILLIKAN'S DETERMINATION OF THE CHARGE e.—Instead of condensing drops around the ions, Millikan[1] formed his drops mechanically by some sort of sprayer, and allowed them to fall into a chamber (*Fig.* 12) saturated with

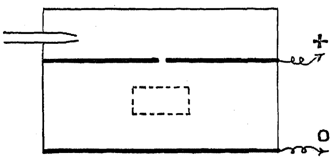

FIG. 12.

the liquid. The chamber was closed top and bottom by a pair of parallel plates, which could be charged to any required difference of potential, thus producing a vertical electric field across the space, or could be connected together, thus allowing the drop to fall under gravity alone. The drops showed no tendency to evaporate, and by suitably adjusting the field a single drop could be kept under observation for several hours.

The drops are not initially charged, but if the air is ionised they acquire charges by collision with the charged ions. Since the diameter of the drop is large compared with that of an ion, its potential rises comparatively slowly, and the drop may accumulate several charges of the same sign before its potential becomes sufficiently high to prevent other like charges from reaching it. If, however, all ions carry the electronic charge e the actual charge E on the drop at any instant should be some exact integral multiple of this charge. E was determined, as in Wilson's experiment, by observing the rate of fall under the action of gravity, and the field required to keep the drop stationary. The drops were observed by means of a long focus microscope.

A very large number of charges were thus measured by Millikan using drops of various sizes and of various liquids, and ions produced by different ionising agents. The charge was found in every case to be an integral multiple of the number $4{\cdot}774 \times 10^{-10}$ electrostatic units, to a very considerable degree of accuracy. The experiments of Millikan bring out very clearly the atomic nature of electricity.

§ (22) DETERMINATION OF e FROM EXPERIMENTS ON THE α-RAYS.—The value of e can also be deduced from experiments on the charges carried by the α-particles emitted by radioactive substances. Since negative electricity is atomic in structure a particle cannot lose less than one electron, and hence every positive charge must also be, numerically, an exact integral multiple of the charge e. The α-rays consist of atoms of helium carrying a positive charge. Owing to the energy of the particles each particle produces a distinct scintillation when it falls on a suitable fluorescent screen. It is thus possible actually to count the number of α-particles passing per second through a given aperture. If a Faraday cylinder connected to an electrometer is then placed behind the aperture the charge carried through the aperture per second by the particles can be measured. The current entering the Faraday cylinder divided by the number of particles entering per second gives the charge on a single particle.

Experiments on these lines were carried out by Rutherford and Geiger,[2] and by Regener.[3] In Rutherford's experiments the trustworthiness of the method of counting the α-particles by use of the fluorescent screen was tested by an electrical method of counting. The two methods gave the same results. According to Rutherford's experiments the charge on the α-particle is $9{\cdot}3 \times 10^{-10}$ electrostatic units. This is obviously twice the electronic charge. The α-particle thus consists of an atom which has lost two charges. The value of e as deduced from these experiments is therefore $4{\cdot}65 \times 10^{-10}$ e.s.u. Regener's experiments give a value for e of $4{\cdot}79 \times 10^{-10}$ e.s.u.

§ (23) DETERMINATION OF e FROM THE NUMBER OF MOLECULES IN A GRAM-MOLECULE OF GAS.—Since the charge e is identical with that carried by a monovalent ion in electrolysis, the value of the electronic charge can be determined from the phenomena of electrolysis if the number of molecules in a gram-molecule of gas is known. The mass of hydrogen liberated by the passage

[1] Millikan, *Phil. Mag.*, 1910, vi. 19, p. 209; *Physical Rev.*, 1911, xxxii. 349; *ibid.*, 1913.

[3] Regener, *Sitz.-Ber. der K. Preuss. Akad. der Wiss.*, 1909, xxxviii. 948.

of one electromagnetic unit of electricity is $1{\cdot}04 \times 10^{-4}$ grams; or in other words, the atoms in one gram of hydrogen convey a charge of $1/1{\cdot}04 \times 10^{-4}$ or $\cdot 96 \times 10^4$ e.m.u. Assuming that the hydrogen ion in solution consists of a single atom carrying a charge e, we have $ne = \cdot 96 \times 10^4$, where n is the number of atoms in a gram of hydrogen. Since there are two atoms of hydrogen in a molecule, and a gram-molecule weighs two grams, n is obviously also equal to the number of molecules in a gram-molecule of the gas, an important number known as Avogadro's constant. If n is known we can immediately determine e.

Numerous determinations of n, based on various atomic properties, have been made. The only method capable of any accuracy is that of Perrin,[1] based on observations of the Brownian movements. He showed that the particles in suspensions which showed the Brownian movements behaved like the molecules of a very dilute gas of very large atomic weight. It was possible, therefore, to apply the kinetic theory of gases to such suspensions, and so, from observations on these visible particles, to determine the various constants in the gas equations with far more certainty than in the indirect experiments made on actual gases. In this way Perrin obtained a value for n of $68{\cdot}2 \times 10^{22}$. Substituting this value in the above equation $ne = \cdot 96 \times 10^4$, he obtained a value for e of $1{\cdot}40 \times 10^{-20}$ e.m.u. or $4{\cdot}2 \times 10^{-10}$ e.s.u.

§ (24) Determination of e from Planck's Theory of Radiation.—The "quantum" theory of radiation, as developed by Planck,[2] provides a method of determining the number of molecules in a given mass of gas from observations on the energy of radiation, and thus affords another method of deducing the value of the elementary electronic charge. The theory assumes that the emission and absorption of radiant energy takes place not continuously, but in definite bundles, or "quanta," the magnitude of which is equal to $h\nu$, where ν is the frequency of the radiation, and h is a universal constant, known as Planck's constant, and has the value $6{\cdot}548 \times 10^{-27}$ erg. sec. On this assumption it can be shown that if L_λ is the proportion of radiant energy of wave-length λ contained in the full radiation from a black body at an absolute temperature T,

$$L_\lambda d\lambda = \frac{8\pi ch\lambda^{-5}}{\epsilon^{ch/RT\lambda} - 1} d\lambda,$$

where c is the velocity of light, h is Planck's constant, and R is the constant in the gas equation $pv = RT$, considering a single molecule of the gas. By differentiating the expression for L_λ with respect to λ and equating to zero we obtain the equation

$$5\left(1 - \epsilon^{\frac{ch}{RT\lambda}}\right) + \frac{ch}{RT\lambda}\epsilon^{\frac{ch}{RT\lambda}} = 0.$$

Solving this for the quantity $ch/RT\lambda$, we find that there are two real roots, viz. 0 and 4·965, and it can easily be shown that the latter corresponds to a maximum. The value of the wave-length λ_m for which the intensity of the radiation is a maximum is thus given by the expression

$$\frac{ch}{RT\lambda_m} = 4{\cdot}965$$

or

$$\lambda_m T = \frac{ch}{4{\cdot}965R} = \text{constant}.$$

This is the well-known displacement law of Wien, for which there is ample experimental evidence. The value of the constant is, according to the measurements of Lummer and Pringsheim,[3] 0·294 cm. deg. Substituting the known values of c and h, we have

$$R = 1{\cdot}346 \times 10^{-16} \text{ erg. deg.}^{-1}.$$

This value for R is, as we have mentioned, for a single molecule. We may therefore write the gas equation in the form $pv = NRT$, where N is the number of molecules present in the volume of gas considered and R is the constant which has been just determined. Now the volume of a gram-molecule of gas at normal temperature and pressure is 22·21 litres. Thus if N is the number of molecules in a gram-molecule of gas at 0° C. (273° abs.) and 76 cm. pressure, we have

$$(76 \times 13{\cdot}6 \times 981) \times (22{\cdot}21 \times 10^3) = N \times 1{\cdot}346 \times 10^{-16} \times \cdot 273,$$

reducing the pressure to dynes per sq. cm. and the volume to cubic centimetres. Thus N, the number of molecules in a gram-molecule, is equal to $61{\cdot}3 \times 10^{22}$. Substituting this value in the relation $Ne = 0{\cdot}96 \times 10^4$, obtained from the electrolysis of hydrogen, we have e, the elementary electronic charge, $= 1{\cdot}563 \times 10^{-20}$ e.m.u. or $4{\cdot}69 \times 10^{-10}$ e.s.u. The excellent agreement of this value with those of Millikan, Rutherford, and others by more direct methods furnishes very strong support both for the fundamental assumption of Planck and for the experimental values of e obtained by other methods.

§ (25) Values of e.—The various recent determinations of e are summarised in the table on the following page. The agreement is very good, except for the determinations of Perrin from the Brownian movement. The latter, of course, refers to the charge carried by a monovalent ion in solution. It is, however, sufficiently close to the other values

[1] Perrin, *Comptes Rendus*, 1908, cxlv. 967 ; 1911, clii. 1380.
[2] See "Quantum," Vol. III.
[3] Lummer and Pringsheim, *Verhand. der Deutsch. Phys. Ges.* i. 230.

to make it practically certain that the two charges are the same, but the agreement is not as close as might have been expected. Millikan claims an accuracy of one part in a thousand for his work, while Perrin considers that his results cannot be in error by more than three per cent. Perrin suggests that Stokes' law does not apply accurately to the drops used by Millikan, and that the allowance made by Millikan for the variation from Stokes' law is insufficient. On the other hand Millikan's value agrees closely with those obtained from the determinations of the charge on the α-particles. The value obtained by Millikan is the one generally accepted at the moment, but it is very desirable that the discrepancy should be cleared up.

Observer.	Method.	e in e.s.u.
Begeman .	Water drops (Thomson's method)	$4{\cdot}67 \times 10^{-10}$
Millikan .	Oil and mercury drops	$4{\cdot}774 \times 10^{-10}$
Perrin .	Brownian movements	$4{\cdot}2 \times 10^{-10}$
Rutherford and Geiger	Charge on α-particle	$4{\cdot}65 \times 10^{-10}$
Regener .	Charge on α-particle	$4{\cdot}79 \times 10^{-10}$
Planck .	Deduction from theory of radiation	$4{\cdot}69 \times 10^{-10}$

Determinations of the electronic charge, e.

§ (26) Mass and Radius of an Electron.—The determination of the value of the electronic charge enables us at once to calculate several other important constants. Assuming that e is $4{\cdot}77 \times 10^{-10}$ e.s.u. or $1{\cdot}59 \times 10^{-20}$ electromagnetic units, then since e/m for an electron is $1{\cdot}764 \times 10^7$ e.m.u. per gram, the mass of an electron is $(1{\cdot}59 \times 10^{-20})/(1{\cdot}764 \times 10^7)$ or about 9×10^{-28} grams. As the mass is electromagnetic we can further deduce the radius of the electron. Assuming Thomson's formula, the mass of an electron is given by $\frac{2}{3}\, e^2/a$ where a is the radius. The radius a is, therefore, of the order of $1{\cdot}9 \times 10^{-13}$ cm. This is about $\frac{1}{100,000}$ part of the value generally assumed for the radius of an atom. To use a comparison suggested by Lodge, the size of an electron bears to that of an atom very much the same relation as that of a pea to a cathedral.

The determination of e also gives us the actual mass of a hydrogen atom. Since the ratio of the mass to the charge for a hydrogen ion in solution, *i.e.* the electro-chemical equivalent of hydrogen, is $1{\cdot}04 \times 10^{-4}$ e.m.u., the mass of the hydrogen atom is given by the expression $(1{\cdot}04 \times 10^{-4}) \times (1{\cdot}59 \times 10^{-20})$ or $1{\cdot}65 \times 10^{-24}$ gm. The masses of the atoms of other elements can be obtained by multiplying this number by the corresponding atomic weight. The values given in this section all depend on the value assumed for e, the electronic charge.

§ (27) Electron Theory of Metallic Conduction.—Since electricity is to be regarded as made up of electrons the passage of an electric current implies the flow of electrons from one end of the conductor to the other. A conductor, therefore, is a substance which contains electrons in such a state that they are free to move under the action of an electric field.

According to the most prevalent theories, a metallic conductor consists of atoms of the metal, some neutral and some positively charged, surrounded by an atmosphere of electrons in a free state. This electronic atmosphere is supposed to be produced by the emission of negative electrons from the neutral atoms. All metals are electropositive and therefore emit electrons readily, though the cause of the emission in the case of an ordinary conductor is perhaps not obvious. The positively charged atoms will, of course, attract electrons from the surrounding space, and the number of free electrons will accumulate until the number of atoms dissociating per second is equal to the number recombining. The conditions of equilibrium are thus similar to those of a liquid evaporating into a closed space, and we may regard the electronic atmosphere as being due to an evaporation of electrons from the atoms of the metal.

Since the electrons are small compared with the spaces between the atoms they will behave like the molecules of a tenuous gas, and we may apply the principles of the kinetic theory of gases to the electronic atmosphere. They will exhibit the usual velocities of thermal agitation, and these velocities will be distributed according to the Maxwell-Boltzmann law. It is interesting to note that these suppositions have been verified experimentally by O. W. Richardson,[1] who has measured the distribution of velocities among the electrons emitted from the surface of an incandescent metal. Since the velocity of thermal agitation is inversely proportional to the square root of the mass of the particle, and the mass of an electron is $\frac{1}{1850}$ that of a hydrogen atom or $\frac{1}{3700}$ that of the hydrogen molecule, the mean velocity of the electron will be $\sqrt{3700}$ that of the hydrogen molecule or about 11×10^6 cm. per sec. at 0° C.

Since these velocities will be equally distributed in all directions in the metal they will produce no transference of electricity as a whole in any direction. If, however, an electric field is applied to the metal, this will produce a steady drift of electrons in the direction of the field, that is to say, it will set up an electric current. Since there is ample experimental evidence that the passage of an electric current through a metal does not

[1] O. W. Richardson, *Phil. Mag.*, 1908, xvi. 890; 1909, xviii. 681.

produce any transference of the material of the conductor we must suppose that the positively charged atoms are not free to move, and thus take no part in the conduction of the current. The complete analysis of the motion of the electrons under the field is very complicated, and has not yet been satisfactorily solved. The theory can, however, be illustrated by making simplifications analogous to those made in the elementary kinetic theory of gases.

Let us assume that all the electrons are moving with the mean velocity of thermal agitation v, and that each travels a constant distance λ between two successive collisions with the atoms of the conductor. This distance, which we may call the mean free path, will be equal to vt, where t is the time which elapses between two collisions. We will also assume that the motion of an electron after collision is entirely independent of its previous history, and that the time taken up by a collision is negligible in comparison with the interval between two collisions.

Now if e is the charge on the electron and X the applied electric field, the force acting upon it is Xe, and the acceleration in the direction of the field is Xe/m. Thus in the interval t which elapses between two collisions the electron acquires a velocity $\mathrm{X}(e/m)t$, and the average velocity produced by the field between two collisions is thus $\frac{1}{2}\mathrm{X}(e/m)t$. As we have assumed that the effect of a collision obliterates the previous history of the electron, this will obviously be the average velocity of the electron through the conductor under the influence of the field. As the velocity acquired under the field is very small compared with the velocity of thermal agitation v it will not materially affect the free time t, and we may therefore write $t=\lambda/v$. The velocity of the electrons in the directions of the field is thus

$$\frac{1}{2}\frac{e}{m}\frac{\lambda}{v}\mathrm{X}.$$

Now if n is the number of electrons per unit volume, the charge conveyed per second across any cross-section of the conductor of area A at right angles to the direction of flow is Aneu, where u is the velocity of the electrons, that is

$$\mathrm{A}\cdot\frac{1}{2}n\frac{e^2}{m}\frac{\lambda}{v}\mathrm{X}.$$

Thus the current i is equal to

$$\frac{1}{2}n\frac{e^2}{m}\frac{\lambda}{v}\mathrm{X}\cdot\mathrm{A}.$$

But by the kinetic theory of gases we may write $\frac{1}{2}mv^2=\alpha\mathrm{T}$, where T is the absolute temperature, and α is Boltzmann's constant. Thus

$$i=\mathrm{A}\frac{ne^2\lambda v}{4\alpha\mathrm{T}}\cdot\mathrm{X}.$$

If the field is uniform, $\mathrm{X}=\mathrm{E}/d$, where E is the potential difference between the ends of the conductor and d is its length. Thus

$$i=\frac{\mathrm{A}}{d}\left(\frac{ne^2\lambda v}{4\alpha\mathrm{T}}\right)\mathrm{E},$$

which gives us Ohm's law since the quantities within the bracket are constant for a given temperature and substance. The quantity in the bracket is obviously the specific conductivity of the substance. It is constant for a given substance at a given temperature. The only quantities which vary from substance to substance are λ and n. As it does not seem probable that there will be any great variations in λ, we must suppose that differences in conductivity are due mainly to differences in the number of free electrons in the different conductors. For most pure metals the specific conductivity is inversely proportional to the absolute temperature. According to our analysis this will be the case if $n\lambda v$ is independent of the temperature.

Since the best conductors of electricity are also the best conductors of heat, it seems natural to suppose that the two phenomena are attributable to the same cause. Assuming that the atmosphere of electrons conducts heat in the same way as a gas, its thermal conductivity k will be given by the equation $k=(\pi/8)nv\alpha\lambda$, where n, v, α, and λ have the same significance as in the previous equation. As insulators conduct heat to a certain extent, there will also be a certain amount of conductivity in the metal apart from its electron atmosphere, but as the thermal conductivity of electrical insulators is very much smaller than that of metals, we may expect that this effect will be a small fraction of the whole. If we neglect it altogether and assume that the thermal conductivity of the metal is entirely due to the electrons, the ratio of the thermal to the electrical conductivity of a conductor will be given by

$$\left(\frac{\pi}{8}nv\alpha\lambda\right)\Big/\left(\frac{ne^2\lambda v}{4\alpha\mathrm{T}}\right)=\frac{\pi}{2}\left(\frac{\alpha}{e}\right)^2\cdot\mathrm{T}.$$

Thus the ratio of the thermal and electrical conductivities at a given temperature is independent of the nature of the conductor. This is the well-known law of Wiedemann and Franz. Moreover, the expression for the ratio consists only of known constants. The constant α is approximately 2×10^{-16} and e is $1{\cdot}59\times10^{-20}$ e.m.u. Thus at 18° C. or 291° absolute the ratio should have the value

$$\frac{\pi}{2}\left(\frac{2\times10^{-16}}{1{\cdot}59\times10^{-20}}\right)^2 291 \text{ or } 7{\cdot}3\times10^{10}.$$

The experimentally determined values for the ratio vary from $6{\cdot}7\times10^{10}$ for copper to 8×10^{10} for iron. Considering the assumptions made during the argument the agreement is very

remarkable. According to the formula, the ratio of the thermal to the electrical conductivity is directly proportional to the absolute temperature. This is also in close agreement with the experimental results for pure metals.

The electron theory also gives at any rate a qualitative explanation of other effects associated with the passage of a current through a conductor. As the number of free electrons per unit volume is different in different metals the pressure of the electronic atmosphere will also be different. Thus if two dissimilar metals are brought into metallic contact there will be a flow of electrons from the one to the other until the difference of potential produced by the transference is sufficient to stop any further flow of electricity between them. There will thus be a permanent difference of potential established between the two metals. Again, if a current is passed from the metal of lower to the metal with the higher electronic pressure, work must be done against the electronic pressure, and this will involve an absorption of heat at the junction between the metals. Conversely the passage of a current in the opposite direction will result in the transference of electrons from a higher to a lower pressure, and heat will be liberated. This is, of course, the Peltier effect. Regarding the electrons again as behaving like the molecules of a gas, it is easy to show that the coefficient Π of the Peltier effect should be given by

$$\Pi = \frac{2}{3}\frac{\alpha}{e}\theta \log_e \frac{N_1}{N_2},$$

where N_1, N_2 are the number of electrons per unit volume in the two conductors. This result is due to Sir J. J. Thomson (Thomson, *Corpuscular Theory of Matter*).

Again, since a moving electron is deflected by a magnetic field, if a magnetic field is applied to a conductor at right angles to the direction of the current flowing through it the electrons will be deflected towards one side of the conductor and a transverse electric field will thus be set up at right angles both to the current and the field. This is of course the Hall effect. Similar qualitative explanations can also be given of other known effects, such as the Nernst and Ettinghausen effect, and the Leduc effect. The explanations, however, are not very satisfactory when applied numerically. In particular the Hall effect is in some metals of the opposite sign to that predicted by the simple electron theory, and so far no satisfactory explanation of the discrepancy has been proposed. The success of the theory in explaining electrical and thermal conductivities, however, would appear to show that the theory is fundamentally sound, and further developments may be hoped for. For a fuller account of the theory, Lorenz's *Theory of Electrons*, Bohr's *Studies over metallernes Elektrotheori*, or O. W. Richardson's *Electron Theory of Matter* may be consulted.

§ (28) THE ELECTRON THEORY OF THE ATOM.—The fact that matter of all kinds is capable of emitting electrons under suitable stimulus furnishes presumptive evidence that these electrons form an integral part of the atom of every element. The further proof that the mass of the electron is entirely electrical naturally suggested the inquiry as to whether all mass might not be of this kind, the mass of an atom being merely due to the electromagnetic mass of the charges contained in it. This view is now very generally held, though the proof is not yet complete. The mass of an electron is about $\frac{1}{1850}$ of that of a hydrogen atom. It would thus require 1850 such electrons to make up the mass of the lightest atom. Considering the smallness of the electron, there is no inherent impossibility in this suggestion, and speculations along these lines were freely indulged in for a time. Actual experiments, however, have proved fairly conclusively that the number of electrons in an atom is of the same order as its atomic weight, and is probably equal to its atomic number. The atomic number of an element is its number in the table obtained by arranging the elements in the order of their ascending atomic weights. Thus hydrogen has the atomic number one, helium two, lithium three, and so on. In the later parts of the series of elements the periodic classification indicates the possibility of the existence of elements as yet undiscovered. These gaps are taken into account in assigning atomic numbers to the still heavier elements. The atomic number can be determined directly by measurements on the characteristic X-ray spectrum of the element. It is now practically certain that the hydrogen atom only contains a single negative electron. If the mass of the hydrogen atom is electrical it must therefore be associated with the positive electricity in the atom, and not with the negative.

Since the atom as a whole is neutral, it must contain sufficient positive electricity to neutralise exactly the charges on the negative electrons. Again, as the most obvious feature of atoms in general is their great stability, the electrical system must be a stable one. Kelvin[1] suggested that the electrons were embedded in a uniform sphere of positive electricity of the dimensions of the atom itself. The possible stable arrangements of electrons inside such a sphere have been worked out in great detail by J. J. Thomson,[2]

[1] Kelvin, *Phil. Mag.*, 1902, iii. 257.
[2] J. J. Thomson, *Phil. Mag.*, 1904, vii. 237 ; *Corpuscular Theory of Matter*, 1907, cap. 6.

who obtained some exceedingly interesting and suggestive results.

The experiments of Geiger and Marsden,[1] and of Geiger [2] on the scattering of α-particles during their passage through thin metal foil, have, however, shown that some of these particles undergo deflexions much greater than could be produced by collision with an atom of the kind suggested by Kelvin. To produce deflexions of the order actually obtained (some of the particles are deflected through more than a right angle) it is necessary to suppose that the mass and the positive charge of the atom are concentrated on a nucleus of dimensions much smaller than the radius of an atom. More recent experiments by Rutherford [3] on the collisions between α-particles and the molecules of a gas indicate that the size of this positively charged nucleus is of the same order as that of an electron.

Rutherford, therefore, suggested [4] that the atom consists of a small positively charged nucleus in which practically the whole of the mass of the atom is concentrated, surrounded by an atmosphere of sufficient negative electrons to make the system as a whole electrically neutral. The resultant charge on the nucleus is supposed to be equal to the atomic number of the element, and the constitution of the nucleus thus determines the mass of the atom, that is its atomic weight. The other chemical and physical properties of the atom are determined by the number and arrangement of the negative electrons around the nucleus. This nuclear atom is the only structure so far proposed which seems capable of providing an adequate explanation of the numerous investigations which have recently been made of the internal structure of the atom.

On the ordinary laws of electricity and classical dynamics such a system as has been proposed by Rutherford could only be stable, if at all, if the electrons were in rapid rotation. On the ordinary principles of electrodynamics, however, an electron moving in a closed orbit would be continually radiating energy. There would thus be a continual drain on the energy of the atom, which would therefore eventually collapse. The nuclear theory thus apparently fails to account for the most fundamental property of an atom, namely, its great stability. To overcome this difficulty Bohr [5] has frankly discarded the classical principles by introducing the following additional hypotheses :

(i.) That the electrons are rotating about the central nucleus in closed orbits, and that these motions are stable when the angular momentum of the electron is an integral multiple of $h/2\pi$, where h is Planck's constant, a universal constant which can be deduced from the laws of radiation and other phenomena, and has the value $6{\cdot}55 \times 10^{-27}$ erg. sec.

(ii.) That instead of radiating continuously in accordance with electromagnetic theory, the electrons only radiate energy when they pass from one stable orbit to another. The radiation thus emitted is assumed to be monochromatic, corresponding to a single line in the spectrum of the element, and its frequency is assumed to be determined by the relation $E_1 - E_2 = h\nu$, where E_1, E_2 are the energies of the electron in the two states, and ν is the frequency of the radiation emitted.

Bohr's theory was specially directed to providing a model which would account numerically for the lines in the spectrum of the atom. The theory has been eminently successful in the case of the hydrogen atom, which is assumed to consist of a positively charged nucleus and a single negative electron. In this simple case Bohr's theory enables him to calculate the constant K in Balmer's series for hydrogen in terms of e, m, and h. The calculated value is $3{\cdot}26 \times 10^{15}$. That obtained from spectroscopic observation is $3{\cdot}29 \times 10^{15}$. The agreement is exact, within the limits of accuracy with which the various quantities have been determined. Some success has also been obtained with the case of helium.

In view of the close agreement between the nucleus theory of the atom and the recent experimental work, the fact that the theory would seem to necessitate a modification of the principles of classical dynamics cannot be made a valid objection. That some such modification is required when dealing with atomic phenomena had previously been indicated by Planck [6] from a study of the phenomena of thermal radiation. The "Quantum" theory of Planck indicates at any rate the general nature of the modifications which will be required, and it seems likely that for some time mathematical attempts to solve the question of the structure of the atoms will take the form of more or less empirical mixtures of "quantum" theory with ordinary electrodynamics.

More recently J. J. Thomson [7] has suggested that the stability of the nuclear arrangement might be secured, by assuming that the ordinary inverse square law for the force between two electric charges was modified when the distance between the charges was less than the radius of the atom. Rutherford's experiments on the collision of α-particles with light atoms [8] seem to afford some support for this hypothesis.

§ (29) THE NUMBER OF ELECTRONS IN THE ATOM.—The number of electrons surrounding the nucleus of the atom can be determined by at least three independent methods. The most certain results are those given by experiments on the scattering of α-particles already alluded to.[1] In this case the deflexions of the α-particles are due to collisions between the α-particle and the positive nucleus of the deflecting atom, the deflexions produced by the electrons also present in the atom being, on account of their relatively small mass, almost negligible. A measurement of the most probable angle of deflexion makes it possible to calculate the magnitude of the charge on the deflecting nucleus. Since the atom is neutral, however, this must be equal to the sum of the charges on the surrounding electrons, and hence the number of the latter can be determined. The numbers obtained in this way were of the order of one-half the atomic weight, that is to say, they were approximately equal to the atomic number.

The number of electrons in the atom can also be estimated from experiments on the scattering of the β-particles by matter.[2] In this case the scattering is mainly due to collisions between the β-particles and the electrons in the atom. The effect of the positive charge, however, cannot be ignored, and the results obtained depend on the assumptions made on this point. Adopting a theory due to J. J. Thomson,[3] with which the experimental results seemed to be in good agreement, Crowther calculated that the number of electrons in an atom was almost exactly three times its atomic weight. A recalculation of the results by Rutherford,[4] starting from different assumptions, gave values agreeing fairly closely with those obtained from the experiments on the α-rays.

Further evidence on the point is furnished by experiments on the scattering of X-rays. The mechanism of the scattering is entirely different from that of the scattering of α- or β-rays. It is assumed that the electrons in the material through which the X-rays are passing are thrown into forced vibrations by the electric field in the rays, and thus in turn become radiators of energy of the same type as that by which they are excited. The intensity of the radiation will obviously be proportional to the number of electrons affected. A mathematical theory of the effect has been given by J. J. Thomson,[5] and experimental determinations of the scattering have been made by numerous observers. The results of Barkla and Dunlop[6] give values for the number of electrons in the atom very nearly equal to one half the atomic weight. Later experiments by Auren[7] however, indicate considerably smaller values for the scattering of the rays than those obtained by Barkla, and it is suggested that only the outermost of the electrons in the atom are actually affected by the rays.

On the whole there is a general agreement between the results obtained by these different methods of approach, and though each may be open to criticism, the cumulative evidence is very strong. Van der Broek[8] seems to have been the first to suggest that the number of electrons in an atom, or, in other words, the charge on the positive nucleus, was equal to the atomic number of the element. This suggestion is now generally accepted, and has been confirmed by more accurate experiments on the scattering of α-particles recently made by Chadwick.[9]

§ (30) THE CONSTITUTION OF THE POSITIVE NUCLEUS.—If Van der Broek's suggestion be accepted the hydrogen atom consists of a single electron associated with a single positive nucleus of equal but positive charge. As no positive charge has been discovered associated with a mass less than the mass of a hydrogen atom, it seems reasonable to assume that mass is a function of the positive charge. The electromagnetic mass of a charge is inversely proportional to its radius. Since the hydrogen nucleus has a mass of about 1850 times that of an electron while the charges are numerically equal, the radius of the positive nucleus must be $\frac{1}{1850}$ that of an electron, if the whole of the mass is electrical, that is to say, its radius must be about 10^{-16} cm. This value has not, of course, been experimentally confirmed. The experiments of Rutherford on the direct collision of the α-particles with hydrogen have, however, shown that the centres of the hydrogen and the helium nuclei must approach within a distance of about 3×10^{-13} cm. of each other, in order to account for the high velocity with which the hydrogen atom is driven forward by the impact. As the helium nucleus is certainly complex, and contains electrons, the hydrogen nucleus must be of exceedingly small dimensions. It seems reasonable to suppose that the hydrogen nucleus consists only of positive electricity concentrated on a sphere so small that its electromagnetic mass is sufficient to account for the whole mass of the atom. The hydrogen atom thus consists of one positive and one negative electron.

The next element, helium, has an atomic weight approximately four times that of hydrogen, and its atomic number is of course two. Now the number of electrons in the atom, and hence the nuclear charge (taking the electronic charge as unity) is equal to the atomic number. The charge on the helium nucleus is therefore $2e$. But since the mass is four times that of the hydrogen nucleus, we must either suppose that in the helium nucleus the positive electricity is in a different state of concentration from that in the hydrogen nucleus, or otherwise that the helium nucleus consists of four hydrogen nuclei cemented together by two negative electrons, thus giving a mass of four times that of the hydrogen atom, with a resultant charge of $2e$. This seems the more probable assumption. The suggestion that the nuclei of elements of higher atomic weight than hydrogen are complex has recently been confirmed by Rutherford.[1] He found that on passing rapidly moving α-particles from Radium C through a tube containing pure nitrogen, particles were projected forward by the impact of the α-particles on the nitrogen atoms, which not only by their range, but also by the values obtained for e/m could be identified as charged atoms of hydrogen. The hydrogen nucleus is therefore a constituent part of the nitrogen atom. Similar results were also obtained with pure oxygen. In a later paper,[2] he showed that, in addition to this emission of hydrogen nuclei, a much larger number of particles were emitted carrying twice the electronic charge and having a mass three times that of the hydrogen atom, that is to say, having an atomic weight of three. As these particles are very freely emitted from both nitrogen and oxygen when bombarded by α-rays it seems probable that they play an important part in the structure of the nuclei of most of the elements. Rutherford suggests that these new particles consist of three hydrogen nuclei cemented together by a single negative electron, and that the hydrogen atoms obtained by collision are due to the break-up of these complex nuclei by particularly violent impacts. On the other hand, the fact that the α-particles emitted during the spontaneous decomposition of the radioactive elements consist entirely of helium seems to make it clear that, in the case of these heavy elements the helium nucleus is also present in their nuclei. The emission of high velocity β-particles during radioactive decomposition may be taken as evidence for the presence of negative electrons within the nucleus, as it is difficult to see how such extremely high velocities could be produced by the comparatively weak electric fields in the outer part of the atom. The most probable hypothesis at present is that the nuclei of the atoms consist of hydrogen nuclei, bound together by a certain number of negative electrons, and that these hydrogen nuclei tend to arrange themselves within the complex nucleus in groups of three or four.

This brings us back again to Prout's hypothesis that all matter is built up from atoms of hydrogen. The objection which proved fatal to that hypothesis, however, namely that the atomic weights of many of the elements were not integral multiples of the atomic weight of hydrogen, is no longer valid. Aston's recent work on the positive rays [3] has demonstrated quite clearly that the elements whose atomic weights are not exact whole numbers (when oxygen is taken as 16), consist of mixtures of two or more substances, differing only infinitesimally in their chemical and physical properties, but of different atomic mass. Thus chlorine, atomic weight 35·4, was found to be a mixture of two gases of atomic weights 35 and 37. Such substance, differing in atomic weight, but identical in their chemical properties are known as isotopes. Aston found that, within the limits of experimental error, every atom had a mass which was an exact whole number when that of oxygen was taken as 16. The masses of the different atoms can thus be expressed by a series of whole numbers. The only exception to this rule is hydrogen itself, which has a mass of 1·008 when oxygen is taken as 16. Thus the mass of the helium atom (atomic weight 4) is somewhat less than the mass of four hydrogen atoms, *i.e.* 4·032. There is some evidence that the energy of the helium nucleus is less than that of four hydrogen nuclei, that is to say, that energy is given out when the helium atom is formed from four hydrogen nuclei. According to Einstein's theory all energy possesses mass. The helium nucleus should therefore have a smaller mass than that of its separated constituents by the mass of the energy emitted from the system during formation. It is possibly simpler to suppose that the electromagnetic mass is slightly affected by the very close interaction of the electrical fields inside the nucleus. Aston's results would indicate that the more complex nuclei are constructed from the nuclei of helium and the new substance rather than from individual hydrogen nuclei, as the atomic masses are not exact integral multiples of that of the hydrogen atom.

The possibility of the formation of isotopes is clearly indicated on the nuclear theory of the atom. The chemical and physical properties of an atom are determined by the arrangement and number of the external electrons. This is fixed by the resultant charge on the nucleus, but is independent,

[1] Rutherford, *Phil. Mag.*, 1919, xxxvii. 581.
[2] Rutherford, *Proc. Roy. Soc.* A, 1920, xcvii. 374.
[3] Aston, *Phil. Mag.*, 1919, xxxviii. 707; 1920, xxxix. 611.

save to a very slight extent, on the way in which that resultant charge is made up. The mass of the atom, on the other hand, depends entirely on the number of hydrogen nuclei contained in the nucleus, irrespective of whether their charges are neutralised by the presence of electrons. Thus a nucleus consisting of three hydrogen nuclei and one electron would have the same resultant charge as a nucleus of four hydrogen nuclei and two electrons, and the two corresponding atoms would, therefore, each have two outer electrons and exhibit the same chemical properties. The former would, however, have a mass of three, the latter of four. Rutherford suggests that the particles of mass three ejected by the collision of α-particles with the atoms of nitrogen and oxygen have this structure, and are, therefore, isotopic with helium.

§ (31) The Arrangement of the Electrons in the Atom.—Although it is generally agreed that almost the whole of the chemical and physical properties of the atom are determined by the number and arrangement of the negative electrons outside the nucleus, very little is known as to their actual arrangement. It is generally agreed that they are arranged in series of rings, but the question as to whether the rings are coplanar, or even as to whether the electrons are in motion or at rest, does not appear to be definitely settled. The general problem of the arrangement of a number of electrons around a central positively charged nucleus is very complex, and has not yet been solved.

The problem is very much simpler in the case of the Kelvin atom, and a complete solution has been given by J. J. Thomson [1] for the case where the electrons are supposed to be confined to a single plane. He showed that a ring system consisting of a given number of electrons will in general only be stable if it contains a certain minimum number of other electrons within its orbit. Thus a ring of six electrons is unstable and would break up into a ring of five with one electron in the centre. The ring of six, however, could be made stable by placing another electron within it. A ring of nine required three electrons within it to make it stable, and an outer ring of sixteen no less than twenty. These inner electrons arrange themselves according to the same laws, and thus break up into a whole series of ring systems. It is found that if the stable systems are arranged in the ascending order of the number of electrons they contain, certain groupings tend to recur from point to point in the series. Thus the grouping, 12, 7, 1, which represents the arrangement of 20 electrons on the Thomson theory, recurs again with an outer ring of 16 when the total number of electrons is increased to 36, the whole group, 16, 12, 7, 1, being repeated further down the series with an additional outer ring of 18. Thus if the chemical and physical properties of the atom are to be referred to the grouping of the electrons around it, these properties will tend to recur periodically as we pass down the table of the elements arranged in order of their ascending atomic weights. This is, of course, the well-known periodic law of Mendeléeff.

A study of the periodic classification of the elements shows that, at any rate for the lighter elements, the characteristic properties repeat themselves for every increase of eight in the atomic number. That is to say, the addition of eight electrons (with, of course, an appropriate increase in the nuclear charge) leaves the general structure of the atom very much unaltered. It would seem, therefore, that the maximum number of electrons in a stable ring, at any rate for the lighter atoms, is eight. This is not indicated by Thomson's figures. A theory of atomic structure on these lines has been worked out by Langmuir.[2]

On the assumption that the equilibrium in the plane of the electron rings is given by the quantum relation, while equilibrium at right angles to this plane is governed by the ordinary laws of electrodynamics, Bohr (*loc. cit.*) has calculated the arrangement of the electrons in some of the lighter atoms. Though the assumptions may be open to objection, the calculated arrangements agree closely with the results to be expected from chemical considerations. Thus lithium is assigned the grouping 2, 1; sodium the grouping 8, 2, 1; and potassium the grouping 8, 8, 2, 1. These figures bring out very clearly the similarity of this group of elements, and similar results are obtained for other chemical groups.

§ (32) Summary of Atomic Dimensions.—Neglecting the more speculative points we may briefly summarise those facts about the structure of the atom which appear reasonably certain. As all the numbers concerned are exceedingly minute it will assist in forming a mental picture of the atom if we multiply all the distances by 10^{13}. On this scale one centimetre becomes equal to about two-thirds of the distance from the sun to the earth. The atom, then, if magnified to these dimensions, would be seen to consist of a central cluster or nucleus, which in the case of a light atom such as oxygen would have a diameter of about 5 cm. The nucleus itself would be found to be constructed of a certain number of negative electrons, having radii of about 1·9 cm. together with a larger number of positively charged particles of radius only

[1] J. J. Thomson, *Corpuscular Theory of Matter.*

[2] Langmuir, *Journ. Amer. Chem. Soc.*, 1919; *Phys. Rev.*, March 1921.

about 1/100th of a millimetre. Thus even with the large magnification imagined, the positive particles would hardly be visible. They account, however, for practically the whole mass of the structure. The nucleus of the oxygen atom would consist of 16 of these positive particles, together with 8 electrons. It is probable that the particles might be found to be grouped together within the cluster in groups of three or four.

Outside this closely packed nucleus the atom would be empty save for a few negatively charged electrons, probably arranged in concentric circles. The outermost of these rings would be about 1 kilometre from the centre of the nucleus, the innermost probably not more than 10 metres. The total number of these electrons is equal to the atomic number of the element. Some of the more important data are given in the following table:

Table of Atomic Data

Electronic charge, e .	$4{\cdot}77^4 \times 10^{-10}$ e.s.u. $1{\cdot}59 \times 10^{-20}$ e.m.u.
e/m for an electron .	$1{\cdot}764 \times 10^7$ e.m.u. per gm.
Mass of an electron .	9×10^{-28} gm.
Radius of electron .	$1{\cdot}9 \times 10^{-13}$ cm.
Mass of hydrogen atom	$1{\cdot}65 \times 10^{-24}$ gm.
Radius of hydrogen nucleus (positive electron)	10^{-16} cm.
Radius of nucleus of a light element	*circ.* 5×10^{-13} cm.
Number of molecules in a gram-molecule	61×10^{22}

ELECTROSTATIC FIELD,[1] PROPERTIES OF THE

§ (1) General Considerations. — The properties of the potential, equipotential surfaces, lines, and tubes of force are described in the article "Potential," and their applications to electrostatics is there explained. It will be useful to recapitulate here and extend some of the results arrived at.

The field in the neighbourhood of any system of charged bodies or of magnets can be mapped out by a series of equipotential surfaces and tubes of force which cut them at right angles.

If these surfaces be drawn so that the difference of potential between any two consecutive surfaces is constant, the resultant force at any point will be inversely proportional to the distance between the surfaces, for if V and $V+\delta V$ be the potential and δn the distance between them, R the force in direction δn, then

$$R\delta n = \text{work in going from } V \text{ to } V+\delta V$$
$$= -\delta V = \text{constant}.$$

Thus $$R = \frac{\text{constant}}{\delta n},$$

i.e. it is inversely proportional to δn. The force is large when the surfaces are close together.

Again, consider a tube of force cutting any of the equipotential surfaces in an area δS. Then $R\delta S$ is constant[1] along the tube, so that R is also inversely proportional to δS. Thus the force is large where the tubes are contracted in area.

The lines of force terminate in charges of electricity.

In some cases they pass away beyond the boundaries of the field, and the charges in which they terminate are so far removed as to exert no influence on the field.

A charged conductor is an equipotential surface; for if a potential difference existed between two points on a conductor a current would flow and the electricity would not be in equilibrium.

There is no force inside an equipotential surface unless the surface surround a charge of electricity. Since there is no charge within the surface there can be no lines of force which terminate within the surface: any lines of force within it must pass from one point A to another point B of the surface; but this is impossible, for A and B are at the same potential; thus there are no lines of force within the surface; thus the potential is everywhere the same and there is no force within the surface.

§ (2) Gauss's Theorem.—If R be the value of the resultant force at any point P of any closed surface in an electrostatic field, δS an element of the surface at the point P, ϵ the angle between the direction of R and that of the outward-drawn normal at P, and Q_1 that part of the charge to which the field is due which lies within the surface S, then

$$\iint KR\cos\epsilon\, ds = 4\pi Q_1,$$

where K is the specific inductive capacity. If Q be the total charge in the field equal, say, to Q_1+Q_2, the force R may be divided into two parts, R_1, due to the charge Q_1 within S, and R_2 arising from Q_2, the charge exterior to S, and we have

$$R\cos\epsilon = R_1\cos\epsilon_1 + R_2\cos\epsilon_2,$$

where ϵ_1, ϵ_2 represent the angles between the

[1] Many of the results given in this article are direct consequences of the fact that the forces dealt with obey the inverse square law. They are true, therefore, *mutatis mutandis* for a magnetic as well as for an electrostatic field of force.

[1] See § (3).

outward-drawn normals and the directions of R_1, R_2 respectively.

Consider now the force R_1 and imagine the whole charge Q_1 concentrated at a point O

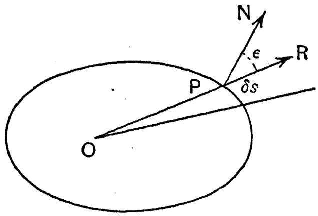

FIG. 1.

(*Fig.* 1) at a distance r from P. Let $\delta\omega$ be the solid angle subtended at O by δS. Then

$$R_1 = \frac{Q_1}{Kr^2},$$

$$\delta S \cos \epsilon_1 = r^2 \delta\omega.$$

Hence $\quad KR_1 \cos \epsilon_1 \delta S = Q_1 \delta\omega,$

and summing up for the whole surface

$$\iint KR_1 \cos \epsilon_1 dS = 4\pi Q_1. \quad . \quad . \quad (1)$$

Now let O (*Fig.* 2) be outside the surface. Any line such as OP drawn from O cuts the

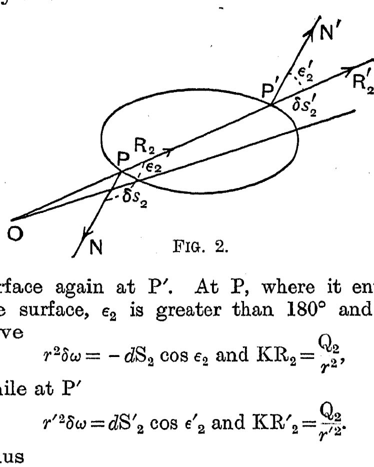

FIG. 2.

surface again at P′. At P, where it enters the surface, ϵ_2 is greater than 180° and we have

$$r^2\delta\omega = -dS_2 \cos \epsilon_2 \text{ and } KR_2 = \frac{Q_2}{r^2},$$

while at P′

$$r'^2\delta\omega = dS'_2 \cos \epsilon'_2 \text{ and } KR'_2 = \frac{Q_2}{r'^2}.$$

Thus

$$KR_2 \cos \epsilon_2 dS_2 = -Q_2\delta\omega = -KR'_2 \cos \epsilon'_2 dS'_2.$$

Thus the portions which the elements at P and P′ respectively contribute to the sum are equal and opposite and their total contribution is zero.

The whole area of S can be divided thus into a series of pairs of elements which when combined contribute nothing to the sum of quantities such as R cos ϵdS. Thus we have

$$\iint KR_2 \cos \epsilon_2 dS = 0. \quad . \quad . \quad (2)$$

Hence combining

$$4\pi Q_1 = \iint K(R_1 \cos \epsilon_1 + R_2 \cos \epsilon_2)dS$$
$$= \iint KR \cos \epsilon dS. \quad . \quad (3)$$

A similar proof holds when the closed surface is more complex in shape, so that a radius such as OP cuts it more often.

If the charge Q_1 is not concentrated at a point consider the various elementary charges of which it is composed. The theorem is true for each of these, and therefore for the whole charge Q_1.

§ (3) APPLICATION TO A TUBE OF FORCE.—Let the surface S consist of the curved surface of a tube of force and two sections dS_1, dS_2 at right angles to the tube; over the surface of the tube ϵ is a right angle and cos ϵ is zero; at one end ϵ is zero, cos ϵ is 1; at the other, ϵ is 180°, cos ϵ is -1; while within the surface the charge is zero. Hence

$$0 = \iint K(R_1 dS_1 - R_2 dS_2),$$

or $\quad \iint R_1 dS_1 = \iint R_2 dS_2.$

Thus, if the sections of the tube be small,

$$R_1 dS_1 = R_2 dS_2, \quad . \quad . \quad . \quad (4)$$

or the value of the product of the force and the area of the cross-section of a tube of force is constant along a tube as stated in § (1).

§ (4) COULOMB'S THEOREM.—If R and R′ are the resultant forces due to any electrostatic system on two sides of a surface electrified to density σ, and ϵ, ϵ' the angles between the outward-drawn normal and the directions of R and R′ respectively, then

$$K(R \cos \epsilon + R' \cos \epsilon') = 4\pi\sigma.$$

This follows from Gauss's Theorem; for imagine the element dS which carries a charge σdS to be surrounded by a surface drawn very close to it in comparison with its own dimensions; then within this surface there is a charge Q_1 given by σdS.

The surface integral is composed of the two terms R cos ϵdS and R′ cos $\epsilon' d$S due to the two opposite surfaces of the element, for that part which is due to the perimeter can be made as small as we please. Hence

$$K(R \cos \epsilon + R' \cos \epsilon') = 4\pi\sigma. \quad . \quad (5)$$

If S be a closed equipotential surface, such as the surface of a conductor, then the force is zero on one side and normal to the surface on the other; in this case we have $R' = 0$, $\epsilon = 0$. Hence over any conductor or other closed equipotential surface

$$KR = 4\pi\sigma,$$

$$R = \frac{4\pi\sigma}{K}. \quad . \quad . \quad . \quad . \quad (6)$$

Or, again, let the surface be a plane of infinite extent; it is clear from symmetry that the force must be the same on either side of the plane. Hence R cos ϵ = R′ cos ϵ', and in this case we have

$$KR \cos \epsilon = 2\pi\sigma.$$

If the plane be equipotential, such as the surface of a conductor, $\cos\epsilon$ is unity and

$$R=\frac{2\pi\sigma}{K}. \quad . \quad . \quad . \quad . \quad (7)$$

This may be proved directly thus. Let r be the distance PO between the element dS of a plane electrified to constant surface density σ and a point O (*Fig.* 3), dR the force at O due to σdS resolved

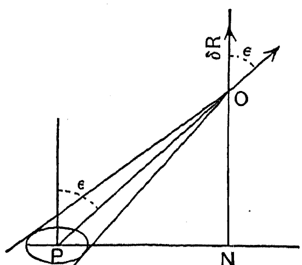

Fig. 3.

along NO, the normal to the plane ω, the solid angle which the element dS subtends at O; then

$$K\delta R=\frac{\sigma dS\cos\epsilon}{r^2}.$$

But $\qquad dS\cos\epsilon=r^2\delta\omega.$

Hence $\qquad K\delta R=\sigma\delta\omega.$

Thus

$KR=\sigma\times$ solid angle subtended by plane.

But when the point O is very close to the plane the solid angle subtended is 2π. Hence

$$KR=2\pi\sigma. \quad . \quad . \quad . \quad . \quad (8)$$

§ (5) Mechanical Force on a Conductor.—We have seen that the electrical force just outside a charged conductor is $4\pi\sigma/K$. Consider a small element of the conductor near the point; if the point be sufficiently close to the surface this element is practically part of an infinite plane and the force it exerts on the point is $2\pi\sigma/K$. Thus, of the whole force $4\pi\sigma/K$, we see that $2\pi\sigma/K$ is due to the neighbouring element and $2\pi\sigma/K$ to the electricity on the rest of the conductor excluding the element. This last force will also act on the electricity on the element, and if δS be its area its charge is $\sigma\delta S$. Hence the force on the element due to the rest of the charge is $2\pi\sigma\times\sigma\delta S/K$ or $2\pi\sigma^2\delta S/K$. We may represent this as a tension pulling the element outwards from the surface and of amount equal to $2\pi\sigma^2/K$ per unit of area. Moreover, if R be the electric intensity we have $\sigma=KR/4\pi$. Hence F, the mechanical force outwards per unit of area, which is equal to $2\pi\sigma^2/K$, is given also by the equation

$$F=\frac{KR^2}{8\pi}. \quad . \quad . \quad . \quad . \quad (9)$$

§ (6) Energy in the Electrical Field.—A charged system of conductors evidently possesses energy. We can show that this may be represented by supposing it distributed throughout the field with an amount $KR^2/8\pi$ per unit of volume.

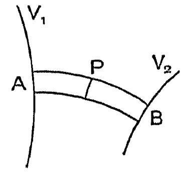

Fig. 4.

For consider a tube of force AB (*Fig.* 4) between two conductors at potentials V_1 and V_2. Let dS be the section of this tube at a point P at which the intensity is R, dS_1, dS_2 areas at A and B respectively, and let σ_1, σ_2 be the densities, e and $-e$ the charges at A and B—the tube is supposed to run from A to B. Then we have seen that

$$KRdS=KR_1dS_1=KR_2dS_2=4\pi\sigma_1dS_1=4\pi e.$$

Hence, if ds be an element of the length of the tube at P and the energy per unit volume be $KR^2/8\pi$, we find

$$\text{Energy in tube}=\frac{1}{8\pi}\int KR^2dSds,$$
$$=\frac{KR_1dS_1}{8\pi}\int Rds=\tfrac{1}{2}e\int Rds,$$
$$=\tfrac{1}{2}e(V_1-V_2),$$

for $\int Rds$ is the work done in carrying unit charge from A to B, and this is V_1-V_2. But $\frac{1}{2}e(V_1-V_2)$ is the energy of the condenser formed by the two ends of the tube at A and B and the intervening dielectric. Thus the assumption that the energy of the tube may be represented as an amount $KR^2/8\pi$ per unit of volume is verified for this tube; it can be verified similarly for all the other tubes and hence for the whole field.

Thus the quantity $KR^2/8\pi$ represents the tension along a line of force and also the energy per unit volume of the field, and we have for the energy of the field the expression

$$\text{Energy}=\iiint\frac{KR^2}{8\pi}dv, \quad . \quad . \quad . \quad (10)$$

where dv represents an element of volume at the point considered.[1]

Electrostatic Induction is measured by the quantity $KR/4\pi$—the electric displacement—R being the electric intensity and K the inductive capacity. See "Units of Electrical Measurement," § (14).

Electrostatic System of Units. A system of units originally due to Weber, developed by the B.A. Committee on Electrical Standards, 1862–63, based on the assumption that the inductive capacity of a vacuum, in practice air, is unity, so that the force

[1] In the magnetic field the mechanical force per unit area $=\mu H^2/8\pi=B^2/8\mu\pi$, and the energy per unit volume is given by the same expressions.

Vibration: a detecting instrument used in inductance and capacity measurements. See "Inductance, The Measurement of," § (30); also "Vibration Galvanometer."

GALVANOMETER CONSTANTS:

Experimental determination of. See "Vibration Galvanometers," § (31).

Deduction of intrinsic constants. See *ibid.* § (32).

GALVANOMETER NEEDLES, ageing of. See "Galvanometers," § (5) (iv.).

GALVANOMETER RESISTANCE, value of, for greatest sensitivity. See "Galvanometers," § (4) (iii.).

GALVANOMETERS

§ (1) INSTRUMENTS for measuring and detecting currents may be divided into three classes:

(i.) Absolute instruments such as current balances, the Helmholtz galvanometer, etc. These are described in the article on "Electric Measurements, Systems of," Part II. §§ (23)-(37).

(ii.) *Galvanometers.*—These are based on the forces between two conductors conveying currents, as in electrodynamometers; on electrothermal phenomena as in thermal ammeters, and on electrochemical and on electro-optical principles; but, in general, galvanometers are based on electromagnetic principles, *i.e.* on the mechanical forces between a magnet and a conductor conveying the current to be measured or detected.

(iii.) *Ammeters.*—The principles are the same as those of galvanometers, but ammeters are built so that the current strength in amperes can be read directly. Ammeters are described in the article on "Direct Current Instruments."

§ (2) TYPES OF GALVANOMETERS BASED ON ELECTROMAGNETIC ACTION.[1]—There are a large number of types of galvanometers based on the electromagnetic forces between conductors carrying current or between a conductor and a magnet, and in many of these the conductor, the magnet, and the control differ appreciably. The conductor may be

(i.) A straight wire or tube, as in the Einthoven galvanometer.

(ii.) A fixed coil, as in the Thomson and Paschen galvanometers.

(iii.) A moving coil, as in the Ayrton-Mather galvanometer.

The current in the conductor produces a magnetic field, and in the cases of (i.) and (iii.) there is an additional magnetic field, which is fixed, with the result that a mechanical force acts on the conductor. The additional magnetic field may be due to

[1] FitzGerald, *The Electrician*, xxxviii.

(*a*) A permanent magnet, as in most Ayrton-Mather galvanometers.

(*b*) An electromagnet, as in the Einthoven galvanometer and Duddell oscillograph.

When the conductor conveying the current is in the form of a fixed coil, there is

(*c*) A movable magnet system, as in the Thomson, Broca, and Paschen galvanometers, which is deflected by the action of the current.

The movable system, whether it is a wire, a coil, or a magnet, is subject to control, and such control may be

(*α*) Torsional or elastic, as in a perfectly astatic Paschen galvanometer, and in suspended coil galvanometers.

(*β*) Magnetic, as in most Thomson galvanometers.

(*γ*) Gravitational, as in the Kelvin current balance.

(*δ*) Due to inertia, as in the ballistic galvanometer and fluxmeter.

§ (3) GALVANOMETER PARTS AND CONSTANTS.—Galvanometers are at times used as measuring devices for very small currents, or changes in current, as when employed in the measurement of insulation resistance. At other times they are used to detect uniformity of potential between two points, as in bridge methods for the measurement of resistance. In other cases very small quantities of electricity are measured or compared, as in some methods for the comparison of capacities, and galvanometers are used also to determine when two small quantities of electricity are equal in amount, as in bridge methods involving inductances and capacities. In order to choose the best type of galvanometer for such measurements it is necessary to have a general knowledge of—

(*a*) Arrangement of and resistance of coils.
(*b*) Deflected magnet systems.
(*c*) Shielded systems.
(*d*) Deflected conductor systems.
(*e*) Field magnets.
(*f*) Suspensions.
(*g*) Period and damping conditions.
(*h*) Sensitiveness and constancy of rest point.

These are considered in the order given.

§ (4) ARRANGEMENT OF AND RESISTANCE OF COILS.—With galvanometers of the Thomson and other patterns in which the conductor conveying the current is in the form of a fixed coil, the windings of the coil should be so disposed as to give the maximum intensity of magnetic field in the neighbourhood of the movable magnet system. For example, suppose that in a Thomson astatic galvanometer a double coil system of many turns is wound about one set of magnets; then the outer layers will be at a considerable distance from the magnets and the effect of the current in the layers will be correspondingly small. If, instead, the

raised to the power 2/5 than to the resistance raised to the power 1/2.

(iv.) *Best Resistance for a Galvanometer.*—It is shown elsewhere that the best galvanometer resistance is equal to that of the circuit of which the galvanometer forms part excluding the galvanometer itself. The galvanometer coil should therefore be wound of high-conductivity material, such as copper or silver, and of a gauge appropriate to the channel in which the coil is to be wound, and such that the completed coil has the requisite resistance. In some cases, such as that of testing insulation resistance, the external galvanometer circuit may be many megohms, and since in practice the resistance of a galvanometer coil of very fine wire is not more than a few thousand ohms, the departure from the "best galvanometer resistance" is considerable.

However, the sensitiveness is not greatly reduced if the resistance of the galvanometer is appreciably different from that giving the best results. Suppose that R_G is the best galvanometer resistance; then the resistance of the galvanometer circuit is $2R_G$ and the deflection of the galvanometer is proportional to $i\sqrt{R_G}$, where i is the current. If, instead, NR_G is the resistance of the galvanometer the new current is $2i/(N+1)$ and the deflection is proportional to $2i\sqrt{NR_G}/(N+1)$. The ratio of the new sensitiveness to the maximum sensitiveness is therefore $2\sqrt{N}/(N+1)$. The following table, showing the relation between N and $2\sqrt{N}/(N+1)$, was first given by Schuster:[1]

N.	$2\sqrt{N}/(N+1)$.	N.	$2\sqrt{N}/(N+1)$.
1	1·000	11	0·553
2	·943	12	·533
3	·866	13	·515
4	·800	14	·499
5	·745	15	·484
6	·700	16	·471
7	·661	17	·458
8	·629	18	·447
9	·600	19	·436
10	·575	20	·426

In practice, except for the measurement of insulation resistance, there is a tendency to choose a galvanometer of too great a resistance. In a Thomson or Broca galvanometer having two coils and intended for general measurements it is of advantage to choose each coil to be of 100 ohms resistance. When the coils are in series the galvanometer resistance is 200 ohms, and if so used in measurements when the external galvanometer circuit has a resistance of 10,000 ohms the sensitiveness is 0·27 time the maximum possible. When the coils are in parallel, the galvanometer resistance is 50 ohms, and the reduction in sensitiveness when the external circuit is 1 ohm in resistance is the same as before.

In the case of moving-coil instruments, the resistance of the suspension strip, when the strip conveys the current, must be counted as belonging to the external galvanometer circuit.

§ (5) Deflected Magnet Systems.—In the Thomson, Broca, Paschen, and other sensitive galvanometers the magnet systems are astatic, that is, they are such that when placed in a uniform magnetic field no turning moment results, whatever be the orientation of the system. In general, perfect astaticism is not obtained, but the directive force is always very small.

(i.) *Thomson Galvanometer.*—The most commonly used astatic combination consists of two similar groups of magnets, A and B, *Fig.* 2, the axes of which are horizontal and in the same vertical plane. The effective magnetic moments of the groups are equal, and the north poles of the upper group point in the opposite direction to those of the lower group. In the Thomson galvanometer there are from three to five magnets in each group, each magnet being about 4 millimetres long. The groups are usually not less than 5 cm. apart and are connected together by a fine wire or strip; a small reflecting mirror M is attached to the system. The fixed coils are sometimes two in number, but occasionally four; in the former case the A group lies centrally with respect to the two coils and the B group is often attached to the back of the mirror. When four coils are used the A group is central with respect to two of the coils and the B group is in the centre of the lower coils. The suspension may be of silk or quartz. In general a carefully constructed system of this kind is sufficiently astatic to necessitate the employment of a control magnet. Such a magnet is often fixed above the galvanometer and creates a magnetic field which is stronger, or weaker, in the neighbourhood of the upper group of magnets than in the vicinity of the lower group. Adjustment of the position of the magnet alters the intensity of the magnetic field near the magnets and so changes the sensitiveness and period.

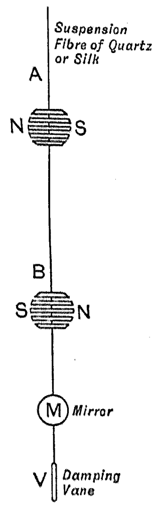

Fig. 2.

The relation between the length of a magnet

[1] *Phil. Mag.*, 1895, xxxix. 175. See also "Resistance, Standards of," § (5) (ii.)

in a group and the diameter of the smallest turn in a coil is of some importance. If the magnets swing in a cylindrical chamber which runs right through the coils, the diameter of the smallest turn must be greater than the length of a magnet, and in such case every turn in the coil produces a beneficial effect. In the case when the magnet is longer than the smallest diameter the inner turns may produce an effect opposite to that of the outer turns.[1]

In regions where the earth's magnetic field changes frequently and suddenly in direction and intensity the Thomson system is not sufficiently astatic, unless very great care is taken, to be of use in precision measurements. In the neighbourhood of electric traction circuits the changes in magnetic intensity are so sudden and of such magnitude that an unprotected Thomson system is in general in constant motion. The difficulty may be greatly reduced by making the system more astatic, but a better remedy is to shield the galvanometer with soft-iron screens.

(ii.) *Paschen Galvanometer.*—In principle this is the same as the Thomson galvanometer but in design it is a great improvement. The magnet system consists of two groups each with about thirteen magnets, the magnets being arranged alternately on opposite sides of a fine glass stem which supports also a very thin glass mirror. The complete moving system of a Paschen galvanometer made by the Cambridge and Paul Instrument Company weighs about 30 milligrams. A special feature of the galvanometer is the winding of the coils which are graded and have the theoretically best cross-section. A horizontal cross-section of the coil system is shown in *Fig.* 1. Four coils are provided, each with two terminals so that various combinations may be used.

(iii.) *Vertical Magnet Systems. The Broca Galvanometer.*—In the Broca galvanometer the magnet system consists of two steel wires or tubes, about 0·5 mm. diameter and 45 mm. long placed vertically and parallel. Each of the magnets is so magnetised that its two ends are of like polarity, with a consequent pole in the middle. The suspended system of a Broca galvanometer is shown in *Fig.* 3, and the galvanometer itself in *Fig.* 3A. The system is astatic if the magnets are symmetrically magnetised, and if not the system becomes astatic when the magnets are parallel to the axis of rotation. The steel wires or tubes (which should be of tungsten steel if possible) are best magnetised by insertion in a small coil wound as a right-handed helix for half its length, and as a left-handed helix for the remaining half; the inner diameter of the coil is slightly greater than the diameter of a wire. After magnetisation the wires are placed in two parallel grooves, about 4 mm. apart, cut in brass sheet, and clamped in position, while the aluminium foil connecting pieces AA are connected to the magnets by wax or cement. The mirror M and damping vane V are rigidly connected by a fine wire to the lower piece of aluminium foil and a quartz or silk fibre is connected to the upper piece of aluminium. By bending the aluminium tongue it is easy to ensure that the magnets hang vertically.

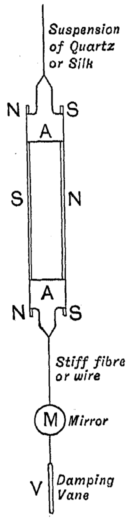

FIG. 3.

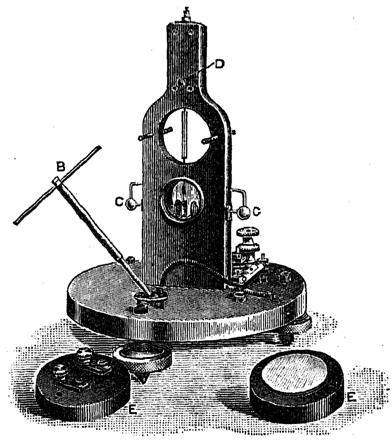

FIG. 3A.

In practice it is not difficult to make the Broca system very astatic; at times systems have been made so astatic that the main control was due to the fibre. In general, however, a small control magnet is used to direct the system. Because of its excellent astatic qualities the Broca galvanometer has replaced the Thomson in laboratories subject to sudden fluctuations in the earth's magnetic field.

(iv.) *Ageing of Galvanometer Needles.*—The magnets used in the Thomson, Broca, and Paschen galvanometers should be as strong as possible, for the period of such instruments is inversely proportional to the strength of the magnets. Very little quantitative information has been obtained of the loss of strength with time of such needles, but that obtained by Ayrton, Mather, and Sumpner in 1890 shows the importance of remagnetising the systems after the lapse of a few years.

The data is as follows, D being the deflection in scale divisions at a constant distance.

[1] Ayrton, Mather, and Sumpner, *Phil. Mag.*, 1890, xxx. 64.

1. Double-coil astatic reflecting galvanometer of 686 ohms resistance. Period = 10 seconds. Current = 1 microampere.

	D.
(*a*) Needles magnetised and tested the same day	1600
(*b*) After about two years' use .	366
(*c*) Needles remagnetised and then used for about one year .	826

2. Single-coil astatic reflecting galvanometer of 26 ohms resistance. Period = 10 seconds. Current = 1 microampere.

	D.
(*a*) As obtained from the makers .	198
(*b*) After about three years' use .	170
(*c*) Needles remagnetised and tested the same day	243

3. Double-coil astatic reflecting galvanometer. Resistance 9744 ohms. Period = 10 seconds. Current = 1 microampere.

	D.
(*a*) As obtained from the makers .	4200
(*b*) After about three years' use .	3000
(*c*) Needles remagnetised and tested the same day	4280

In the case of a Broca galvanometer which had been in use for four years the writer found the magnetisation of the magnets had fallen to one-quarter of the initial value. When the magnets of galvanometers are made with properly hardened tungsten steel and artificially aged the fall of magnetisation with time is very small.

§ (6) Shielded Systems. *Du Bois-Rubens Galvanometer.*—Owing to sudden fluctuations in the earth's magnetic field, and because of disturbances in laboratories, it is often necessary to shield the suspended systems of galvanometers from the influence of external fields. The shields are of iron or steel, spherical or cylindrical, and may consist of one, two, three, or more nearly complete shells. The Du Bois-Rubens galvanometer usually has two spherical shells. Very complete data on shielding are given by E. F. Nichols and S. R. Williams,[1] who made experiments on shields of cast silicon steel, before and after annealing, and on others made from ordinary soft-iron water-pipes. The results obtained with the latter are given in the following table :

Shield No.	Inner Radius.	Outer Radius.	Weight in Grams.	Shield used.	Shielding Ratio.
	cm.				
1	2·7	3·0	1530	1	19
2	3·9	4·5	3120	1+2	104
3	5·2	5·7	4260	1+2+3	252
4	6·5	7·1	6130	1+2+3+4	723
5	9·0	9·7	9650	1+2+3+4+5	2725

It is apparent from these figures that a Thomson galvanometer can be efficiently protected from local variations in the magnetic field by the provision of shields of soft iron.

The magnetic shield of the Paschen galvanometer is of great importance; the instrument is extremely sensitive to external fields and also to temperature changes. Because of the latter Paschen was in the habit of filling the space between his magnetic shields with cotton-wool, and had a large covering of cotton-wool over his external shield.

§ (7) Deflected Conductor Systems.—Deflected conductor systems may be divided into three classes: (1) those consisting of a single straight conductor, as in the Einthoven galvanometer; (2) those consisting of a single loop of wire, as in a thermo-galvanometer; (3) those consisting of a coil of many turns, as in a D'Arsonval galvanometer. Instruments of the second class consisting of Boys' radiomicrometer and Duddell's thermo-galvanometer are described in the articles on the "Radio Micrometer," Vol. III., and on "Radio-frequency Measurements," § (18) (v.), § (19) (ii.).

(i.) *Einthoven Galvanometer.*[2]—In this, the movable element is either a fine glass or quartz fibre or tube, coated with a conducting layer of silver, gold, or platinum, or a fine metal wire of platinum, tungsten, silver, gold, copper, phosphor bronze, or aluminium. The fibre is placed in an intense magnetic field due to an electromagnet and is kept in tension by a weak spring. Adjustment of the tension alters the frequency and also the damping. In some instruments two strings are used, and in others as many as twelve have been placed in the magnetic field and operated on by separate electromotive forces in separate circuits.

When a current passes through a fibre the latter moves at right angles to the magnetic field, and its motion is observed by means of a microscope with micrometer eyepiece or by projection of an image of the string on to a screen or photographic film. When used in conjunction with a photographic recording apparatus, alternating or pulsating currents such as are received in wireless telegraphy may be recorded. The high-resistance instrument has been used extensively in physiological investigations, especially for recording the electrical currents produced during the beating of a heart.

The resistance of a silvered glass fibre 0·0025 mm. in diameter and of length suitable for a galvanometer may be as great as 12,000 ohms, but copper wires having a resistance as small as 6 ohms have been used.

The tension of the string can be altered within limits. The upper limit is when the tension is so great that the elastic limit is approached; the lower limit is the total absence of tension. In the latter case, how-

[1] *Physical Review*, 1908, xxvii.

[2] A. H. Crebore, *Phil. Mag.*, 1914, xxviii.

ever, the string still has a frequency depending on its length, diameter, density, and elasticity.[1] The frequency is given by

$$f=\frac{2m^2r}{8\pi l^2}\sqrt{\frac{E}{\rho}},$$

where l and r are the length and radius of the wire respectively, E is the elasticity, and ρ the density: m is a constant equal to 4·73. A copper wire 0·01 mm. in diameter and 10 cm. long has a natural frequency of about 3 per second.

The electromagnet of the Einthoven instrument is shaped so as to concentrate the field on the air-gap in which the fibre moves. The iron is magnetised to saturation, and consequently small changes in the magnetising current have little effect on the intensity of the field in the gap.

(ii.) *Deflected Coil Systems.*—The suspended coil principle was used first by Sir William Thomson in 1870, and the use of such coils for galvanometers was dealt with subsequently by Maxwell. However, no considerable use was made of such deflected systems until attention was recalled to them by D'Arsonval in 1882.

The deflected coil system consists of a circular or rectangular coil of many turns of fine wire suspended between the poles of a permanent magnet or an electromagnet. Often inside the coil a solid core of soft iron is fixed. Connections to the coil are made either through two wires or strips constituting a bifilar suspension or through one suspending wire and a fine loosely coiled metallic spiral leading to the lower end of the coil. Ayrton, Mather, and Sumpner have pointed out that suspended coils should be long and narrow, and that there should be no internal core. Subsequently Mather[2] determined the best shape of the section of the coil perpendicular to the axis about which it turns.

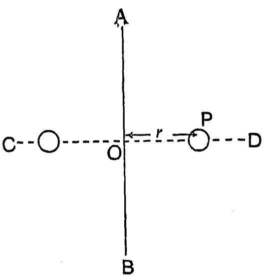

FIG. 4.

Let O (*Fig.* 4) represent in plan the axis about which the coil turns, and let it be placed in a magnetic field parallel to CD. Let P be an element of the section of the coil, the length of wire being at right angles to the paper. Then the deflecting moment exerted by unit length is Hiar sin θ, where H is the intensity of the magnetic field, i the current density, a the area of the element, and r its distance from the axis. The element has a moment of inertia about O equal to mar^2, where m is the mass per unit cube. Mather points out that it is important for the period of oscillation to be not inconveniently long and for the power consumed by the instrument to be as small as possible; then, since for a constant period the controlling moment at unit angle must be proportional to the moment of inertia, the best section of coil will be such that the total deflecting moment for a given total moment of inertia is a maximum.

For the element considered the ratio of the deflecting moment to the moment of inertia is

$$\frac{\mathrm{H}iar\sin\theta}{mar^2}=\mathrm{C}\frac{\sin\theta}{r},$$

where C is a constant depending on H, i, and m. Hence sin θ/r is a measure of the efficacy of the element and its position. If, now, a curve is drawn whose polar equation is $r=x_1\sin\theta$, then it may be shown that a given length of wire wound within this space is more efficient than if wound outside it. Hence the curve $r=x_1\sin\theta$, *i.e.* a circle tangential to AB at O is the best form of the section of the moving coil. The complete section consists of two circles touching at O.

The kind of improvement obtained by winding coils of this shape is shown in the following table, which is a portion of one given by Mather:

No.	Shape of Section.	Deflecting Moment / Moment of Inertia	Proportions in Particular Cases.	Deflecting Moment per Unit Moment of Inertia.
1		$\frac{4}{3b}$	..	1·02
2		$\frac{4\sin\theta}{3b\theta}$	$\theta=30°$ $\theta=45°$	0·91 0·95
3		$\frac{8}{3\pi b}$	..	0·80
4		$\frac{b}{b^2+(c^2/2)}$	$c=\frac{1}{11}b$	0·40

Shapes 1, 2, and 3 are not quite possible in practice, because insulation must be allowed for. Usually in Ayrton-Mather galvanometers the coil is of a narrow shuttle-shaped form and moves between the poles of a powerful permanent magnet with a narrow air-gap. The coil is wound with special non-magnetic wire, and, after winding, it is treated by a chemical process to eliminate any traces of magnetic material in the silk or covering of

[1] Wertheim Salomonson, Konink. Akad. van Wetenschappen te Amsterdam.
[2] *Phil. Mag.*, 1890, xxix. 434.

the wire. The whole of the suspended system is enclosed in a dust-tight tube to prevent contamination with magnetic matter; an excellent coil may be ruined by a slight amount of careless handling or a few minutes' exposure to a dusty atmosphere.

§ (8) Field Magnets.—In the Einthoven and suspended coil galvanometers the conductor conveying the current moves in the magnetic field of a powerful magnet, and the sensitiveness of the galvanometer is directly proportional to the intensity of the field. It is well known that permanent magnets lose their strength with time, and to ensure comparative constancy of strength it is usual to slightly demagnetise the magnet. Some makers do this by heating the hardened steel in a steam bath for one day, after which it is magnetised strongly and afterwards heated again in the steam bath for six hours. Another and better procedure is to demagnetise the magnet to 80 per cent of its initial magnetisation; in such cases, if the magnet is of properly hardened tungsten steel, the constancy is satisfactory.

Electromagnets are used for Einthoven galvanometers and many oscillographs, and the question of loss of magnetisation with time does not then arise.

§ (9) Suspensions.—The usual fibres employed for suspending the movable systems of galvanometers are of silk, phosphor bronze, silver, platinum-silver, and quartz. In the best types of Thomson galvanometer—including the Paschen—quartz fibres are used; in those used in less accurate measurements the suspensions are of silk. Wires and strips of phosphor bronze and silver are used for suspended coil galvanometers, and platinum-silver strips and wires are used in twisted strip ammeters. If special leads are provided for the leading in wires of suspended coils the latter may be supported by quartz fibres

In the Thomson type of galvanometer the suspensions may be regarded as being cylindrical wires. If the length is l, the radius r, the twisting couple due to the current in the coils u, and, as a result of this couple the magnet system is deflected through an angle θ, then

$$\theta = \frac{2lu}{\pi n r^4},$$

where n is the coefficient of torsional rigidity of the fibre. The values of n for some solids are given below.

Steel	$8{\cdot}2 \times 10^{11}$ dynes/cm.^{2}
Brass	3·8 ,,
Quartz (fused)	2·9 ,,
Glass	2·4 ,,

After deformation by twisting, a fibre does not always completely recover its initial shape, and as a result the rest point of the galvanometer is variable. Of all known substances, quartz recovers its original shape best;[1] in other words, it exhibits elastic fatigue less than any other known body, and it is because of this it is so largely used for suspensions. Quartz fibres were first made by C. V. Boys,[2] and when drawn fine the breaking strength exceeds that of steel. Unspun silk is used in galvanometers for measurements of small precision; they are, however, troublesome, for they are much affected by changes in the humidity of the atmosphere, the result being a shift of the rest point.

If, in any galvanometer, the control is entirely due to a single cylindrical wire or quartz fibre, the deflection produced is inversely proportional to the fourth power of the radius of the wire; it is of great importance, therefore, that the fibre should be of as small a radius as possible consistent with the necessary mechanical strength. Quartz fibres can be made exceedingly fine; the diameters of quartz fibres used in galvanometers vary from 0·003 mm. to 0·025 mm.

§ (10) Period and Damping Conditions.—When the angle of deflection of a galvanometer is small, the deflecting moment may be regarded as proportional to the value of the current. It may be represented by Gi, where G is a constant depending on the galvanometer and i is the current. The restoring moment also is proportional to the angle of deflection and is equal to $c\theta$, where θ is the angle of deflection and c is the restoring moment for unit angle of deflection.

In its motion the system is retarded by air currents and by induced currents, and for small velocities the retardation is proportional to the angular velocity of the system. The angular velocity is $d\theta/dt$, and the retarding moment may be written $bd\theta/dt$, where b is a constant known as the coefficient of damping; it is the ratio of the retarding torque on the moving system to the rate of displacement.

The angular acceleration is $d^2\theta/dt^2$, and if K is the moment of inertia of the rotating system, the moment tending to change the angular velocity is $Kd^2\theta/dt^2$. This must be equal to the sum of the deflecting moment Gi, the restoring moment $c\theta$, and the retarding moment $bd\theta/dt$. Hence, when there is no applied voltage,

$$K\frac{d^2\theta}{dt^2} = -c\theta - b\frac{d\theta}{dt},$$

or

$$K\frac{d^2\theta}{dt^2} + b\frac{d\theta}{dt} + c\theta = 0,$$

which equation represents the motion of the moving system of a galvanometer. The form

[1] Threlfall, *Phil. Mag.*, 1890, xxx. 99.

[2] C. V. Boys, *Phil. Mag.*, 1890, xxx. 116. See also "Radio Micrometer," Vol. III.

of the solution of this equation depends upon whether the roots of the quadratic equation

$$Km^2 + bm + c = 0$$

are real or imaginary.

(i.) *Oscillatory Condition of Galvanometer System.*—When

$$\frac{b^2}{c} < 4K$$

the roots are imaginary, and the solution is

$$\theta = A\epsilon^{-(b/2K)t} \cos\left\{\left(\frac{c}{K} - \frac{b^2}{4K^2}\right)^{\frac{1}{2}} t + \alpha\right\},$$

where A and α are arbitrary constants. Hence θ is alternately positive and negative, the period being

$$\frac{2\pi}{\sqrt{(c/K) - (b^2/4K^2)}}.$$

Therefore the galvanometer system oscillates.

(ii.) *Non-oscillatory Condition of Galvanometer.*—When

$$\frac{b^2}{c} > 4K$$

the solution of the differential equation changes its character. In this case we have

$$\theta = A\epsilon^{-m_1 t} + B\epsilon^{-m_2 t},$$

where $-m_1$, $-m_2$ are the roots of the quadratic equation

$$Km^2 + bm + c = 0.$$

Hence
$$m_1 = \frac{b}{2K} + \sqrt{\frac{b^2}{4K^2} - \frac{c}{K}},$$

and
$$m_2 = \frac{b}{2K} - \sqrt{\frac{b^2}{4K^2} - \frac{c}{K}}.$$

$d\theta/dt$ vanishes when $t=0$, and if θ_0 is the value of θ when $t=0$,

$$\theta = \frac{\theta_0}{m_1 - m_2}(m_1\epsilon^{-m_2 t} - m_2\epsilon^{-m_1 t}),$$

$$\frac{d\theta}{dt} = \frac{m_1 m_2}{m_1 - m_2}\theta_0(\epsilon^{-m_1 t} - \epsilon^{-m_2 t}).$$

Hence $d\theta/dt$ never vanishes except when $t=0$ and when t is infinity, so that θ never changes sign but continually diminishes. The galvanometer system is non-oscillatory and is overdamped.

(iii.) *Critical Damping.*—A galvanometer system is critically damped when the motion of the needle is just becoming non-oscillatory. The system returns to the rest point in the minimum time, but the velocity never changes in direction. In this case

$$\frac{b^2}{c} = 4K.$$

When a current i flows through the galvanometer and the ratio of the displacing torque to the current is G, the mechanical power is $Gi d\theta/dt$, *i.e.* the torque Gi multiplied by the angular velocity, and this product must be equal to i times the back voltage.[1] Consequently, if $(r + R_G)$ is the resistance of the circuit and e is the impressed voltage,

$$i = \frac{e}{r + R_G} - \frac{G}{r + R_G} \cdot \frac{d\theta}{dt}.$$

Hence the equation of motion of the moving system may be written

$$K\frac{d^2\theta}{dt^2} + \left(b' + \frac{G^2}{r + R_G}\right)\frac{d\theta}{dt} + c\theta = \frac{Ge}{r + R_G},$$

where R_G is the resistance of the galvanometer and r is the resistance of the remaining portion of the circuit. The damping factor consists of two parts, one of which $(G^2/(r + R_G))$ represents the extra retarding torque due to induced currents when the circuit is closed, and the other (b') is the damping constant with open circuit. In galvanometers of the Thomson type the damping due to induced currents is small, and if critical damping is desired the retardation by air friction must be capable of adjustment.

(iv.) *Critical Damping with Suspended Coil Galvanometers.*—With suspended coil galvanometers critical damping is achieved by adjustment of the magnitude of the induced currents by alteration of the resistance. Thus the condition for critical damping is

$$\left(b' + \frac{G^2}{r + R_G}\right)^2 = 4Kc,$$

and the particular value of r which satisfies this equation is the resistance external to the galvanometer requisite to ensure critical damping. If the resistance of the apparatus with which the galvanometer is used is less than the external critical resistance, additional resistance is added in series with the galvanometer. On the other hand, if the resistance of the circuit is too great, critical damping may usually be obtained by connecting a suitable resistance in parallel with the galvanometer coil. Sometimes the system is damped by short-circuited turns of the coil.

(v.) *Critical Damping with Thomson Type of Galvanometer.*—In galvanometers of the suspended magnet type the damping due to induced currents is small, and if critical damping is desired, the moment of inertia must not be too great and the retardation due to air friction must be capable of adjustment. In the Paschen galvanometer no means of adjusting the damping is provided; however, the moment of inertia is very small, and the air retardation reduces the number of complete oscillations to a reasonable amount. In modern Thomson and Broca galvanometers the damping effect due to air is adjustable; a light aluminium vane about 80 sq. mm. in area is attached to the lower end of the suspended system and swings between two parallel damping plates, of somewhat greater

[1] Wenner, *Bureau of Standards, Bull.*, 1916, xiii.

surface, fitted to the frame of the galvanometer. The distances of the damping plates from the vane are adjustable, and the damping increases with decrease of the distances. It is easy in this way to make the system critically damped, over-damped, or oscillatory. A similar damping device has been used with magnetometers. It is necessary for the surfaces of the vane and damping plates to be conducting, as otherwise electrostatic effects are often troublesome after the vane has made contact with and slightly rubbed the plates. The surfaces must not, therefore, be lacquered; coating with platinum black is recommended.

(vi.) *Critical Damping with Einthoven Galvanometer.*—The damping of an Einthoven galvanometer with a given conducting string may be adjusted by altering either the frequency of the string, the intensity of the magnetic field in which the string moves, or the external resistance. Critical damping results when

$$4\pi f=\frac{8\mathrm{H}^2 r}{\pi^2\rho\delta\mathrm{R}},$$

where f is the frequency of the string, H the intensity of the magnetic field, r the resistance of the effective portion of the string, ρ the resistivity of the string, δ its density, and R the resistance of the circuit, all in consistent units. In the type of Einthoven galvanometer used in sound-ranging and in ballistic work for the measurement of the velocity of projectiles, the strings are of tungsten, copper, silver, or phosphor bronze, and the frequency of the strings is adjusted by altering the tension on them. When the frequency is fixed it is usually possible to alter the resistance of the external circuit until critical damping results. In the most sensitive instruments a string is a very fine glass fibre or tube coated with silver and weighs about 10^{-6} grams; the moment of inertia is in consequence very small, and with a string frequency of about 200 critical damping is usually obtained.

Wertheim-Salomonson has pointed out that the most suitable metal for the string is aluminium. From the equation for critical damping it is apparent that the frequency of the string will vary inversely as the product of the density and resistivity. A small product is therefore of considerable advantage. Wertheim - Salomonson gives the following data for platinum, gold, silver, copper, and aluminium:

Material.	δ.	ρ.	$\delta\rho\times10^4$.
Platinum	21·2	$0{\cdot}094\times10^{-4}$	1·99
Gold	19·3	·022 ,,	0·425
Silver	10·6	·0175 ,,	0·185
Copper	8·9	·0162 ,,	0·144
Aluminium	2·7	·0287 ,,	0·0774

Wires of aluminium 0·030 mm. thickness have been used, and wires of platinum and copper of 0·010 mm. thickness have been employed. When small frequencies are required the wires should be annealed *in situ* by the passage of an electric current.

(vii.) *Galvanometers with Small Damping. Ballistic Galvanometer.*—A ballistic galvanometer is designed to measure the total quantity of electricity which passes through it in a very short interval of time. The damping must be very small and the moment of inertia must be great; as a result the period is great and the whole quantity of electricity it is desired to measure passes through the galvanometer before the system has made any appreciable movement from its initial position. The ballistic galvanometer is described in the article on "Magnetic Measurements," § (4).

§ (11) Sensitiveness.—The sensitiveness of a galvanometer has been expressed in a variety of ways. The current sensitivity has been defined (*a*) as the *current* required to produce a deflection of 1 millimetre on a scale placed 1 metre from the galvanometer mirror; and (*b*) as the *deflection* on the scale produced by unit current. If the first were 10^{-10} ampere, the latter would be 10^{10} divisions. The more modern practice is to measure current sensitivity as the deflection in millimetres produced on a scale 1 metre away by a current of 1 microampere. The *voltage* sensitivity is usually defined as the deflection obtained at the distance stated when the voltage applied to the instrument is one microvolt. The voltage sensitivity is therefore the current sensitivity divided by the resistance of the galvanometer.

It is clearly unfair to compare galvanometers with different periods and different resistances unless allowance is made for these differences. It has already been shown that the sensitiveness of a galvanometer varies as the square root of the resistance if the insulation is negligible and the channel in which the coil is wound is constant; in practice the insulation modifies this relationship so that the sensitiveness is more nearly proportional to the power 2/5 of the resistance. When in a Thomson galvanometer the damping is small the relation between the sensitiveness and the period is given by

$$\mathrm{T}=2\pi\sqrt{\frac{\mathrm{I}}{\mathrm{MH}}},$$

where T is the period, I the moment of inertia of the suspended system, M the moment of the magnet, and H the intensity of the magnetic field. As the deflection due to a current through the galvanometer is inversely proportional to H, it follows that the sensitiveness is proportional to the square of the period.

If the current in amperes is i and the deflection in millimetres at 1 metre is D, then

$$i=\frac{10\mathrm{H}}{\mathrm{G}}\cdot\frac{\mathrm{D}}{2000},$$

or $$\mathrm{D}=\frac{200i\mathrm{MT}^2\mathrm{G}}{4\pi^2\mathrm{I}},$$

where G is the constant of the galvanometer and varies with $\sqrt{R_G}$ or $(R_G)^{\frac{2}{5}}$, R_G being the resistance of the galvanometer.

(i.) *Factor of Merit.*—Since D varies with the period and the resistance of the galvanometer, it is desirable when comparing galvanometers to reduce the sensitivities to the values they would possess if all the galvanometers had the same period and resistance. This suggestion was made first by Ayrton, Mather, and Sumpner in 1890. Later they suggested 10 seconds as the standard period and 1 ohm as the standard resistance of the galvanometer. The question as to whether the relation "sensitiveness varies as $(R_G)^{\frac{1}{2}}$" or "sensitiveness varies as $(R_G)^{\frac{2}{5}}$" depends largely on the galvanometer. Some experimenters assume the former to be true, but many makers of instruments prefer the latter as being closer to practice. When the sensitiveness has been reduced to allow for period and galvanometer resistance it is called either "Normal Sensitiveness" or "Factor of Merit." The accepted period being 10 seconds, it follows that for any galvanometer the Factor of Merit is

$$\frac{100\mathrm{D}}{\mathrm{T}^2(R_G)^{\frac{1}{2}}}\text{ or }\frac{100\mathrm{D}}{\mathrm{T}^2(R_G)^{\frac{2}{5}}},$$

T being the period in seconds, R_G the resistance of the galvanometer, and D the deflection in millimetres at 1 metre. For current sensitivity the deflection should be taken as that due to one ampere or one microampere through the galvanometer coils. For voltage sensitivity the Factor of Merit is the deflection obtained when the voltage applied to the galvanometer coils is one volt or one microvolt. Usually the microampere and microvolt are used as standards.

In 1890, and again in 1896, Ayrton, Mather, and Sumpner[1] gave Factors of Merit for a number of galvanometers. Since then there have been many improvements in galvanometer construction; the following Factors are from a catalogue by The Cambridge and Paul Scientific Instrument Company:

Type of Galvanometer.	Period in Seconds (T).	Deflection for 1 Microampere (D).	Resistance of Galvanometer (R_G).	Factor of Merit $100\mathrm{D}/\mathrm{T}^2(R_G)^{\frac{2}{5}}$.
Thomson . . .	14·4	6830	1965	158
Broca . . .	10	350	8·8	147
	10	2200	860	148
Paschen . . .	6	8560	12·2	8,720
	6	2080	0·75	6,500
Ayrton-Mather .	8·2	245	20	110
	8·3	757	400	100
	3·0	18	7	90
	2·8	550	275	744
Einthoven (silvered glass)	0·004	7·3	8720	120,000
Einthoven (aluminium wire)	0·039	13·2	6·9	40,000

In the case of the Einthoven instrument angular deflections are not observed, but the displacements of the fibre are always magnified by optical means. The deflections given in the table are those obtained after a magnification of 600.

(ii.) *Zero-keeping Qualities.*—The sensitivity of a galvanometer as calculated by the method described is not entirely satisfactory, as no account is taken of the wandering of the rest point. Clearly, if, on an average, after a small deflection, the rest point wanders by an amount d, this limits the precision with which the deflection should be read. Even in null methods of using galvanometers, as in bridge measurements of resistance, reversals of the current must be made, and the galvanometer system is in general deflected through a small angle for every change. If, when no current passes through the galvanometer, the rest point changes while measurement is made, the effective sensitiveness is reduced. For example, if two galvanometers have the same Factor of Merit, and the position of each galvanometer spot can be read with ease within 0·1 mm., but the rest point of one galvanometer changes during a measurement by 1 mm. while the other is constant, the useful sensitiveness of the latter instrument, in null methods, is 10 times that of the former.

The change in the rest point of a galvanometer is due to several causes. In the Thomson type of instrument variations in the earth's magnetic field are often responsible for such changes, but this difficulty may be overcome by shielding the magnet system. The suspension when of silk is affected by changes in the humidity of the atmosphere, and markedly better results have been obtained by enclosing a galvanometer to prevent any interchange of air or moisture. Electrostatic disturbances

[1] *Phil. Mag.*, 1890, xxx. 58; *ibid.*, 1898, xlvi. 349.

are not infrequent, and may be caused by electrostatic attractions between the suspended system and the near surfaces of the fixed galvanometer frame. The surfaces of the galvanometer coils should be covered with tinfoil and the sheets of foil connected together. If an air damping system is provided, the surfaces should be coated with platinum black. Small quantities of radioactive compounds are sometimes inserted in the space between the coils and the suspended system.

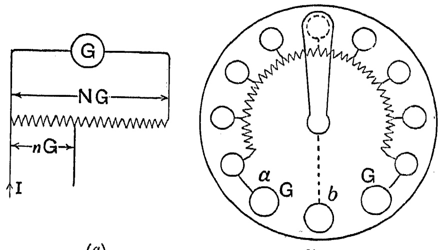
In suspended coil galvanometers the most frequent cause of change is due to the metallic suspending fibre. If the fibre is too coarse the galvanometer is insensitive; if too fine, elastic fatigue is observed. In suspended coil galvanometers one end of the coil should be attached to the frame and magnet; this reduces electrostatic troubles.

If a suspended coil is associated with magnetic matter (dust is often sufficient) the controlling force may be many times that due to the suspension, and the sensitiveness is reduced in proportion. Instrument-makers of the first class have special dust-proof rooms for the assembly of the coil parts and of the suspension; the wire is made from electrolytic copper or silver and is drawn through diamond dies; the silk is of exceptional purity, and after completion of the coil it is treated with chemicals to remove all traces of iron.

(iii.) *Galvanometer Shunts.*—Resistances are often placed in parallel with suspended coil galvanometers to make them aperiodic, and, at times, with all kinds of galvanometers, to reduce the sensitiveness.

Let R_G be the resistance of the galvanometer and R that of the shunt; then if I is the current in the main circuit, that in the galvanometer is $IR/(R_G+R)$. The maker often provides a set of shunt coils for use with a particular galvanometer.

A universal shunt system has been designed by Ayrton and Mather which is capable of being applied to *any* galvanometer. This is shown diagrammatically in *Fig.* 5 (*a*). R_G is the resistance of the galvanometer, and across its terminals there is a high resistance of NR_G ohms. The current I in the main circuit enters and leaves as shown in *Fig.* 5 (*a*) and the current through the galvanometer is $In/(N+1)$, that is, the fraction of the current which flows through the galvanometer is not dependent on the galvanometer resistance. By having a number of tapping points so that $n/(N+1)$ is equal to 0·1, 0·01, etc., the effect of the shunt may be varied. The value of the main current I varies with the value of n owing to the change in the effective resistance of the circuit, and such a change naturally affects the real sensitiveness. In order that the sensitiveness may not be unduly reduced R must be much larger than the resistance of the galvanometer.



(*a*) (*b*)

FIG. 5.

Fig. 5 (*b*) shows an arrangement of coils often adopted in the Ayrton and Mather shunt.

§ (12) CHOICE OF A GALVANOMETER.—Experience is the only safe guide to the choice of a galvanometer for any particular purpose. It is useful, however, to tabulate the points which must be considered.

(i.) *Resistance.*—The resistance should be appropriate for the measurement in order to secure good sensitivity. If a variety of measurements are to be made and the circuits vary greatly in resistance it is of advantage to choose as a suspended magnet system a Thomson type having at least two coils, each of 100 ohms resistance. If a suspended coil galvanometer is chosen, the resistance of the coil should be about 100 ohms.

(ii.) *Period.*—For general use a short-period galvanometer is most advantageous. A convenient period is 10 seconds.

(iii.) *Damping.*—Except for the measurement of a quantity of electricity, *i.e.* except when the galvanometer is required to be used ballistically, the damping should be critical. In choosing a Thomson or Broca galvanometer preference should be given to one having variable air damping. In the suspended coil type the damping can be adjusted by adding resistance in series or in parallel with the coil.

(iv.) *Constancy of Rest Point.*—If the place where the experiments are to be made is subject to large magnetic disturbances and a suspended magnet system must be chosen, a Broca galvanometer is probably best. If any type of galvanometer will serve, a suspended coil type like the Ayrton-Mather galvanometer is very suitable. In general a Broca galvanometer is not much disturbed by leakage effects due to electric trams and trains.

(v.) *Suspension.*—The constancy of rest point depends also on the suspension; if the type permits, a quartz fibre is best. For very sensitive work a silver strip suspension may be used in a suspended coil instrument except when ratios of deflections have to be measured: in such cases a phosphor bronze suspension should be used. This also is best for general work.

(vi.) *Immunity to Mechanical Disturbances.*—When a system is subject to much vibration, such as is common in many London laboratories, a marked advantage is obtained by mounting the suspended system so that there is symmetry about the axis of rotation. A trial of the instrument is needed to see if this condition is sufficiently well fulfilled.

(vii.) *Optical System.*—The definition of the light spot used in reading deflections and rest points should be as perfect as possible in order that time may be saved and fatigue of the eye prevented. The galvanometer should therefore be provided with a good mirror, which should not be so thin as to change in radius of curvature with time. Plane mirrors are frequently employed with a lens mounted in front of the galvanometer; in this way the focal length of the optical system can be readily altered.

(viii.) *Visibility of Parts.*—The parts should be sufficiently accessible to ensure that the clearances are ample and to enable reasonable adjustments, such as damping, to be made with ease.

F. E. S.

GASES, DIELECTRIC CONSTANTS OF. See "Capacity and its Measurement," § (19).

GAUSS. The name given to the unit of magnetic force or the intensity of a magnetic field on the C.G.S. practical system of units.

1 Gauss = 1 unit of magnetic force.

See "Units of Electrical Measurement," § (27).

GAUSS THEOREM. See "Electrostatic Field, Properties of," § (2).

GEISSLER TUBES, for exhibition of discharge through gases. See "Electrons and Discharge Tube," § (1).

GIEBE, E., air condensers of. See "Capacity and its Measurement," § (32).

GLASS, tabulated values of dielectric constants of various kinds of. See "Capacity and its Measurement," § (24).

GLASS PLATE CONDENSERS. See "Capacity and its Measurement," § (31).

GLAZEBROOK'S REVOLVING COMMUTATOR, use of, for the measurement of capacity. See "Capacity and its Measurement," § (41).

GOLD:
Electroplating. See "Electrolysis, Technical Applications of," § (12).
Extraction and refining of. See *ibid.* §§ (18), (19).

GOLDSCHMIDT ALTERNATOR: a machine for the production of radio-frequency oscillations. See "Wireless Telegraphy Transmitting and Receiving Apparatus," § (5).

GOTT'S COMPARISON METHOD, for the measurement of capacity. See "Capacity and its Measurement," § (47).

GRAY'S MAGNETOMETER. See "Magnetic Measurements and Properties of Materials," § (2) (iv.).

GRID: the control electrode of a thermionic valve. See "Thermionic Valves," § (1).
Action of, in thermionic valves. See *ibid.* § (2).

GROVER, F. W., work of, on the measurement of the capacity and power factor of a condenser. See "Capacity and its Measurement," § (48).

GUARD RING: a device for checking distortion of the electric field at the edges of condenser plates, etc. See "Capacity and its Measurement," § (7).

GUARD WIRES: earthed wires employed to protect overhead telegraph circuits from power circuits. See "Telegraph, The Electric," § (14).

GUMLICH YOKE AND ISTHMUS METHOD, for high magnetisation tests. See "Magnetic Measurements and Properties of Materials," § (42).

GUMLICH'S MAGNETOMETER. See "Magnetic Measurements and Properties of Materials," § (2) (iii.).

H

HALLWACHS' EFFECT: another name for photoelectric fatigue. See "Photoelectricity," § (2).

HAMMERS, ELECTROMAGNETIC, for chiselling and riveting. See "Electromagnet," § (5).

HARMONIC ANALYSIS, by vibration galvanometers. See "Vibration Galvanometers," § (47).

HARTMANN-KÄMPF ALTERNATOR, for audio-frequency work. See "Inductance, The Measurement of," § (8).

HAY'S C.B. DUPLEX SYSTEM: a system of telegraphy employing a central battery, in which each circuit carries simultaneously a message in each direction. See "Telegraphy, Central Battery System of," § (3).

HEAT TREATMENT, application of, to test specimens used in magnetic work. See "Magnetic Measurements and Properties of Materials," § (19).

HEAT TREATMENT OF STEELS: procedure with small specimens for magnetic work.

See "Magnetic Measurements and Properties of Materials," § (54).

HEAVISIDE LAYER: a layer of ionised air in the upper atmosphere. Effect of, on electromagnetic waves, and hence on directional wireless telegraphy. See "Wireless Telegraphy Transmitting and Receiving Apparatus," § (13).

HEAVY CURRENTS, measurement of, at radio frequencies. See "Radio-frequency Measurements," § (20).

HEMATITE, magnetic properties of. See "Magnetic Measurements and Properties of Materials," § (73).

HENRY: the practical unit of inductance.

$$1 \text{ henry} = 10^9 \text{ centimetres.}$$

See "Inductance, The Measurement of," § (1).

HERTZ RADIATOR, THE: a device for producing electric waves. Frequency and damping of. See "Wireless Telegraphy," § (6).

HETERODYNE METHODS, use of, for the detection of continuous waves in wireless telegraphy. See "Wireless Telegraphy," § (25).

HETERODYNE WAVEMETERS, use of, in radiotelegraphic work. See "Radio-frequency Measurements," § (16).

HIBBERT MAGNETIC STANDARD: a standard of magnetic flux. See "Magnetic Measurements and Properties of Materials," § (3).

HIGH-FREQUENCY EXPERIMENTS, on the magnetic properties of iron. See "Magnetic Measurements and Properties of Materials," §§ (65), (66), and (67).

HISSING ARC. See "Arc Lamps," § (4).

HOLDEN'S PERMEABILITY BRIDGE. See "Magnetic Measurements and Properties of Materials," § (28).

HONDA AND OKUBO, theory of magnetism. See "Magnetism, Modern Theories of," § (1).

HOPKINSON BAR AND YOKE, use of, in magnetic testing. See "Magnetic Measurements and Properties of Materials," § (24).

HOT WIRE AMMETERS, use of, at radio frequencies. See "Radio-frequency Measurements," § (19).

HOYT-TAYLOR BALANCE: an arrangement of loop aerial and underground wire devised to balance out atmospherics. See "Wireless Telegraphy Transmitting and Receiving Apparatus," § (10).

HUGHES SYSTEM: a low-speed system of telegraphy in which the receiving instrument prints the message in roman type on a paper slip. See "Telegraphs, Type-printing," § (2).

HYDROGEN, ELECTROLYTIC PREPARATION OF. HYDROGEN GAS-MAKING. See "Electrolysis, Technical Applications of," § (29).

HYDROGEN ATOM, determination of mass of, given value of e. See "Electrons and the Discharge Tube," § (25).

Structure of. See *ibid.* § (28).

HYPOCHLORITES, ELECTROLYSIS OF: Kellner cell and Haas-Oettel cell. See "Electrolysis, Technical Applications of," § (25).

HYSTERESIS: the tendency shown by iron and steel to retain the magnetism which has been imparted to them by any magnetising force. See "Magnetic Hysteresis"; "Magnetic Measurements and Properties of Materials," § (1); also "Magnetic Hysteresis."

In the magnetic circuits of transformers. See "Electromagnet," § (6)

HYSTERESIS LOSS, determination of, from the hysteresis loop. See "Magnetic Measurements and Properties of Materials," § (22); also "Magnetic Hysteresis."

HYSTERESIS OF DIELECTRICS. See "Dielectrics," § (6) (ii.).

HYSTERETIC CONSTANT: a magnetic constant for each material, which is a measure of the loss of energy occurring in that material due to hysteresis. See "Electromagnet," § (6).

— I —

ILIOVICI PERMEAMETER. See "Magnetic Measurements and Properties of Materials," § (35).

IMPEDANCE. If a simple harmonic electromotive force of amplitude E and frequency p acts on a circuit of self-inductance L and resistance R, the current I is given by the equation

$$I = \frac{E}{\sqrt{R^2 + L^2p^2}} \sin\left(pt - \tan^{-1}\frac{Lp}{R}\right).$$

The quantity Lp is the reactance of the circuit and $\sqrt{R^2+L^2p^2}$ is the impedance. If the circuit has capacity C and no inductance the current is

$$\frac{E}{\sqrt{[R^2+(1/C^2p^2)]}} \sin\left(pt + \tan^{-1}\frac{1}{CRp}\right).$$

The reactance is then $1/Cp$, and the impedance

$$\sqrt{\left(R^2 + \frac{1}{C^2p^2}\right)}.$$

If there are both inductance and capacity

in the circuit the reactance is $Lp - (1/Cp)$, and the impedance

$$\sqrt{\left\{R^2 + \left(Lp - \frac{1}{Cp}\right)^2\right\}}.$$

See "Inductance, Measurement of," § (3).

Impedance Measurements, determination of capacity by means of. See "Capacity and its Measurement," § (38).

Impurities in Surrounding Gas, Effect of, on the thermionic emission from palladium. See "Thermionics," § (4) (iv.) (*b*).

On the thermionic emission from platinum. See *ibid.* § (4) (iv.) (*a*).

On the thermionic emission from tungsten. See *ibid.* § (4) (iv.) (*c*).

INCANDESCENCE LAMPS

§ (1) Historical.—The earliest work on incandescent filament lamps was carried out by various experimenters from as far back as 1841, when J. W. Starr, an American, carried out much experimental work and eventually took out patents for "a metallic or carbon conductor intensely heated by the passage of electricity for the purpose of illumination." These early stages in the evolution of the electric incandescent lamp were terminated in 1878 by the work of T. A. Edison and J. W. Swan, who, working independently, produced between 1878 and 1880 the first practical carbon filament lamps. Edison aimed at producing filaments from natural fibres of grasses or bamboo, whilst Swan developed the parchmentised cotton thread and eventually the squirted thread of cellulose, which was destined to become the universal process. The carbon filament lamps of the types developed by Edison and Swan, and improved by Sawyer's process of "flashing" in an atmosphere of hydrocarbon gas, held their own with but slight modifications for some twenty years, and it was not until 1904 that the General Electric Company of America produced the so-called metallised carbon filament lamp. Metallised or graphitised carbon filaments were produced by treatment of the ordinary filaments at a higher temperature. The result was a more refractory material which stood, without disintegration, a temperature which permitted the efficiency to be increased from 0·25 to approximately 0·3 average candle[1] per watt.

The Nernst lamp introduced about 1897 never really promised to attain popularity, in spite of the great amount of ingenuity expended in its development. Its overall efficiency approximated to that of the metallised carbon filament lamp. In 1898 the first of the practical metal filament lamps appeared in the form of the Osmium Lamp; to be followed in 1902 and 1903 by the Tantalum Lamp with an efficiency of approximately 0·45 candle per watt.

From 1904 the highly refractory properties of tungsten filaments began to be realised, and it became obvious that the future of the incandescent lamp for some time to come would be with the tungsten filament lamp. For several years no method was found of producing tungsten in the form of metallic wire, and all the earlier filaments were made by squirting threads of tungsten powder held together by a binder which had eventually to be eliminated, except in the case when colloidal tungsten was the binder. So perfect had this process become that when, in 1906 drawn tungsten wire was produced in the laboratories of the General Electric Company of America, it was only the greater convenience of manipulation during manufacture which commended this form of wire for practical adoption by lamp makers generally. The use of drawn tungsten wire is now almost universal, and the vacuum lamp has for a time settled down to a form which yields an efficiency of from 0·6 to 0·7 average candle per watt over sizes ranging from 20 to 200 watts and voltages up to 250. The fine filaments required for low-watt high-voltage lamps necessitate running at an efficiency which is some 15 per cent lower than for the larger watt low-voltage types.

§ (2) General.—The chief limiting factor in the improvement of tungsten filament lamps is not the melting-point of the tungsten but the temperature at which it disintegrates or volatilises. The melting-point of tungsten is in the neighbourhood of 3600° K., but the practical operating temperature in a vacuum is approximately 2300° K. If run at a higher temperature than this the volatilisation of the tungsten soon blackens the bulb and also increases the resistance of the filament itself. Filaments will burn for very short periods at temperatures which yield efficiencies of the order of three candles per watt, and if it were possible to prevent volatilisation, efficiencies of this order would undoubtedly be possible in practice. The apparent impossibility of achieving this result has led to the adoption of the device of surrounding the filament with an inert gas, the function of which is to suppress the tendency for the tungsten particles to leave the filament owing to their collision with the molecules of the gas. In such gas-filled or "half-watt" lamps the filament wire must be compressed into as small a space as possible so as to diminish the cooling effect of the gas. Even though the filaments are run at a temperature of 2800° K. this cooling effect renders the gain in efficiency relatively small in all but the larger sizes of lamps.

[1] The term "average candles" is synonymous with "mean spherical candles."

§ (3) The Tungsten Wire.—Tungsten wire is made from finely divided tungsten powder. The powder is made by two methods, according as wolframite or scheelite ore is employed.

Starting from wolframite, the ore is crushed to a coarse powder, mixed with soda-ash, and roasted in a reverberatory furnace at a temperature just high enough to keep the mass in a pasty condition. After cooling, the product is crushed, and the sodium tungstate leached out. The solution of sodium tungstate is heated to boiling, and calcium tungstate is precipitated by the addition of a solution of calcium chloride. After washing the calcium tungstate to remove all excess chlorides, it is decomposed with hot hydrochloric acid, the tungstic oxide is allowed to settle, the solution decanted off, and the oxide washed on a suction filter. The tungstic oxide so obtained is purified by dissolving in ammonia, evaporating the filtrate consisting of a solution of ammonia paratungstate to the consistency of a white mud, and decomposing the mud with nitric acid. The yellow tungstic oxide so obtained is washed with distilled water on suction filters, and dried.

If scheelite ore be employed, it is crushed and decomposed by heating with strong hydrochloric acid. The residue of tungstic acid is subjected to a second extraction with hydrochloric acid, and after washing in the usual way is taken up with ammonia and the resulting solution of ammonium tungstate decanted through a filter. The solution of ammonium tungstate is then run into hot hydrochloric acid when the tungstic acid is precipitated in a pure form. After washing with distilled water it is dried at 200°-300° C.

The oxide formed by either of these methods is fired in Battersea crucibles to about 1000° C. for several hours, crushed, and then reduced at a temperature of about 950° with hydrogen. The resulting metal is practically pure except for slight impurities which the oxide has taken up from the Battersea crucible during firing. These impurities have in the past been considered necessary to control grain growth in the filament during the life of the lamp.

If desired, a small percentage of thoria can be mixed with the tungsten oxide in order to produce the same effect as the impurities derived by firing in the Battersea crucible.

The powder so formed is weighed out into batches sufficient to make slugs of about $\frac{1}{4}$ inch square section and 6 inches long. These are formed by pressing the powder into dies under hydraulic pressure, after which they are sintered at a temperature of about 1100° C. The slugs are then brought up near to their melting-point by passing a current of about 1400 amperes through them in an atmosphere of hydrogen. During this process they contract, and the metal is given a definite crystalline structure. The slugs are then swaged at a temperature which may lie between 1600° and 2000° K. Swaging consists in passing the metal repeatedly between rapidly moving hard-steel machine-operated hammers in such a way that it becomes formed into a long wire of final diameter about 0·8 mm. In this condition it has considerable tensile strength, and a microscopic examination shows that the original crystals have become elongated in the direction of the length of the wire. The wire can now be drawn through diamond dies, provided it is heated at the point of passing through the dies. The smallest sizes of wire employed in practice are of the order of 0·02 mm. diameter. Wire so formed has physical properties which enable it to be easily handled. It has both high tensile strength and pliability, induced by the fibrous structure given to the wire in the drawing process. These properties are lost when the filament is heated in the lamps, due to a change in crystal structure known as equiaxing. The fibrous structure is no longer maintained but gives place to small equiaxed crystals which tend afterwards to grow at the temperatures of operation. The wire in this condition is brittle and fragile, the degree of which depends presumably on the ultimate size and shape of the grains and nature of the grain boundaries which may sometimes extend right across the filament. The condition of the filament after equiaxing has taken place is largely governed by the presence of small quantities of impurity in the metal. The function of these impurities is probably to act at the intercrystal boundaries, regulating the sizes of the crystals and preventing subsequent crystal growth.

The firm of Pintsch in Berlin produced in 1914–1916 a "single crystal" wire. A thread of sintered tungsten powder was passed slowly through a heater in which the temperature gradient was adjusted to give the most favourable conditions for crystal growth. A crystal commences to grow and, spreading across the whole cross-section of the wire, incorporates within itself each new grain which it approaches in its growth. If the rate of travel of the metal corresponds with the rate of crystal growth there results a wire which, being made up of one crystal, has within itself no crystal boundaries; hence, it is claimed, it is not subject to the disadvantage introduced by grain boundaries.

§ (4) Construction of Lamp.—The production of the mount for the filament, the winding of the filament, and the sealing in of the completed mount to the glass bulb are operations which call for much skill and organisation as processes of routine manufacture and glass working, but do not make any special demands on the physicist.

The production of satisfactory vacuum tight "sealing-in" wires has entailed in the past a large amount of experimental work. In the early days a short length of platinum wire was welded between two lengths of copper wire and sealed into the glass "pinch" or "press" in such a way that the platinum was buried in the glass and effectually stopped any leakage path there might be along the surface of the copper wires. It is commonly considered that platinum is the only possible metal to use for sealing into glass, because its coefficient of expansion is approximately the same as that of glass. The correct coefficient of expansion, however, does not seem to be the only quality requisite for a good sealing-in wire. The quality of "wetting" between the glass and the metal appears to be equally important, but the exact physical nature of this quality is not easy to define. Glasses vary in their coefficient of linear expansion from 8×10^{-6} to 10×10^{-6}, so that a satisfactory platinum substitute must therefore "wet" well and also have a coefficient of expansion similar to that of the glass for which it is intended. There are two common substitutes, in both of which nickel steel forms the core, because the coefficient of expansion of this alloy can be adjusted by varying the nickel content. In the one a nickel steel rod of suitable coefficient of expansion is coated with copper, after which a thin sheath of platinum is drawn over. The whole is taken up to the melting-point of copper, which causes the coating between the platinum and the steel to make a tight joint with both, and permits the rod to be drawn down in dies like ordinary wire. Short lengths of this are used as described above. The saving of platinum by this process is considerable, being about two-thirds. In the other platinum substitute, the nickel steel wire with copper coating is used without any platinum, but the proper "wetting" action is achieved by a coating of borax on the surface of the copper. Such wire can be employed without any joints and has come into very wide use.

§ (5) Evacuation.—Evacuation is one of the chief problems in electric lamp manufacture. The vacuum in a tungsten lamp should be of the order of 0·0001 mm. If the pressure is as high as 0·005 mm., but below about 1 mm., space currents will pass sufficient for the resulting discharge within the bulb to destroy the lamp. It has also to be remembered that a lamp must not only start with a high vacuum but must retain it throughout its life. The presence of any trace of water vapour cannot be tolerated, as it acts as a catalyst, becoming dissociated at the high temperatures and oxidising the filament, whereupon the tungsten oxide becomes reduced again with the formation of water vapour and the process repeats itself, thus leading to a transference of tungsten from the filament to the glass walls of the bulb. To ensure a permanent vacuum, all possible occluded gas must be removed from the glass before the lamp is removed from the pumps. The glass forms the main reservoir of gas, there being too small a volume of metal present to add much to the total occluded quantity. The gas is partially removed from the glass by heating the lamps to a temperature approximating 400° C. during evacuation. Sometimes the filaments are also glowed during evacuation so as to render all internal parts as hot as possible before the lamps are sealed off from the pumps. The really high vacua achieved in modern lamps are secured automatically by the use of phosphorus within the bulb. This material has the property, in the presence of an electric discharge, of being capable of "cleaning up" a considerable quantity of residual gas. Other materials also have a similar action, but phosphorus is one of the most reliable in this respect. The mechanism of this action is not altogether clear and certain phases of it are quite obscure. The use of such an agent, however, has the practical result that much of the work of producing a high vacuum may be left to its action, and that it is only necessary to ensure, when exhausting lamps, that more gas is not left in the bulb and occluded on the walls than the phosphorus is capable of dealing with.

§ (6) The Gas-filled Lamp.—The filaments of gas-filled lamps are coiled into close spirals so that conduction of heat through the gas and convection by it may be a minimum. In order to obtain the requisite candle-power it is necessary to have a certain area of incandescent metal free to radiate into space, but owing to the presence of gas this area should be located within as small a volume as possible. Other limiting factors, however, come in to prevent the achievement of the ideal arrangement. Firstly, the diameter of wire which is necessary for commercial voltages can only be made up into spirals of a certain size, otherwise they will sag and open out at the temperatures at which they must operate. Secondly, the very high temperature conditions prevailing in the gas immediately surrounding the incandescent wire reduce its electrical resistance, which increases the tendency for an electrical discharge to take place. If this transpires, the lamp is quickly destroyed and sufficient gas clearance is thus essential between the points of highest potential difference.

The two principal inert gases employed are nitrogen and argon; both these gases fulfil to a fair extent the conditions necessary to make an efficient lamp. These conditions are: (1) That the gas should be inactive, *i.e.* it

should have no action on the filament. (2) That the thermal conductivity, specific heat, and density of the gas should be as low as possible. (3) That the gas should not dissociate when raised to the temperature of the filament, thus causing loss of heat of the filament by the heat absorbed on decomposition. (4) That the gas should be of such a nature that the tendency for an electrical discharge to take place should be a minimum.

Nitrogen, which is the cheaper of the two, has a slight action on the filament, forming a nitride of tungsten; this action is only noticeable in types of lamps having a thin filament, when also its higher conductivity is more marked. In these lamps argon is used to good advantage, but it conducts the electricity more easily, and if used quite pure a discharge tends to take place. To prevent this a few per cent of nitrogen are added.

§ (7) Physical Characteristics of Lamps.—The governing factor in the design, production, and operation of incandescent filament lamps is the relatively large changes in the characteristics of a lamp which are produced by a small change in filament temperature, combined with the sensitiveness of that temperature to changes in the electrical input to the lamp, or the dimensions of the filament. Consider, for instance, a standard vacuum lamp with an efficiency of 0·8 average candle per watt (1·25 watts per M.S.C.P.). The true filament temperature will be approximately 2275° K.

A 1 per cent increase in volts or a 2 per cent increase in filament diameter will produce a change of approximately 3·6 per cent in candle power, 2 per cent in efficiency, and 14 per cent in life.

The following table is useful as showing how a 1 per cent change in electrical input or in filament dimensions affects the performance of a lamp as regards candle power, efficiency, and approximate life:

Vacuum Lamp—Tungsten Filament, Approximate Temperature 2300° K. Rate of Variation of Performance with Change of Electrical Input and Filament Dimensions.

	Filament Temperature.	Candle Power.	Candles per Watt.	Approximate Life.
	per cent.	per cent.	per cent.	per cent.
For constant filament size:				
1 per cent increase in volts	+0·34	+3·6	+2·1	−14
1 per cent increase in amps. . . .	+0·55	+5·9	+3·3	−22
1 per cent increase in watts . . .	+0·21	+2·2	+1·3	− 8_5
At constant volts:				
1 per cent increase in filament diameter .	+0·17	+1·8	+1·0	− 7
1 per cent increase in filament length .	−0·33	−3·5	−2·0	$+13_5$

The figures in this table show that individual incandescent lamps, although given the standard rating, must necessarily be liable to vary somewhat from the ideal lamp which the manufacturer sets out to make. Lamps as made tend to group themselves round that ideal, but it is necessary to settle certain limits within which it is reasonable to require any lamp to fall which purports to comply with the rating. Diagrams showing these limits have candle power plotted as

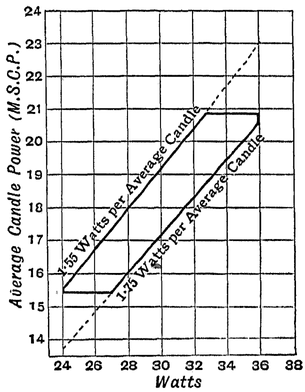


Fig. 1.

ordinates and watts as abscissae. Every lamp having a definite efficiency will lie on a straight line which runs diagonally across the diagram. As it is usual in commerce to rate incandescent lamps in watts per candle rather than in candles per watt, these lines run from the lower left-hand part of the diagram to the upper right-hand side. A limit (or target) diagram prescribed by the British Engineering Standards Association for 220-volt 30-watt vacuum lamps is shown in *Fig.* 1.

It will be seen by the proximity of the diagonal boundaries that the narrowest limits are placed upon watts per candle. The temperature of the filament corresponds closely with the watts per candle, and as life is largely a function of filament temperature the effect of narrowing the limits of watts per candle is to secure lamps which are relatively uniform as regards life. By life is here meant both maintenance of candle power and avoidance of filament breakage. The testing of the life of incandescent lamps re-

quires the greatest care if trustworthy results are desired. The life of a lamp varies roughly as the sixth power of the watts per candle. As the watts per candle vary inversely as about the square of the voltage, the life will be seen to be very sensitive to voltage adjustments and variations. Furthermore, even over the narrow range of watts per candle permitted within the limits of the diagram there will be a variation of life of about ± 40 per cent. It is thus clear that a criterion as to the life quality of any batch of lamps can only be obtained by adjusting the voltages of the individual life test lamps to values which will bring them exactly to the standard or rated efficiency (*i.e.* to a uniform filament temperature).

§ (8) Filament Temperatures.—The determination of the true efficiency of a lamp entails the measurement of its average candle power and its watts. A direct measure of efficiency may be secured by the measurement of filament temperature, using a Lummer Brodhun contrast photometer. The hue of the illuminated field in such a photometer changes according to the temperature of the tungsten filament which is illuminating it, and by using a suitable certified colour identity standard a simple filament temperature gauge is obtained, employing only the photometric apparatus commonly found in a works photometric laboratory. Such an arrangement is of special use when the temperature of gas-filled lamp filaments is to be estimated, because with such lamps there are other agencies besides radiation for removal of heat energy from the filament, so that watts per candle are no longer an accurate measure of filament temperature. Ordinary optical pyrometry at these temperatures is not a very exact art, partly owing to the differences in the quality of the radiation coming from different points on the filament convolutions.

Indicating Instruments. Instruments in which the value of the quantity measured is deduced from the deflection of a moving part, against the force of gravity or of a spring. See "Alternating Current Instruments," § (7).

Inductance:

Campbell Standard of Mutual: an absolute standard of mutual inductance which is constructed so that an accurate knowledge of the dimensions of the coils is not required. A coil of square winding section is placed coaxial with and midway between two cylindrical helices which are connected in series and whose dimensions may be determined with high precision. The mean diameter of the coil is arranged so that the mutual inductance between it and the two helices has a maximum value. See "Inductance, Calculation of Coefficients of (Mutual and Self)," § (3).

INDUCTANCE (MUTUAL AND SELF), CALCULATION OF COEFFICIENTS OF, WITH FORMULAE AND TABLES

The calculation of the mutual inductance between two coils from their linear dimensions is of primary importance in the absolute determination of the ohm and the ampere, and consequently the development of suitable formulae for this purpose has received much

attention. A very complete collection of the formulae which have proved useful has been made by Rosa and Grover of the U.S. Bureau of Standards and published by them in Circulars S. 169 and S. 320. The footnotes of these circulars also constitute a complete bibliography of the subject.

The mathematical methods employed are treated in detail in Gray's *Absolute Measurement in Electricity and Magnetism.*

§ (1) Fundamental Formula.—The mutual inductance between two circuits A and B is measured by the magnetic flux threading B when unit current flows round A. The obvious method of calculation is, therefore, to divide the contour of A into line elements; then, using the well-known formula for the field due to a current element, to calculate the flux through B for each element by surface integration over B, and finally to obtain the total flux through B by contour integration round A. However, by making use of Stokes' theorem, the surface integral over B may be converted into a contour integral round B, and therefore the mutual inductance may be obtained by double contour integration [1] round A and B.

Thus the field H at a point r, ϕ due to a current element Idl is $Idl \sin \phi/r^2$ directed normally to the plane r, Idl, and such that I, r, H form a right-handed system. Now H is the curl of a vector G of magnitude Idl/r parallel to the current element Idl, so that by Stokes' theorem the surface integral of H over any surface is equal to the contour integral of G round that surface. Hence if dl, dl' are line elements of A and B respectively, the mutual inductance between A and B is given by

$$\int dl \int dl' \frac{\cos \theta}{r}, \quad . \quad . \quad . \quad (1)$$

in which θ is the angle between dl and dl' and the integrations are round the contours of A and B.

The above expression is known as Neumann's formula.

§ (2) Coaxial Circles. (i.) *Maxwell's Formula.*—The mutual inductance between two coaxial circles is readily derived from Neumann's formula.

If A, a are the radii of the two circles, and b the distance between their planes, the distance between two elements which are inclined at an angle θ is

$$r = \sqrt{A^2 + a^2 + b^2 - 2Aa \cos \theta},$$

and since $dl = A d\theta$ the mutual inductance M is given by

$$M = 2\pi A a \int_0^{2\pi} \frac{\cos \theta d\theta}{\sqrt{A^2 + a^2 + b^2 - 2Aa \cos \theta}},$$

which by the substitution $\theta = \pi - 2\psi$ yields

$$M = 4\pi \sqrt{Aa} \left\{ \left(\frac{2}{k} - k \right) K - \frac{2}{k} . E \right\}, \quad . \quad (2)$$

[1] See also "Electromagnetic Theory," § (4).

in which

$$K = \int_0^{\frac{\pi}{2}} \frac{d\psi}{(1 - k^2 \sin^2 \psi)^{\frac{1}{2}}}, \quad E = \int_0^{\frac{\pi}{2}} (1 - k^2 \sin^2 \psi)^{\frac{1}{2}} d\psi,$$

and

$$k^2 = \frac{4Aa}{(A + a)^2 + b^2}.$$

Now K and E are complete elliptic integrals of the first and second kinds respectively and have been tabulated in terms of the angle $\phi = \sin^{-1} k$ by Legendre. Moreover, Maxwell, to whom the above formulae is due,[2] has computed a table of values of $\log (M/4\pi \sqrt{Aa})$ for values of ϕ ranging from 60° to 90°. By means of this table it is possible to obtain M to seven-figure accuracy, if the value of ϕ falls within the above limits. Table I. on the two following pages may be used if an accuracy of 1 in 1000 is all that is required.

(ii.) *Other Formulae.*—By suitable manipulation of formula (2) a large number of alternative formulae may be obtained. These formulae have a twofold use. Some may be used for computation in cases where formula (2) ceases to be accurate, while others form starting-points for the derivation of formulae for more complex cases. Thus by applying Landen's transformation to (2) Maxwell obtained the formula

$$M = 8\pi \sqrt{Aa/k_1}(K_1 - E_1), \quad . \quad . \quad (3)$$

in which K_1, E_1 are complete elliptic integrals to modulus k_1, and $k_1 = (1 - k')/(1 + k')$, $k'^2 = 1 - k^2$. This formula is more accurate than (2) when ϕ is nearly 90°.

Again, by differentiation of (2) it may be shown that M satisfies the equation

$$k^2(1 - k^2)\frac{d^2M}{dk^2} - k(1 + k^2)\frac{dM}{dk} - 3M = 0,$$

and by appropriate changes of the independent variable five series formulae for M may be obtained from this equation, two converging most rapidly for circles far apart and three for circles close together.[3] Certain of these formulae may be employed so as to obtain the mutual inductance between coaxial cylinders, or again for determining the mutual inductance between eccentric parallel circles. The method employed in this latter case is based on the fact that as one of the circles moves from its concentric position the value of the mutual inductance varies as a potential function of the position of the centre of the moving circle.[4]

Finally, Nagaoka [5] has made use of Jacobi's q-series to develop from (2) three formulae of wide range and remarkable convergency.

TABLE I

Mutual Inductance between Coaxial Circles

The table gives the values of log $M/\sqrt{Aa}$ for various values of the variable $\sigma^2=\dfrac{(A-a)^2+b^2}{(A+a)^2+b^2}$, where A, a are the radii of the circles and b their distance apart.

§ (3) Uniform Cylindrical Helix and Coaxial Circle.—The use of coils approximating to coaxial circles is not advisable in the construction of absolute standards of mutual inductance on account of the difficulty of measuring their dimensions with sufficient precision.

However, by placing a coil of square winding section coaxial with and midway between two cylindrical helices which are connected in series, and arranging the mean diameter of the coil so that the mutual inductance between it and the two helices has a maximum value, an accurate knowledge of the dimensions of the coil is no longer necessary. Moreover, the dimensions of the helices may be determined with high precision. This is the system adopted in the standard of mutual inductance constructed by Campbell, to whom the above principle is due.[1] Use has been made of the same principle in proportioning the coils and discs of the Lorenz apparatus at the National Physical Laboratory.[2]

Accurate and rapid methods for calculating the mutual inductance between a helix and coaxial circle are therefore of the first importance.

An exact (elliptic integral) formula for the case in which the circle is an end plane of the helix was obtained by J. Viriamu Jones [3] by integration from Neumann's formula (1). Greenhill[4] has shown that the same formula may be obtained more simply from Maxwell's formula (2) for the mutual inductance between coaxial circles.

Jones's formula is as follows :

$$M=\Theta(A+a)ck\left\{\frac{K-E}{k^2}+\frac{1-c^2}{c^2}(K-\Pi)\right\}, \quad (4)$$

in which Θ = angular length of helix,

A = radius of helix,

a = radius of circle,

d = axial length of helix,

$c^2=4Aa/(A+a)^2$,

$k^2=4Aa/\{(A+a)^2+d^2\}$.

K, E, Π are complete elliptic integrals of the first, second, and third kinds respectively, K and E to modulus k, and

$$\Pi=\int_0^{\frac{\pi}{2}}\frac{d\psi}{(1-c^2\sin^2\psi)(1-k^2\sin^2\psi)^{\frac{1}{2}}},$$

which may be expressed in terms of tabulated functions.

If the radius of the circle is equal to that of the helix, $c=1$ so that (4) reduces to the simpler form

$$M=2\Theta A(K-E)/k. \quad . \quad . \quad (5)$$

Numerical computation from Jones's formula is naturally very laborious, while if the simplified form (5) is adopted, Campbell's principle can no longer be utilised.

Another formula for the case treated by Jones is a series formula due to Rosa.[5] When the helix is not too short this is simpler for computation than (4), but its slow convergency in the case of short helices involves great arithmetical labour if the utmost accuracy is desired. If the circle is not in the end plane of the helix the case may be treated by the method of differences, but here again when the helix is short precision is difficult to obtain.

In these cases it is perhaps better to adopt some method of approximate integration. It may be shown that so far as its mutual inductance on a coaxial circle is concerned, a helix may be replaced by a current sheet having the same number of turns. The calculation then consists in dividing the cylinder into circular filaments and integrating along the axis. If an accurate table of mutual inductances between circles is available the integration may be carried out numerically, say by the method of equidistant ordinates. The following method is, however, to be preferred, as it requires fewer circles than the equidistant ordinate method for the same degree of accuracy.

Replace the current sheet by two or more equivalent circles (of the same radius as the current sheet) situated at the positions indicated in column 2 of the table. Distribute the total turns (N) among the circles as in column 3, and calculate the mutual inductances of these circles on the given circle. Their sum then gives the approximate mutual inductances of the helix on the circle, the accuracy of course increasing as the number of replacing circles increases.

$2t$ = axial length of Helix.

No. of Replacing Circles.	Displacement of Circles from Mean Plane of Helix.	Turns associated with Replacing Circle.
2	$\pm t/\sqrt{3}$	N/2
3	$\pm\sqrt{3/5}t$	5N/18
	0	8N/18
4	$\pm 0{\cdot}86113632t$	0·17392742N
	$\pm 0{\cdot}33998104t$	0·32607258N
	0	0.284444444N
5	$\pm 0{\cdot}906179846t$	0·118463442N
	$\pm 0{\cdot}538469320t$	0·239314335N

[1] *Proc. Roy. Soc.*, 1907, lxxix. 428.
[2] F. E. Smith, *Roy. Soc. Phil. Trans.*, A., 1914, ccxiv. 27.
[3] *Roy. Soc. Proc.*, 1898, lxiii. 198.
[4] *Roy. Soc. Phil. Trans.*, 1919, ccxx. 35.
[5] *Bureau of Standards Bulletin*, 1907, iii. 209.

That the above method is capable of yielding results of great accuracy is shown by the following examples:

A.	a.	$2t$.	Distance of Circle from Mean Plane of Helix.	N.	M.	Method.
16	10	16	16	160	6900·15 6901·0 6900·3 6900·14_9	Jones 3 Circles 6 Circles (3+3) 10 Circles (5+5)
14·5	10	5	7·5	100	9175·9 9175·9_4	Jones 5 Circles

The dimensions in the first example are approximately those of the Ayrton-Jones current balance, and in the second those of the Campbell Standard of Mutual Inductance.

§ (4) Short Coaxial Cylinders.—The above method of replacement by equivalent circles may also be applied to determine the mutual inductance between two short cylindrical coils. For ordinary purposes only two, or at most three, circles are required. Thus in the case where three circles are used, if the circles replacing the first coil are denoted by A, B, C, and those replacing the second coil by a, b, c, the mutual inductance between the coils is given by

$$\frac{N_1N_2}{384}\Big\{25(M_{Aa}+M_{Cc}+M_{Ac}+M_{Ca}) + 40(M_{Ab}+M_{Ba}+M_{Bc}+M_{Cb})+64M_{Bb}\Big\},$$

N_1, N_2 being the total turns in either coil.

§ (5) Long Cylinder and Internal Concentric Coaxial Short Cylinder.—This case has some importance, as it is the form often employed in the construction of the standard field used in the calibration of ballistic galvanometers.

Let the dimensions of the long cylinder be as follows: Length $= 2x$, radius $=$ A, number of turns $= N_1$. For the short cylinder, length $= 2l$, radius $= a$, number of turns $= N_2$.

Then as a first approximation the mutual inductance is given by multiplying the field at the centre of the long coil by the product of the number of turns into the area of the short coil. This gives

$$M_0 = 2\pi^2 N_1 N_2 a^2/d,$$

in which $d^2 = A^2 + x^2$.

This must be modified by two corrections:

(a) For the radial variation of the field,
(b) For the axial variation of the field.

When the correction (a) is applied we obtain the mutual inductance if the length l is negligible, and correction (b) takes into account the length of the short coils. Correction (a) is obtained by a simple application of Rosa's circle-cylinder formula already referred to. Using three terms of Rosa's series, M_0 must be multiplied by

$$1+\tfrac{3}{8}\frac{A^2a^2}{d^4}+\tfrac{5}{64}\frac{A^4a^4}{d^8}\Big(3-4\frac{x^2}{A^2}\Big).$$

Correction (b) is obtained by replacing the short coil by three equivalent circles. The mutual inductance between the long coil and either of the two outer circles is less than that between the long coil and central circle because of the diminution in the axial field as we proceed from the mid-point of the long coil. The diminution may be calculated with the help of a table of mutual inductance between coaxial circles; for the effect is as if an annulus of width $\sqrt{3/5}\,.\,l$ were transferred from one end of the long coil to the other. The method gives for correction (b)

$$-\tfrac{5}{9}\sqrt{\tfrac{3}{5}}\,.\,\frac{l}{x}N_1N_2\{m(x-\tfrac{1}{2}\sqrt{\tfrac{3}{5}}l)-m(x+\tfrac{1}{2}\sqrt{\tfrac{3}{5}}l)\},$$

in which the notation $m(d)$ indicates the mutual inductance between two circles of radii A and a at distance d.

In illustration of this method let $A=5$, $a=4$, $2x=30$, $2l=5$, $N_1=300$, $N_2=200$.

The first approximation gives

$$M_0 = 1{\cdot}19848 \text{ millihenries.}$$

After applying correction (a)—

$$M_1 = 1{\cdot}20123 \text{ millihenries.}$$

After applying correction (b)—

$$M = 1{\cdot}19990 \text{ millihenries.}$$

Complicated series formulae for this case have been given by Roiti,[1] Searle and Airey,[2] and Russell,[3] and the above example has been treated by Rosa using each of the above series. He finds by Roiti's formula

$$M = 1{\cdot}1998950,$$

by Searle and Airey's formula

$$M = 1{\cdot}1998957,$$

by Russell's formula

$$M = 1{\cdot}19989.$$

Rosa states that the convergence is most satisfactory in the case of Searle and Airey's formula.

It is important to notice the balancing effect of the radial and axial corrections. In fact Gray [4] shows that if the ratio of length to

[1] *Bureau of Standards Bulletin*, iii. 309.
[2] *Electrician*, 1905, lvi. 318.
[3] *Phil. Mag.*, 1907, xiii. 420.
[4] *Absolute Measurements*, ii. Part I. 274.

radius in either coil is $\sqrt{3}$ to 1 and a/A is small, the two corrections cancel each other and the simple form M_0 is sufficient.

The case when the short coil is external to the long coil is obtained by interchanging A and a in the above method.

§ (6) SELF INDUCTANCE OF CIRCULAR COILS.—The self inductance of circular coils of various sections may be obtained by integration, treating the problem as one for the mutual inductance between two coincident coils. The more important results obtained by this method are as follows :

(i.) *Circular Section.*[1]—

$$L=4\pi N^2a\left\{\left(1+\frac{\rho^2}{8a^2}\right)\log_e 8a/\rho+\rho^2/24a^2-1\cdot 75\right\}, \quad (6)$$

in which a is the radius of the coil, ρ that of the section, and N is the total number of turns. When N=1, this gives the self inductance of a ring of circular wire when the current is uniformly distributed over the section. It is thus only suitable for steady or low frequency alternating currents. In the case of very high frequency currents the current distributes itself only on the skin of the conductor, and the appropriate formula in this case [2] is

$$L=4\pi a\left\{\left(1-\frac{\rho^2}{4a^2}\right)\log_e 8a/\rho-2\right\}. \quad (7)$$

(ii.) *Single layer cylindrical coil of N turns.*[3]—

$$L=\tfrac{8}{3}\cdot\frac{\pi N^2a^3}{b^2k^3}\left\{(1-k^2)K-(1-2k^2)E-k^3\right\}, \quad (8)$$

in which a is the coil radius, b the coil length, $k^2=4a^2/(4a^2+b^2)$. K and E are complete elliptic integrals of the first and second kind with k as modulus.

Eight series formulae may be developed from the above exact formula[4] one or the other of which is suitable for any ratio of a to b. For practical purposes it is useful to write

$$L=N^2aQ, \quad (9)$$

and to tabulate Q as a function of a/b. See Table II.

(iii.) *Single-layer flat coil of* n *turns per centimetre inner radius* r, *outer radius R.*—Spielrein[5] has developed two formulae suitable for this case which will cover all possible values of r/R. Computation is facilitated by writing

$$L=n^2R^3Q', \quad (10)$$

in which Q' is a tabulated function of r/R. See Table III.

L = self inductance of coil.
n = turns per unit length.
R = outer radius of coil.
r = inner radius of coil.

(iv.) *Rectangular Section.*—This case has been treated by Weinstein,[6] Stefan[7] and Lyle.[8]

Lyle's formula is the most accurate one and is as follows :

$$L=4\pi aN^2\left\{\left(1+m_1\frac{d^2}{a^2}+m_2\cdot\frac{d^4}{a^4}+m_3\frac{d^6}{a^6}\right)\log_e\frac{8a}{d}-l_0+l_1\frac{d^2}{a^2}+l_2\frac{d^4}{a^4}+l_3\frac{d^6}{a^6}\right\}, \quad (11)$$

in which a is the mean radius of the coil,
N the number of turns,
$d^2=b^2+c^2$ where
b = the axial width of the coil,
c = the radial depth of the coil,

and m_1, m_2, m_3, l_0, l_1, l_2, l_3 are functions of b/c, which are given in Tables IV. and V. on following page:

1·10	2·182315	·3839	−5·28	·8472152	2·399492	−1·3062	+6·86	1·10

This formula fails when d/a becomes large. For long coils ($b/a>4$) the following formula [1] will give an accuracy of 1 in 10,000:

$$L=L_0\left(1-\alpha\frac{b}{R}+\beta\frac{b^2}{R^2}-\gamma\frac{b^4}{R^4}\right), \quad . \quad (12)$$

in which

$$L_0=\tfrac{2}{3}\pi^2\frac{R^2}{b}\left(1+2\frac{r}{R}+3\frac{r^2}{R}\right)N^2.$$

N is the total number of turns,
b is the coil length,
r the inner radius,
R the outer radius,

and α, β, γ are functions of r/R given in Table VI.

TABLE VI

Coefficients α, β, γ in Formula (12)

$\frac{r}{R}$.	α.	β.	γ.
0·0	0·73238	0·33333	0·0953
0·2	0·73699	0·33719	0·0973
0·4	0·75574	0·35579	0·1071
0·6	0·78447	0·39042	0·1306
0·8	0·81718	0·43906	0·1701
1·0	0·84883	0·50000	0·2306

In the intermediate region for which neither of the above two formulae apply, reference should be made to the method of Rosa.[2] It should also be noted that the current is assumed to be distributed uniformly over the rectangular section, *i.e.* the coil is supposed wound with square wire of negligible insulation space. A correction is therefore required when using circular wire. The method of obtaining this correction is given by Maxwell,[3] and involves the use of tables (for which see Rosa, *loc. cit.* p. 140).

§ (7) RECTILINEAR CIRCUITS.—The mutual inductance between rectilinear circuits of thin wire may be calculated from Neumann's formula (1), and usually only elementary integrations are involved. The simplest and most important case is that of two parallel filaments of length l and separation d. The mutual inductance for this case is

$$M=2\left(l\ \log_e\frac{l+\sqrt{l^2+d^2}}{d}-\sqrt{l^2+d^2}+d\right). \ (13)$$

In many cases d/l is small, and then

$$M=2l\left(\log_e\frac{l}{d}-1\right) \text{ approximately.} \quad (14)$$

Formula (14) may be applied to determine the self inductance of long straight conductors of various sections by integration over the section of the conductors. The result is the same as if the conductor were replaced by two equivalent filaments at distance apart D such that

$$\log_e D=\lim_{n\to\infty}\frac{1}{n}\Sigma\log_e d,$$

in which the summation is between every possible pair of elementary filaments in the section.

D is called the "geometric mean distance" (G.M.D.) of the section.

When D is known the self inductance of the conductor in question is given by

$$L=2l\left(\log_e\frac{l}{D}-1\right). \quad . \quad . \quad (15)$$

The same method will apply to the mutual inductance between two parallel conducting bars provided the current distribution is uniform. For the details of calculation of geometric mean distances reference should be made to Maxwell's *Electricity and Magnetism* (vol. ii. §§ 691-693), and to a paper by Rosa (*Bureau of Standards Bulletin,* 1907, iv. 325).[4]

The more important geometrical mean distances are given below.

(A) For self inductances.

(1) Rectangular area ($a\times b$) from itself:

$$\log_e D=\log_e\sqrt{a^2+b^2}-\tfrac{1}{6}\frac{a^2}{b^2}\log_e\sqrt{1+\frac{b^2}{a^2}}-\tfrac{1}{6}\frac{b^2}{a^2}$$
$$\log_e\sqrt{1+\frac{a^2}{b^2}}+\tfrac{2}{3}\frac{a}{b}\tan^{-1}\frac{b}{a}+\tfrac{2}{3}\frac{b}{a}\tan^{-1}\frac{a}{b}-\tfrac{25}{12}.$$

If $b=0$, the above reduces to

$$D=0{\cdot}22313a.$$

If $b=a$,

$$D=0{\cdot}22352(2a),$$

while for any values of a and b, if we write

$$D=0{\cdot}2235(a+b),$$

the error is always less than 2 in 1000.

(2) Circular area of radius a:

$$D=ae^{-\frac{1}{4}}=0{\cdot}7788a.$$

(3) Annular area, external radius a_1, internal radius a_2.

The exact formula is

$$\log_e D=\log a_1-\log x/(x^2-1)^2+(3-x^2)/4(x^2-1),$$

in which $x=a_1/a_2$.

Computation is, however, simplified by expanding in powers of $(x-1)/x$ ($=t$ say).

Then

$$\log_e D=\log_e a_1-t/3+t^3/30+t^4/40+\ldots$$

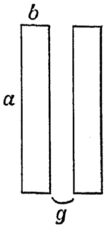
(B) For mutual inductances between parallel bars.

[1] Butterworth, *Phil. Mag.*, 1915, xxix. 591.
[2] *Bureau of Standards Bulletin*, 1912, viii. 138.
[3] *Elect. and Mag.* ii. § 693.

[4] See also a paper by Silsbee (*Bureau of Standards Scientific Paper*, No. 281, 1916, p. 375).

(1) Two circles whose centres are at a distance d apart:

$$D=d.$$



(2) Two rectangular bars (each $a \times b$) separated by insulation of width g perpendicular to the side a. The general formula is very complicated, but in the important case where b/a and g/a are small and the bars form a go and return circuit of length l, the total self inductance is given by

$$L=4l\left\{\frac{\pi}{3}(3\beta-\delta)-\tfrac{25}{12}\beta^2-\tfrac{1}{12}\beta^4-\tfrac{1}{12}\beta^2\delta^2\right.$$
$$\left.+\frac{1}{12\delta^2}(\alpha^4\log\alpha-2\beta^4\log\beta+\gamma^4\log\gamma-2\delta^4\log\delta)\right\},$$

in which

$$\alpha=(2b+g)/a,\ \beta=(b+g)/a,\ \gamma=g/a,\ \delta=b/a.$$

(3) Circular annular area and internal area of *any* shape.

If a_1, a_2 are the external and internal radii of the enveloping annulus,

$$\log D=\frac{a_1{}^2\log_e a_1-a_2{}^2\log_e a_2}{a_1{}^2-a_2{}^2}-\tfrac{1}{2}$$
$$=\log_e a_1-t/2-t^2/12+t^4/60\ \ldots$$

in which $t=(a_1-a_2)/a_1$.

S. B.

INDUCTANCE, THE MEASUREMENT OF

I. Introductory

§ (1) Self and Mutual Inductance.—The effects of inductance (whether mutual or self) only occur when the current is varied, this being expressed mathematically in the equations

$$e_1=L\frac{di_1}{dt}\text{ and }e_2=M\frac{di_1}{dt},$$

where e_1 and e_2 are the voltages induced (at any moment) in a primary and secondary circuit respectively by variation of i_1, the current in the primary, L being the self inductance of the primary, and M the mutual inductance between primary and secondary. In most practical work the unit in which L and M are expressed is the *henry*. With an inductance of 1 henry the induced voltage is 1 volt when the current is changing at the rate of 1 ampere per second.

With an ironless circuit possessing self inductance, the current produces a magnetic field whose lines interlink the circuit, 1 henry giving 10^8 line-turns per ampere of current, and similarly for the flux-turns in a secondary circuit when mutual inductance is present. Thus if a current i produces a flux Φ in a circuit of N turns, we may usually write

$$L=10^{-8}N\Phi\text{ henries},$$

remembering, however, that if ferromagnetic material is present the conditions are more complicated. In what follows we shall in general express all inductances in henries and the convenient submultiples, millihenries (mH or mhen) and microhenries (μH or μhen). To convert to absolute units the relation is

$$1\text{ henry}=10^9\text{ abhenries},$$

an abhenry being the absolute electromagnetic C.G.S. unit of inductance. As the dimensions of inductance (when expressed in the electromagnetic system) are merely length, 1 abhenry is sometimes written as 1 cm.; in this notation

$$1\text{ microhenry}=1000\text{ cm.}$$

§ (2) Effective Resistance and Inductance.—If a direct current I passing through a circuit dissipates power of the amount RI^2, then R is called the *resistance* of the circuit. If, however, the current is an alternating one of effective value I, and if the circuit contains inductive coils with iron cores, condensers with absorptive dielectrics, vibrators, or other apparatus which consume alternating power, then in general more power will be dissipated by the alternating current than by the direct. If the alternating current I spends $R'I^2$ watts, R' is called the *effective resistance* of the circuit. Usually it varies with the frequency of the alternating current, sometimes also with the value of the current (*e.g.* when magnetic hysteresis is present). Sometimes the direct current resistance is called the ohmic resistance, but a more suitable name is much to be desired.

The apparent self inductance of a coil as measured at its terminals is altered if iron or closed secondary circuits are brought near it, and the term *effective self inductance* is convenient to describe the modified value.

§ (3) Impedance and Reactance.—In a circuit of resistance R and self inductance L, let

v be the instantaneous terminal voltage,
i the instantaneous current,
V and I being the corresponding effective values.

Also let the *pulsatance* $\omega=2\pi n$, where n is the frequency, and let $j=\sqrt{-1}$.

Then in symbolic notation

$$z=v/i=R+Lj\omega,\quad .\quad .\quad .\quad (1)$$

where z may be called the symbolic or vectorial *impedance*. Taking effective (or square root of mean square) values, we have

$$Z^2=V^2/I^2=R^2+L^2\omega^2.\quad .\quad .\quad .\quad (2)$$

Z is called the *impedance*, and $L\omega$ the *reactance* of the circuit; the reciprocal of the reactance is called the *admittance*. If there

is series *capacitance* K also in the circuit, instead of equation (1) we have

$$z = R + \left(Lj\omega - \frac{1}{Kj\omega}\right) . \quad . \quad . \quad (3)$$

and $$Z = R^2 + \left(L - \frac{1}{K\omega^2}\right)^2 \omega^2. \quad . \quad . \quad (4)$$

The total reactance is now $\left(L\omega - \frac{1}{K\omega}\right)$. It will be noticed that a series condenser of capacitance K is equivalent to a negative self inductance of value $1/K\omega^2$. This equivalence furnishes us with a very useful practical device, by which any method of measurement involving self inductances may give a corresponding method involving one or more condensers instead. It is only necessary to write the equivalent $1/K\omega^2$ for each L to be changed in the original equations and then to examine the new equations to see that they are not practically impossible. For example, they must not require negative values of resistance—a condition which at once makes a method impossible.

When $LK\omega^2 = 1$, the reactance is zero, and the circuit behaves as if it were non-inductive, the impedance reaching its minimum value R. The circuit is then said to be electrically tuned for pulsatance ω (or frequency n).

II. Sources of Current

§ (4) Introductory.—For all measurements of inductance a source of current that can be varied in some systematic manner is required. In the older days this variation usually consisted of a single make and break or reversal of a steady direct current, but in modern times the use of periodically interrupted or alternating currents has become general; as the frequency of such current is increased the inductive effects become more and more prominent, and following on the introduction of suitable detecting and measuring instruments for alternating currents the modern methods give very much greater sensitivity and accuracy of observation than the earlier ones. When direct current is used all that is necessary as a source is an ordinary battery, preferably of steady voltage; for alternating or interrupted current a very wide range of frequency has to be dealt with, and a great variety of arrangements have been used, some of them extremely simple and cheap, and others much more elaborate and often requiring considerable power to drive them. We proceed to describe a number of different types, giving their capabilities and ranges of frequency, so that the experimenter may be able to select a type meeting his requirements and adapted to the power available.

§ (5) Use of Transformer.—First it should be remarked that in nearly all cases it is best to connect working apparatus to the source through a small transformer having a number of separate windings, so as to afford a wide choice of working voltage. This transformer must have a well-closed magnetic circuit, for any magnetic leakage in the vicinity of the testing apparatus is almost certain to give trouble and cause errors that may not easily be detected. (For the same reason it may often be necessary to arrange the source at a long distance from the test table.) It is of great advantage to have a conducting screen[1] interposed between the primary and secondary windings of the transformer and connected to earth. It must of course be of such a form as not to allow any eddy-current effect. The function of such a screen is to minimise the effects of leakage and more particularly of capacity to earth in parts of the testing circuit.

It is always desirable to repeat readings with the connections to the secondary of the transformer reversed. If any difference is observed, it nearly always indicates prejudicial effects of capacity to earth (or magnetic leakage).

The following data of a type of small transformer much used in the National Physical Laboratory will indicate a construction found by long experience to work satisfactorily. The core consists of an anchor ring of inner diameter 12 cm., outer 20 cm., and about 16 sq. cm. cross-section, formed of silicon-iron (Stalloy) stampings insulated from one another. The windings are insulated from one another by silk ribbon, each set of turns (except the 1s) being evenly distributed round the ring to avoid magnetic leakage. After winding the whole is immersed in hot melted paraffin wax. The numbers of turns in the sections are as follows: 100, 100, 100 for primary; 100 for earth screen; 100, 100, 100, 100, five of 10, and five of 1 as secondaries. The earth screen here consists of a set of turns completely covering the ring, one end being earthed and the other left free. Sometimes it is advantageous to have also an outer winding as part of the earth screen.

§ (6) Alternator.—An alternator forms a convenient source, especially if it gives approximately sine wave voltage and can be run at constant speed. Current from an alternating lighting supply is sometimes quite suitable. When the alternator is driven by a direct current motor run from an unsteady source the speed can be kept wonderfully steady by means of a Helmholtz automatic regulator mounted on the shaft of the alternator. The principle on which it acts is simple. When the speed rises slightly above the normal a weight controlled by a spring is slightly displaced by the increased centrifugal action, and closes an electric contact which short-circuits a portion of the regulating resistance in the shunt circuit of the motor, and thus lowers the speed. With Giebe's

[1] G. A. Campbell, *Electrical World and Engineer*, 1904, xliii. 647.

modification[1] constancy of speed to 1 part in 1000 is in general easily obtained.

When extreme constancy of speed is required the best plan is to mount a suitable commutator on the shaft of the alternator and connect it up with a good mica condenser as if measuring the capacity by Maxwell's method. (See article on "Capacity.") The movement of the galvanometer light-spot to one side or the other of the scale gives an extremely sensitive indication of whether the speed is above or below the normal desired value, and thus enables an auxiliary observer to control the speed with the greatest nicety by the application of some form of variable brake (*e.g.* by simple hand pressure on the rim of a fly-wheel).

For low frequencies (10 up to 200 ~ per sec.) a quite ordinary alternator is sufficient. With motor driving the very slow speeds can be best obtained by separately exciting the motor field with normal voltage and running the armature from a few storage cells. For audio frequencies (200 up to 10,000 ~ per sec.), which include the range used in telephonic work, special alternators have been designed. The simplest of these machines are of the inductor type, in which a toothed iron disc is rotated close to the poles of an electromagnet magnetised by a winding carrying direct current. Secondary coils are wound on the magnet near the poles, and as the teeth pass the poles the resulting variation of magnetic flux induces an alternating voltage in these polar coils, from which alternating current can be obtained.

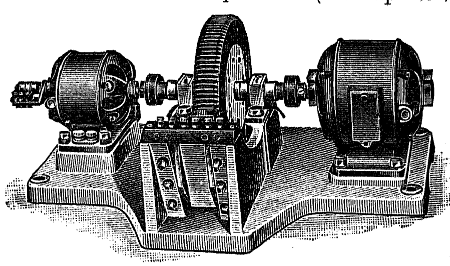


FIG. 1.—Dolezalek High-frequency Alternator.

A machine of this type designed by Dolezalek,[2] and supplied by Messrs. Siemens Bros. & Co., is shown in *Fig.* 1. The toothed disc has 100 teeth and is built up of several hundred thin iron sheets. It can be run at a speed of 3000 revs. per min., which gives a frequency of 5000 ~ per sec. The output at 3600 ~ per sec. is about 7 watts with 200 ohms in the external circuit and resonance. The machine is run by a direct-coupled motor, and in order to keep the speed more steady a small dynamo is coupled to the other end of the shaft. By loading this dynamo much greater steadiness of speed is obtained when the bearing friction is made only a fraction of the total power used.

A smaller type, shown in *Fig.* 2, goes up to 3600 ~ per sec. with a disc of 60 teeth, and has an output of 1·7 watts at 3000 ~ per sec. (for 200 ohms and resonance). The motor has two slip rings connected with the armature winding for connecting up a brake resistance applying a variable load for controlling the speed. The wave form is not free from harmonics, but these may be largely suppressed by inserting a variable condenser in the working circuit and adjusting it to give resonance for the fundamental frequency. The tuning is best done by having a thermal or other suitable ammeter in the working circuit and altering the capacity until the ammeter shows maximum current. This electrical tuning is of general application to almost any source of alternating current. It not only tends to suppress harmonics, but also, by reducing the total impedance of the circuit, often allows a much greater output to be obtained from the source.

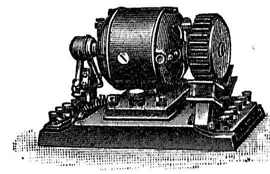

FIG. 2.—Small Dolezalek High-frequency Alternator.

In G. A. Campbell's Wave Filter,[3] by means of a multiple system of condensers and inductances, the harmonics are very effectively suppressed.

§ (7).—The Duddell alternator[4] shown in *Fig.* 3 is a much more elaborate and powerful machine and is designed to give very nearly a pure sine wave form. For this reason the stator consists of a well-laminated smooth

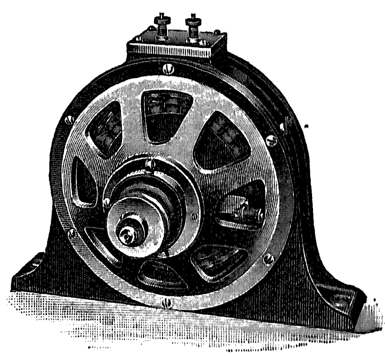

FIG. 3.—Duddell Alternator for Audio Frequencies.

[1] E. Giebe, *Zeits. Instrumentenk.*, 1909, xxix. 205; *Electrician*, 1909–10, lxiv. 509.

[2] F. Dolezalek, *Zeits. Instrumentenk.*, 1903, xxiii. 240.

[3] G. A. Campbell, *Phil. Mag.*, 1903, p. 313 (5).

[4] W. Duddell, *Phys. Soc. Proc.*, 1912, xxiv. 172.

ring wound like a gramme ring, the comparatively long air-gap between it and the rotor ensuring that the armature reaction is kept low, and hence the wave form only slightly distorted when the machine is loaded. The rotor, of 20 cm. diameter and with 30 salient poles, carries the field winding and is run up to a maximum speed of 8000 revs. per min. The working range of frequency is from 100 up to 2000 ~ per sec. As an output of 10 watts can be obtained at any frequency of this large range, the output at the highest speed is considerable, being about 500 watts (5 amperes at 100 volts). The field excitation is from a battery at 35 volts. The wave form is not absolutely pure, but contains a slight third harmonic.

§ (8).—Distinct in type from either of the above machines is the high-frequency alternator described by Hartmann-Kämpf.[1] It requires no exciting current, as permanent magnets are used. These are of horseshoe form, 24 of them being mounted in ring form with their poles facing inwards and surrounding a slot-wound armature. The ring of magnets and the armature are rotated in opposite directions, each with a maximum speed of 4000 revs. per sec. The minimum output is 500 watts. By passing the current through an iron-cored choking coil a fair approximation to sine wave form is obtained.

§ (9).—When only a very small amount of power is required, a minute inductor alternator can be easily constructed by taking the magnet (with its polar windings) from a two-pole telephone receiver and fixing it with its poles very close to the rim of a finely toothed disc of well-laminated iron. The disc can be mounted directly on the spindle of a small motor or else on a separate spindle with belt drive. The current is taken from the polar windings.

§ (10) Interrupters.—Very often a quite satisfactory source consists of an interrupter of some kind by which the current from a battery (or other direct current source) is made and broken periodically. Sometimes this intermittent current is applied directly to the measuring apparatus, but more often it is turned into alternating current by interposing a transformer. There are many types of such interrupters for various purposes other than that of measurement. For example, under the name of "buzzers" they are very largely used in signalling of all kinds, and many of the types evolved for this purpose are quite useful for inductance testing. It will suffice, however, to describe one or two types, but before proceeding to details we shall discuss a trouble which is common to nearly all such apparatus, namely, the sparking at the contacts.

Suppression of Contact Sparking.—When a circuit is broken by separating two metallic conductors the resulting spark is often troublesome, especially when the circuit has considerable inductance (or, to be more precise, a high time constant), which is a quite usual case in inductance testing. In the majority of interrupters the contact surfaces or points are made of platinum because of its high melting-point and resistance to oxidation; in some instances it has been found possible to replace it by solid tungsten.[2]

But even with the best material for the contact pieces there is usually trouble of sticking, uncertainty of contact, etc., unless means are used to lessen or suppress the spark. Either of the two following methods will in general reduce and often practically suppress the objectionable sparking. When, however, the interrupter has to deal with considerable amounts of power, the problem of spark suppression does not admit of such easy solution.

Method A.—Across the contact break are connected (as shown in *Fig.* 4) a condenser and a non-inductive resistance in parallel, the resistance being adjusted to give minimum sparking. The disadvantage of this method is that a certain amount of current always remains flowing even when the contact is left broken. This does not occur in the following method.

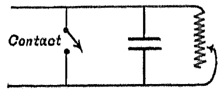

Fig. 4.

Method B.—As shown in *Fig.* 5, a condenser and a resistance in seriesare connected across the break. When the interrupter is working on any actual load the resistance can usually be adjusted so as to make the sparking negligible. (This system is also of great value for relays and other instruments with delicate contacts.)

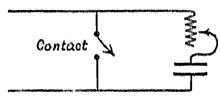

Fig. 5.

For either method an ordinary paraffin-paper condenser of 1 or 2 microfarads capacity is generally sufficient. In Method A the resistance may have to be high (thousands of ohms), while in Method B it may range from 1 ohm up to several hundred ohms. In certain cases a condenser alone may be formed best, and sometimes (as used by Helmholtz, 1872) a resistance without any condenser will suffice.

§ (11) Wire Interrupter.—For frequencies from 30 or 40 up to 300 ~ per sec. the wire interrupter forms a steady but easily adjustable source. It was used by Gray in 1875 and by Niemöller[3] in 1879, but more fully discussed by M. Wien later,[4] and a very elaborate and accurate type has been described by Hartmann-Kämpf.[5]

In most of the types a steel wire (under

[5] R. Hartmann-Kämpf, *Elektro-akustische Untersuchungen*, 1903.

tension), maintained in steady vibration by an electric circuit, interrupts periodically another circuit from the same or another battery. The following description refers to the form used at the National Physical Laboratory. The general arrangement is shown in *Fig.* 6, and the connections of the circuits in *Fig.* 7. On a long iron bed AB are mounted the two lathe-heads C and D, having screws of coarse and fine pitch respectively, and a wire GH of piano steel is stretched between them, the two screws giving coarse

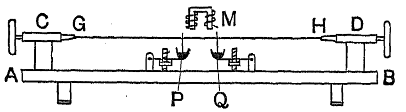

FIG. 6.

and fine adjustment of the tension. Two short pieces of nickel wire are soldered to the wire GH near its middle point and project downwards into mercury cups (P and Q), each consisting of a porcelain crucible mounted on a pivoted support which can be raised or lowered by a nut on a vertical screw in order to keep the mercury surface at just the right level. An electromagnet M is supported with its poles directly over the middle of the wire, and its height is also adjustable.

The driving circuit (*Fig.* 7) is from G through contact P, magnet M, and resistance r, the contact being shunted merely by a resistance S. These resistances r and S are

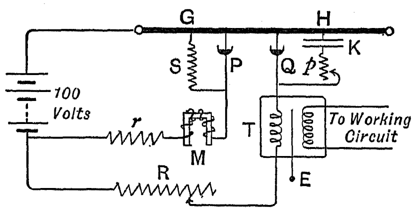

FIG. 7.

ordinary 200-volt glow-lamps. If the height of P is properly adjusted and the wire is set into vibration (by slightly twanging it) this electrical circuit will maintain it in steady vibration at its natural frequency, which can be set to a desired value by altering the tension and tuning by the method of beats against a tuning-fork or other standard of pitch.

The second circuit is from G through contact Q, primary winding of transformer T, and resistance R, the working circuit being taken from the secondary of the transformer.

To prevent the oxidation of the mercury by the spark the mercury surface is covered with a layer of paraffin oil 5 or 6 mm. deep. This gradually forms a sludge with the mercury. To keep the contacts in good order the sludge should be skimmed off from time to time and a little fresh paraffin added. The paraffin oil is preferable to alcohol, which is commonly used, as the oxidation of the alcohol forms aldehyde which makes the air of the room both unpleasant and unhealthy.

For the lower frequencies it is sometimes convenient to clamp a small weight to the middle of the wire. For the higher frequencies two sliding bridges can be placed under the wire to reduce the working length.

§ (12).—The wire interrupter of Arons [1] works on a different principle. The wire is of non-magnetic material and, near its middle point, passes through the transverse field of a powerful electromagnet. In series with the wire is a mercury contact which is opened and closed by a stirrup carried by the wire. The exciting current of the magnet is kept constant (from a separate source) and the current through the wire only is interrupted.

The great advantage of the wire interrupter is that it gives a very steady (and easily adjustable) frequency. The current in the working circuit, however, is by no means of sine wave form, unless the harmonics are suppressed by electrical tuning.

A wire interrupter may be set up at no great distance from the testing table, but care must be taken to avoid disturbances from the alternating magnetic field of the electromagnet (of the first type). The field at a distance can be considerably reduced by specially designing the magnet. To detect the presence of errors due to such stray fields, the magnet circuit should be reversed and the measurement repeated, a change in the result usually indicating disturbance of this kind. Similarly with nearly all the other sources here described, the observer must always be on his guard against stray alternating magnetic fields.

§ (13) TUNING-FORK INTERRUPTER.—A tuning-fork may be maintained in vibration by the same method as the wire, the contact breaker being a platinum or nickel wire dipping into mercury. This system works quite well with a large fork for frequencies up to 200 or perhaps 250 ~ per sec. For higher frequencies the contact breaker often consists of a slightly springy platinum wire or strip [2] working against a flat surface of platinum mounted on the end of a screw by which the contact can be adjusted. As in the case of the wire interrupter a second contact can be arranged so as to keep the driving circuit independent of the working load. A tuning-fork thus maintained gives a tolerably steady frequency. Variations of frequency of several parts in 1000 may, however, sometimes occur, due to alteration of voltage of the driving battery or change of adjustment of the contact break. The working current is not of sine wave form. If only a quite small

[1] L. Arons, *Wied. Ann.*, 1898, lxvi. 1177, and E. Orlich, *Elekt. Zeits.*, 1903, xxiv. 502.

[2] A. Guillet (*Lum. élect.*, October 16, 1909, p. 81) uses a contact against a stretched wire.

amount of power is required in the working circuit, a much nearer approach to sine wave form may be obtained by A. Campbell's method,[1] in which a fork, driven by the ordinary contact method, carries on one of its limbs a flat coil, which is thus vibrated in the non-uniform field of a powerful magnet and generates alternating voltage for the working circuit. This system suits forks of 5 to 30 ~ per sec. having large amplitudes.

§ (14) ELECTRIC TRUMPET OR BUZZER.—An ordinary signalling electric trumpet or buzzer often forms a very convenient source of current. The General Electric Company's type is illustrated in *Fig.* 8, the three standard sizes having frequencies lying between 300 and 1000 ~ per sec. The working parts are shown in diagram in *Fig.* 9.

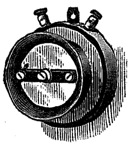

FIG. 8.—Trumpet Buzzer (General Electric Co.).

A platinum point carried by a setting screw A just touches a small platinum plate fixed to the centre of the telephone diaphragm D, behind which there is a bipolar electromagnet M with solid iron cores. The buzzer may be used as supplied by merely putting a transformer into its circuit along with a 6-volt battery, at the same time checking the spark with a condenser and resistance (K and *r*). But in general a more efficient way is to use the system suggested by Mr. D. W. Dye as shown in *Fig.* 9. The electromagnet is re-

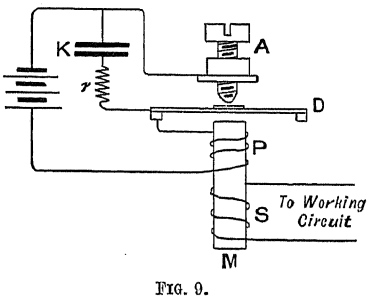

FIG. 9.

wound (with silk-covered wire) with two windings P and S, and from the latter the working circuit is taken. Between P and S is an earth-screen winding. The secondary winding S can be designed so that its resistance suits the apparatus used in the working circuit.

A buzzer of this kind with a battery of accumulators of 6 or 8 volts gives sufficient power for most testing purposes. The frequency of the current is not constant, but alters with change of adjustment of the contact, variation of battery voltage, and working load ; it must be determined independently at the time of test, if a knowledge of its exact value is required. It remains, however, sufficiently constant for most purposes for hours at a time ; indeed the arrangement has often been run continuously for several days, and when in good working order can be switched on and off as readily as an ordinary lighting supply. The wave form obtained is not sinoidal, but, if desired, tuning can be applied by a series condenser in the working circuit. The buzzer (with 6 volts) unfortunately gives out a very loud note; it is necessary, therefore, to enclose it in at least two boxes well padded with wadding and, if possible, place it in a distant room, bringing the switch leads and the working circuit leads only to the testing table. Distance from the testing apparatus has also the advantage of getting rid of trouble due to stray magnetic fields.

§ (15) MICROPHONE HUMMER.—When constancy of frequency and a tolerably pure wave form are required, a microphone hummer is sometimes a convenient source. In the interrupters, since the circuit is completely broken

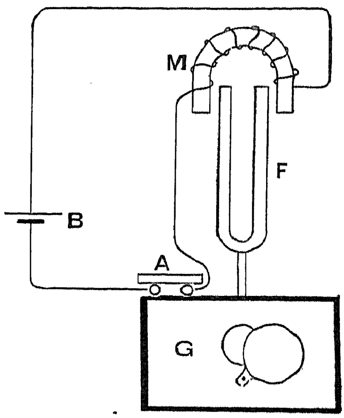

FIG. 10.

in each oscillation, the wave form of the current is naturally far from pure. In a microphone, on the other hand, we have an apparatus which when vibrated causes periodic variations in the current without any complete break of contact ; these variations have usually a wave form not far from sinoidal. In 1890 Appleyard[2] showed how a tuning-fork could be electrically maintained by the help of a microphone. His apparatus, shown in diagram in *Fig.* 10, was very simple, consisting of a tuning-fork F mounted on a resonator box G, on the top of which rested a microphone A (three carbon rods). A battery B of one cell was connected through the microphone to an electromagnet M whose two poles were close to the ends of the prongs of the fork. If the fork is set vibrating, the shaking of the microphone causes ripples in the battery current, which, acting through the magnet

[1] A. Campbell, *Phys. Soc. Proc.*, 1919, xxxi. 85.

[2] R. Appleyard, *El. Review*, 1890, xxvi. 57 and 656.

M, keep the fork in vibration. Since that time various experimenters, using this principle, have developed a number of different types of microphone hummer for use as a source of small alternating current. Taylor [1] used the system with (*a*) a tuning-fork and (*b*) a telephone diaphragm as vibrator. The electrical connections, which are much the same for both types, are shown in *Fig.* 11. A battery B is connected through a microphone capsule A carried by a telephone diaphragm D to the primary of a transformer T. The secondary of the transformer is connected in series with adjustable self inductance L and capacity K to a polar winding Q on the permanent magnet M, one or both of the poles of M being close to the diaphragm. A portable form of this type designed by Dolezalek [2] and supplied by Messrs. Siemens Bros., giving a frequency about 550 ~ per sec., is shown in *Fig.* 12.

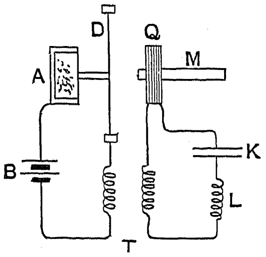

FIG. 11.

§ (16).—A tuning-fork hummer, however, gives a far more constant frequency than the type with a diaphragm. Forks of frequencies from 250 up to 500 ~ per sec. can be run without difficulty, using an ordinary capsule

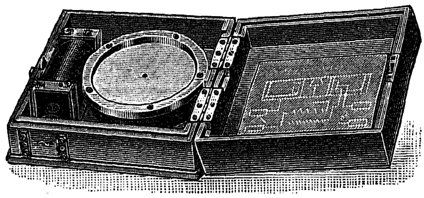

FIG. 12.—Dolezalek's Diaphragm Microphone Hummer.

microphone such as is used for the transmission of speech, but special precautions [3] must be taken for those of lower frequency (50 to 100 ~ per sec.). A capsule microphone (*e.g.* the "solid-back" type, which has a mica diaphragm) has a natural frequency of its own, usually of the order of 1000 ~ per sec. For the lower frequencies it should be loaded with a considerable added mass (of the order of 100 to 200 gm.) in order to bring the natural frequency nearer that which is to be generated. Also the circuit containing the secondary of the transformer should be tuned so as to have the effective electrical frequency near the frequency of the fork. For the lower frequencies condensers of the order of 20 to 30 microfarads are sometimes required. It should also be remembered that ordinary granule microphones usually work best when the plane of the diaphragm is not vertical but tilted at a certain angle (sometimes about 40°) to the vertical. For this reason it is best to mount the microphone capsule in such a way as to allow the angle of tilt to be varied in order to obtain by trial the best position.

§ (17).—The higher frequencies (1000 up to 4000 or 5000 ~ per sec.) are best obtained by using a straight steel bar as vibrator, as in Campbell's microphone hummer [4] (*Fig.* 13). In this a mild-steel bar of 25 mm.

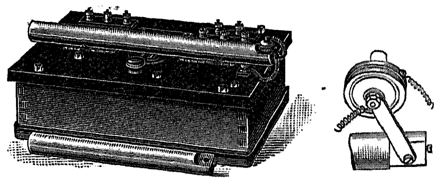

FIG. 13.—Campbell Microphone Hummer.

diameter is supported by pieces of cork or knife-edges at two nodal points. For such a bar the length l in cm. to give any desired frequency n can be found from the formula $l \doteqdot 1075/\sqrt{n}$. The magnet poles are very close to the bar, the distance being adjustable by a screw. Either a permanent magnet or an electromagnet may be used. In the latter case the magnet should be polarised by a direct current in a separate winding. This is most simply achieved by the system shown in *Fig.* 13A, in which the current through the

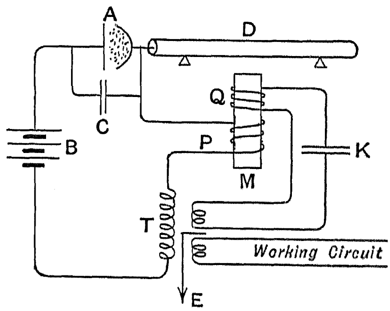

FIG. 13A.

microphone keeps the magnet polarised. This composite system also works well with tuning-forks. Care must be taken to connect the ends of the polar winding in the right direction

[1] J. E. Taylor, *J. Inst. El. Eng.*, 1901, xxxi. 396.
[2] F. Dolezalek, *Zeits. Instrumentenk.*, 1903, xxiii. 240.

to the transformer terminals. The working current is taken from a third winding on the transformer, and this method applies to other types as well. The advantages of a microphone hummer of this type are the great constancy of frequency (to 1 or 2 parts in 1000) and good wave form, but in many cases these are outweighed by the fact that the output, especially above 1500 ~ per sec., is very small and sometimes not sufficient to give high accuracy.

§ (18) Humming Telephone.—In 1890 Hibbard[1] discovered that if a telephone and microphone are connected through a transformer as for speech (*Fig.* 14), and the telephone is held against or near to the diaphragm of the microphone, a musical note is given out and continues as long as the instruments remain in that position. The pitch of the note is usually rather unstable, altering if the relative positions of A and B are changed. Many years later Professor Larsen,[2] of Copenhagen, found that the pitch depended on the dimensions of the air spaces in the telephone and microphone and between them, and starting from this discovery he constructed a simple alternating current generator giving steady frequency, which can also be regulated between wide limits. *Fig.* 15 shows the general

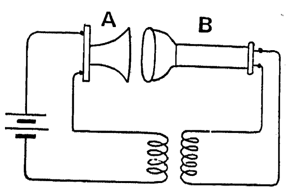

Fig. 14.

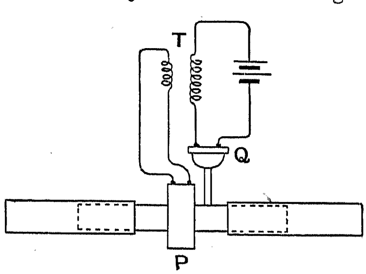

Fig. 15.

arrangement of the apparatus. A watch-shaped telephone P has two equal open brass tubes fixed to it, one in front of and one behind the diaphragm. Over each of them slides another tube, by which the length of the vibrating column of air facing the diaphragm can be adjusted at will. The microphone Q is connected by a narrow tube with the air in one of the fixed tubes at a point near the telephone. By adjustment of the two sliding tubes the frequency can be altered continuously from 600 up to 1100 ~ per sec., for this range the tube lengths being changed from 8 cm. to 21 cm. After switching on the battery the frequency sometimes gradually changes by perhaps 1 per cent, but after that remains constant to about 2 parts in 1000 for hours. The generator only requires two dry cells as battery power. The working circuit is taken from the terminals of the secondary coil of the transformer.

§ (19) Musical Arc.—Duddell's[3] musical arc forms an alternating current generator giving a very large range of frequency and a considerable amount of power. Professor C. L. Fortescue finds that, instead of an ordinary carbon arc, a "Pointolite" lamp used as a musical arc works very well as a small-power source of alternating current. In the Pointolite lamp of the Edison-Swan Company a small electric arc is formed between electrodes consisting of a tungsten wire and small sphere enclosed in a gas-filled glass bulb. The arc is started by a special arrangement, but after starting, the regulation is quite automatic and

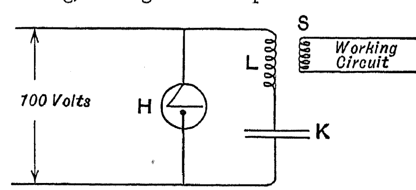

Fig. 16.

the lamp can be run without much attention from any supply circuit of 100 volts or higher. The 100 c.p. size takes 7 amperes at starting and 1·5 amperes when running. *Fig.* 16 shows the connections for the musical arc. A circuit consisting of a coil of self inductance L and a condenser of capacity K is connected across the arc terminals of the Pointolite lamp. The working current may be taken from a coil S placed as a secondary to L. The frequency n is obtained approximately by the formula $n = 159{\cdot}2/\sqrt{KL}$, K being in microfarads and L in henries. It is desirable that the coil L should be of large time constant (*i.e.* L/Resistance should be large). The wave form is not free from harmonics.

§ (20) Vreeland Oscillator.—The Vreeland sine wave oscillator[4] works by the action of an oscillating electric circuit upon a double mercury vapour arc. The arrangement is shown in diagram in *Fig.* 17. A large exhausted glass bulb A has a mercury cathode at B and two carbon anodes at P and Q. A battery F (or other direct current source) is

[1] A. S. Hibbard, *El. World*, Sept. 19, 1890. Also see F. Gill, *J. Inst. El. Eng.*, 1901, xxxi. 388.

connected as shown, the positive terminal being joined through regulating resistances and reactance coils to the anodes P and Q. The side electrode D is only used to start the arc, which is done by switching on at S and tilting up B until the mercury surfaces at B

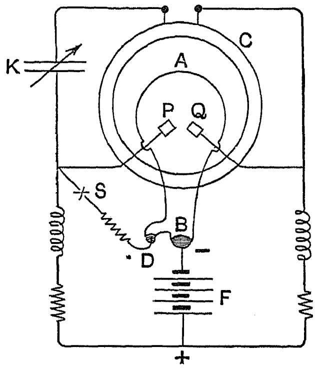

FIG. 17.

and D come into contact. Across the terminals of P and Q is connected an oscillatory circuit consisting of an adjustable condenser K and two (inductive) deflecting coils, represented in the diagram by C, in front of and behind the globe. If the symmetry is so exact that the arcs at P and Q are equal, no current will flow round the oscillatory circuit KC; but if they are not quite equal the potential at one end of the oscillatory circuit will be slightly higher than at the other end, and a current will flow in KC, the deflecting coils, these coils now increasing the arc at the side of higher potential until the condenser K is fully charged. Then the condenser begins to discharge and the reverse process takes place, the arc at the other side becoming the larger, and so on periodically, an oscillatory current being maintained in the KC circuit. The working circuit is taken from a coil closely coupled to the deflecting coils. A steady frequency can be obtained at any desired value from 160 up to 4000 ~ per sec. by adjusting the condenser K. The current given is of exact sine wave form. In working care must be taken to avoid the stray field of the large deflecting coils.

§ (21) TRIODE VACUUM TUBE GENERATOR.—The audion or triode electric valve, which is now so widely used in radio-telegraphy, furnishes without doubt one of the very best sources of alternating current. Such a valve consists essentially of a highly exhausted glass globe containing at one side a tungsten filament (kept glowing by current from a low-voltage battery) and at the other side a metal plate. Between the filament and the plate there is another electrode usually called the "grid," which has various forms in the different types, commonly being constructed of wire gauze or perforated metallic foil. In *Fig.* 18 are shown the connections of a triode when used as a generator. The filament F is kept glowing by current from a 4- or 6-volt battery D, the current being regulated by a rheostat so as to bring the filament to the proper working temperature. (It is well to have an ammeter in this circuit.) A battery B is connected to the filament as cathode and the plate P as anode, the latter connection being through the self inductance L_1 and the capacity K in parallel. From the filament to the grid there is another circuit similarly having inductance L_2 and capacity C in

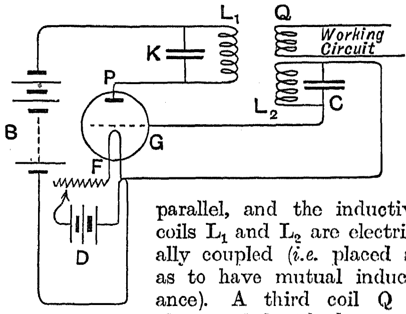

FIG. 18.

parallel, and the inductive coils L_1 and L_2 are electrically coupled (*i.e.* placed so as to have mutual inductance). A third coil Q is also coupled with them, and from it the working circuit is taken. The action of the combination is as follows. A small oscillation set up in the L_2C circuit causes variations of potential difference between the filament and the grid. By the amplifying properties of the valve these variations produce magnified variations of voltage between the filament and the plate, which cause the circuit L_1K to oscillate. This circuit reacts inductively on the L_2C circuit, and thus the oscillations are increased and a steady state maintained. Various other triode generators have been devised, but the system above described gives sufficient illustration of the principles involved.

Without much difficulty an enormous range of frequency is obtained—from 1 cycle in 5 seconds up to several million cycles per second. The adjustment of the frequency is made by varying the condensers or inductances. The higher frequencies (say from 300 ~ per sec. upwards) are easily obtained; for the lower range there is more difficulty, as the inductances and capacitances have to be large. In the latter case the coupling should be close, and, in order to keep the time constants of the coils L_1 and L_2 high, these coils should be of large size. To obtain power of 20 watts, coils having a total weight of 20 kg. (of copper) are suitable, with a large triode tube and a 500-volt battery at B. At the higher

frequencies, however, much larger amounts of power are easily obtained. For testing purposes at audio frequencies and lower, K and C may be subdivided paraffin-paper condensers of good quality, giving capacitance up to 40 or 50 μF. The frequency may be set by tuning the note given out with a tuning-

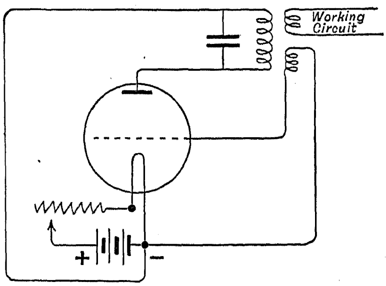

FIG. 18A.

fork or other standard of pitch, or by measuring it electrically as described below (equation 85). When very accurate adjustment is required a variable air condenser should be put in parallel with one of the two condensers and (or) a continuously variable self inductance should form a small part of either L_1 or L_2. The wave form of the current obtained is a good approximation to a sine wave, and the frequency remains remarkably steady if the batteries are in good condition and sufficient for their load.

When only very small amounts of power are required the high-voltage battery B may be omitted and the circuits connected as in *Fig.* 18A.

§ (22) TUNING-FORK MAINTAINED BY TRIODE.—Eccles[1] has shown that a tuning-fork can be maintained in vibration by means of a

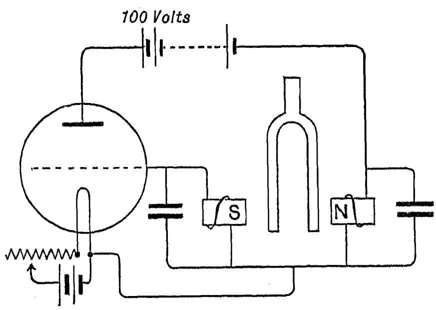

FIG. 18B.

triode valve instead of by contacts or a microphone. In one form two electromagnets act on the prongs of the fork, their windings being respectively in the grid and plate circuits of the tube. The vibration of the fork induces alternating voltage in the grid circuit, which controls the current in the plate circuit and its magnet, and the vibration of the fork is thus maintained. To ensure that the fork shall respond readily to its excitation it is well to put condensers across each of the magnet coils, as shown in *Fig.* 18B, so as to get approximate tuning in the electrical circuits.[2] When the electrical conditions are right a very constant frequency is obtained.

III. MEASURING AND DETECTING INSTRUMENTS

§ (23) INTRODUCTORY.—In the measurement of inductance various instruments are used for measuring voltage or current or merely detecting these, some of them being in common use for electrical measurements in general, and others being more specially designed for this purpose. As general instruments may be mentioned ammeters, voltmeters, and wattmeters, all of which should be suitable for alternating currents and not affected by variations in frequency or wave form. Thermal ammeters and electrostatic voltmeters fulfil these conditions, and electrodynamometers of various types are also useful. Ordinary galvanometers are sometimes wanted, but ballistic galvanometers are more specially used as detectors in some of the null methods. In the majority of modern methods, however, the detecting instruments are either vibration galvanometers or telephones.

§ (24) BALLISTIC GALVANOMETER.—A ballistic galvanometer is one designed for the measurement of the quantity of electricity sent through it in a short interval of time, this quantity being measured by the "throw" of the pointer (or light spot), that is to say, the distance on the scale which the pointer moves until it first comes to rest before swinging back again. In order that this may be a correct measure of the quantity passing, it is an essential condition that the whole discharge shall be complete before the pointer has moved appreciably. To ensure this, the galvanometer is constructed so as to have a relatively long time of swing (say from 8 to 20 seconds complete period); this is usually achieved by increasing the moment of inertia of the moving part and using a weak control. Both moving needle and moving coil types of ballistic galvanometer are used, but the latter is more common in modern practice. Sometimes the damping is small, and the swings of the pointer or light spot die down slowly, but it is generally better to work with considerable damping so that the pointer only just passes the zero point on returning from its first throw. A fuller discussion of the ballistic

[1] W. H. Eccles, *Phys. Soc. Proc.*, 1919, xxxi. 269.

[2] S. Butterworth, *Phys. Soc. Proc.*, 1920, xxxii. 354.

galvanometer will be found in the article on "Galvanometers."

§ (25) ELECTRODYNAMOMETER.—Various experimenters [1] have used electrodynamometers as detectors in inductance measurements, not connecting the moving coil and fixed coil circuits in series (as is done for the ordinary measurement of current), but separating them and combining them in a variety of ways with the other circuits. An electrodynamometer for this purpose should be as sensitive as possible, and to this end a light moving coil with a long and thin suspension will be found advantageous. In an instrument of this kind used at the National Physical Laboratory it was found that with the necessarily weak control considerable disturbances were caused by electrostatic forces acting on the moving coil system. To get rid of these as far as possible the moving coil was screened from the fixed coils by means of tinfoil (with slits in the proper directions to avoid eddy currents) connected to one end of the moving coil which had comparatively few turns. The mica vane for air damping was similarly covered with tinfoil.

§ (26).—In many methods it is desirable that the effective inductance of the moving coil circuit should be zero, and for this purpose Rosa used Sumpner's method [2] of compensating for self inductance, which consists in putting in series with the inductive circuit a condenser shunted by a resistance.

In *Fig.* 19 let L be the self inductance and R the resistance of the circuit in question, K a condenser

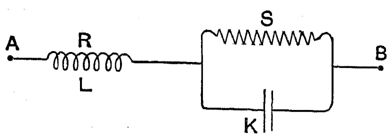

FIG. 19.

and S a resistance, ω being written for $2\pi \times$frequency. Then the (vectorial) impedance of the circuit AB is equal to

$$R+Lj\omega+\frac{S/Kj\omega}{S+1/Kj\omega},$$

which reduces to

$$R+\frac{S}{1+S^2K^2\omega^2}+\frac{L-S^2K}{1+S^2K^2\omega^2}\cdot j\omega.$$

The last term of this expression is the reactance, and hence the reactance of the circuit is zero when $S^2K=L$, a condition which can easily be carried out by suitable choice of K and S. It should be noticed that the compensation is correct at all frequencies, thus differing totally from the case in which reactance is made zero by electrical tuning, where $LK\omega^2=0$ and the circuit is only non-inductive for one frequency. With the Sumpner compensation the circuit is non-inductive, but the total effective resistance is

$$R+S/(1+S^2K^2\omega^2),$$

which is dependent on the frequency. In most ordinary cases $S^2K^2\omega^2$ can be neglected in comparison with 1, in which case the total resistance is practically equal to R+S, and the compensation becomes complete. Rosa adjusted the compensation experimentally by connecting A and B, sending current through the fixed coils, and setting K and S until the deflection was zero.

§ (27) ALTERNATING CURRENT GALVANOMETERS.—By putting an iron core into the fixed coils of an electrodynamometer the magnetic field, and hence the sensitivity, can be largely increased. The instrument is then known as an electromagnet moving coil galvanometer or merely as an alternating current galvanometer. Stroud and Oates [3] introduced such a galvanometer and showed that it gave high sensitivity when used in measurements of inductance and capacity. Abraham [4] a few years later brought out an electromagnet moving coil galvanometer and investigated how its behaviour depended on the reactance of the moving coil circuit. He greatly improved it by adding the capacitance resistance compensation to that circuit. Working independently of these observers, Sumpner and Phillips [5] introduced a number of electromagnet instruments, and of these the Sumpner electrodynamometer is fitted for highly sensitive measurements of inductance and capacitance. It is shown in *Fig.* 20. The electromagnet is built up of thin laminations of alloyed iron sheet of high resistivity and having small hysteresis loss,

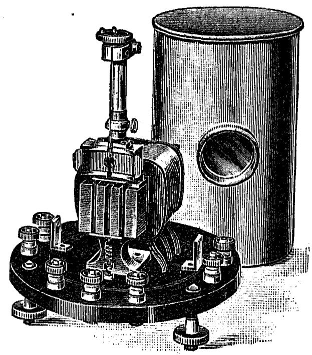

FIG. 20.—Sumpner Electrodynamometer.

and the magnetic circuit is designed so that the air-gap flux density is accurately proportional to the applied voltage and in quadrature with it. Thus the deflection of the moving coil is only due to that component of the current through it which is in quadrature with the voltage applied to the field magnet. The magnet is wound with three coils, two having 2000 turns each, and one having 200 turns. With the first two coils in series the windings will bear a voltage up to 200 volts at 50 ~ per sec., but in normal working 40 volts is sufficient. The moving coil, which has only a few turns (to keep the inductance low), is suspended in two air gaps of the magnet, and a vane in a closed chamber gives air damping.

§ (28).—Weibel [1] has described several highly sensitive electromagnet galvanometers designed for use in inductance and capacity tests. He has also given a thorough investigation of the mathematical theory of such instruments, and has derived the equation of motion of the moving coil. He shows that the damping and the period of swing both depend on the circuit external to the moving coil, the period being shortened by inductance and lengthened by capacitance. In his instruments, as in the most sensitive direct current galvanometers, the moving coils had to be treated with potassium copper chloride to remove the magnetic dirt. To minimise electrostatic disturbances the moving coil was screened. The galvanometers worked well at low frequencies; one of them showed high sensitivity at a frequency of 2100 ~ per sec., but for satisfactory working required many precautions to be taken. In all instruments of this class the results in most cases are affected by the harmonics present in the current from the source.

§ (29).—This remark also applies to another type of sensitive detector of alternating current, Bellati's so-called electrodynamometer,[2] in which a soft-iron needle is at an angle of 45° to the axis of a surrounding coil. An ordinary moving magnet mirror galvanometer will work on this principle if the magnet system is turned so as to make even a small angle with the faces of the coils when in its position of rest.

§ (30) Vibration Galvanometer.—In certain respects the best detecting instrument for inductance testing is the vibration galvanometer. It might be more appropriately named a resonance galvanometer, for the fundamental principle of its working is that the moving system (magnet, moving coil, etc.) is tuned so as to have its natural frequency the same as that of the alternating source used. When current of this frequency is sent through the galvanometer the moving part is set into resonance, and a very much larger deflection is obtained than if the same current had any other frequency. Thus two very important properties are attained, namely, (1) great increase of sensitivity (sometimes as much as 500-fold), and (2) high selectivity, the harmonics in the wave form having practically no effect. This selective property is of great value, for even with a source of impure wave form the results obtained correspond exactly with the condition of pure sine wave form. As the frequency is lowered, the sensitivity tends to approach that of a good direct current galvanometer. At the lower frequencies (from 150 ~ per sec. downwards) the vibration galvanometer is much more sensitive than a telephone, while at the higher audio frequencies (1000 ~ per sec. and upwards) the telephone is much better than the galvanometer. For further information on vibration galvanometers the reader is referred to the separate article on the subject.

§ (31) Telephone.—The ordinary Bell telephone is the most widely used detecting instrument for alternating current. It consists essentially of three simple elements—a permanent magnet, polar coil or coils, and a thin iron plate mounted with rim clamping close up to one or both poles of the magnet. It has been altered very little in form for many years, but it is still open to improvement in detail. For example, as Wagner [3] has pointed out, by making the pole pieces of silicon iron and replacing the usual ferrotype diaphragm by one of silicon iron there is considerable gain in efficiency. Although the ordinary type can be used over a wide range of frequency, the sensitivity is by no means constant at different frequencies. As M. Wien [4] showed, there are several frequencies at which the diaphragm resonates, and at these frequencies the current sensitivity rises very considerably. For example, in a certain Bell telephone points of resonance were observed at frequencies of 1100, 2800, and 6500 ~ per sec., and in a Siemens telephone at 720, 2100, and 5000 ~ per sec. The very large increase in the motion of the diaphragm for a given current as the frequency is brought to the point of resonance is shown in the curve of *Fig.* 21, which is drawn from the results of observations of Kennelly and Affel [5] on a certain telephone receiver. The amplitude of oscillation of a point near the centre of the diaphragm is plotted against the frequency. The actual sensitivity, however, does not depend only on the motion of

the diaphragm, but also on the sensitivity of the ear, which latter factor varies greatly

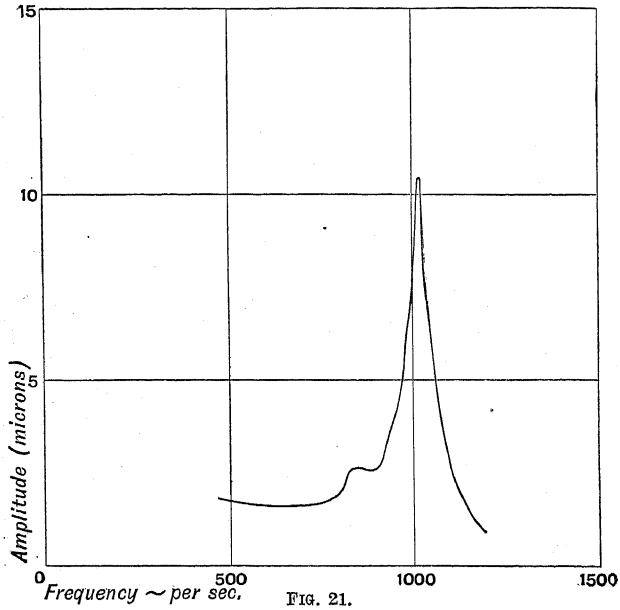

FIG. 21.

with change of frequency (and differently in different individuals).

Lord Rayleigh[1] and others have investigated the working sensitivity of the telephone at various frequencies by observing the minimum current necessary to give an audible sound in the telephone.

The results obtained by M. Wien for the Siemens telephone mentioned above are given in Table I.

TABLE I

Frequency.	Current.
~ per sec.	microamperes.
64	18·0
128	2·2
256	0·26
512	0·017
720	0·015
1 024	0·030
1 500	0·060
2 030	0·008
2 400	0·020
4 000	0·50
8 000	7·0
16 000	22·0

From this example it is clear that a telephone behaves much better at certain frequencies than at others, and for this reason, when working at any particular frequency, it is desirable to choose a telephone suited to the frequency. For the higher frequencies it is often of advantage to replace the ferrotype diaphragm of the ordinary speech telephone by a thicker one of tinplate. Rough tuning may be carried out by slackening the ear-piece (*i.e.* the cap which clamps the plate) and gradually tightening it again till maximum sensitivity is observed.

[1] *Phil. Mag.*, 1894, xxxviii. 294.

§ (32) TUNED TELEPHONES.—A. Campbell found that an ordinary telephone can be tuned over a considerable range by means of a small screw working through the ear-piece and pressing against the plate at an excentric point. Other experimenters have introduced more accurately tunable telephones. The monophonic receiver of Abraham[2] is more sensitive than an ordinary telephone. The diagram in *Fig.* 22 shows the system of working, A being the general arrangement of parts, and B showing the diaphragm in plan. The diaphragm D is mounted on two flattened wires (or strips) SS. These are fastened at one end, and at the other are fixed to the wheel W turning on a spindle and carrying an arm through which the tension of the wires is adjusted by means of the milled-head screw P.

Telephones tuned for only one fixed frequency have also been found useful. Mercadier's monotelephone,[3] in which a large iron plate (one or two millimetres thick) rests horizontally on three points with a telephone magnet underneath it, was used with success by Dongier[4] for inductance measurements, but in general it is not sufficiently sensitive.

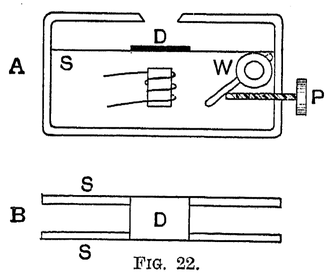

FIG. 22.

R. W. Paul introduced highly sensitive ordinary telephones tuned for fixed frequencies by proper choice of the dimensions of the diaphragm.

S. G. Brown has brought out a telephone in which the ordinary diaphragm is replaced by an iron reed to which is screwed a slightly conical aluminium

[4] R. Dongier, *Comptes Rendus*, 1903, cxxxvii. 115.

diaphragm, the rim of which is sometimes attached to the case by a flexible ring of tissue paper.

§ (33) TELEPHONE WITH ACOUSTICAL RESONANCE.—M. Wien[1] found that by adding a suitable acoustic resonator to a telephone the sensitivity for a fixed frequency could be increased. It appears probable that this method could be used with advantage in inductance testing where rapidity of working may not be important. (It cannot be used for quick signalling purposes, as the resonance takes an appreciable time to build up the full amplitude.)

§ (34) MICROPHONE-TELEPHONE AS DETECTING INSTRUMENT.—As already stated, the sensitivity of a telephone becomes small as the frequency is brought down to the lower values (100 ~ per sec. and lower), and below a certain limit (about 30 ~ per sec.) the ear no longer hears a musical note. To detect currents at these lower frequencies and even down to zero frequency (direct current) Kennelly, Laws, and Pierce[2] combined a

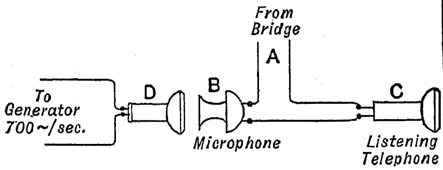

FIG. 23.

telephone with a microphone to work on a kind of relay system, as in *Fig.* 23.

By the leads A the bridge (or other testing circuit) is connected to the observer's telephone C in series with a microphone B. Close up to the microphone is fixed another telephone D which is kept sounding a loud note by current from a source of higher frequency (*e.g.* 700 ~ per sec.). As long as no current passes from A round the microphone circuit nothing will be heard in the listening telephone, but if any current passes (whether low frequency or direct) the maintained vibration of the microphone causes ripples in it and the high note is heard in the telephone. The stimulation of the microphone could be effected by a loud high note produced by other means, such as a siren or whistle. In all cases it is essential to have the microphone and source of sound in a silencing box at a distance from the observer.

§ (35) WORKING CONDITIONS FOR TELEPHONE.—The telephone for any particular measurement should be chosen not only to suit the frequency but also to have resistance of the proper order for the bridge or other arrangement used. Ordinary bipolar telephones can be obtained having any resistance from 4000 ohms down to a fraction of an ohm. Sometimes when only a high resistance telephone is available, while a low resistance bridge is required, better results are obtained by interposing a transformer between the bridge and the telephone, few turns being connected to the bridge and many to the telephone. The converse arrangement can also be used with a low resistance telephone, and the same system is also applicable to a vibration galvanometer. In using a telephone trouble may arise from capacitance to earth through the observer's body. If a hand telephone is used it should never be held directly in the hand but always by a handle of ebonite or other good insulating material. If the telephone is brought near the testing apparatus errors are sometimes caused by stray magnetic fields, the presence of which may be detected by moving the telephone into various positions while listening. Sometimes this trouble is avoided by mounting the telephone on a stand which can be turned into a position at which the effect of stray field is zero, and connecting it to the observer's ear by a stethoscope tube.

§ (36) VIBRATION ELECTROMETER.—There are certain cases where the test circuits have high impedance and hence require a detecting instrument whose impedance is also high. A vibration electrometer has this property. Greinacher[3] uses for this purpose a modified form of the Wulf electrometer, of which the essential parts are shown in *Fig.* 24. The moving part is a very thin (Wollaston) platinum wire P mounted near a metal strip S. The upper end of P is fixed, and the lower end is fastened to the middle of a quartz fibre Q, by which it is kept in tension. When the highest sensitivity is required, S is maintained at a potential of 40 volts above that of the case by means of a battery. The instrument is connected to the bridge through a transformer, whose secondary terminals are connected to the wire and the case respectively.

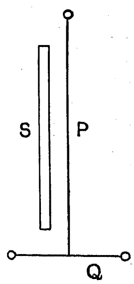

FIG. 24.

§ (37).—A different type of vibration electrometer has been introduced by Curtis.[4] In this a light rectangular aluminium vane (2 cm. × 1 cm.) is mounted vertically on a tunable bifilar suspension between four vertical metal plates (each 1 cm. square) which correspond to the quadrants of an ordinary electrometer, and are connected up in pairs diagonally. The vane is free to vibrate about a vertical axis, and its natural

[1] M. Wien, *Phys. Zeits.*, 1912, xiii. 1034.

[3] H. Greinacher, *Phys. Zeits.*, 1912, xiii. 388, and *Elektrotechn. u. Maschinenbau*, 1914, xxxii. 415.
[4] H. L. Curtis, *Bureau of Standards Bulletin*, 1915, xi. 535.

frequency can be tuned up to about a maximum of 100 ~ per sec. The working is heterostatic, the vane being maintained at a higher potential than its surroundings by a battery. The plates are normally from 1 to 2 mm. apart. With the 1 mm. separation a battery voltage as high as 170 volts may be used. The volt-sensitivity increases as the potential of the vane is raised, and, with the other adjustments constant, the resonance frequency is lowered at the same time. As the energy losses are almost entirely due to air damping, the instrument is worked in an enclosure that can be exhausted. The sensitivity increases as the pressure is lowered, and even at a pressure as low as 0·005 mm. of mercury the fraction of the damping due to the suspension is small. As the damping is diminished, however, the frequency range becomes more and more limited, and hence the lowering of the pressure must not be carried too far.

In the paper mentioned above Curtis gives the mathematical theory of the instrument and shows experimentally that the behaviour of the instrument is in agreement with this. The following statement indicates the order of sensitivity obtained. At a pressure of 0·005 mm. of mercury with 140 volts on the vane and at a frequency of 50 ~ per sec., 1 volt on the plates (2 mm. apart) gave a deflection of 50 mm. at 1 m. scale distance. Since the current taken by the electrometer is very small (the impedance being so high), the current sensitivity is very high, being of the order of 10,000 mm. at 1 m. per microampere.

IV. Resistances for Use in Inductance Measurements

§ (38) Introductory. — In nearly all methods of measuring, inductance standard resistances, whether in the form of single coils, resistance boxes, or rheostats, form an essential part of the apparatus. In most cases it is desirable that such resistances should be as free as possible from self inductance and self capacitance (which may be considered as negative inductance). As the inductiveness of a circuit is most appropriately measured by the value of its "*time constant*," we shall consider the origin and definition of this quantity before proceeding to describe the construction of non-inductive resistances.

§ (39) Time Constant.—If a steady voltage V is suddenly applied to the ends of a circuit having resistance R and self inductance L, the current produced in the circuit does not attain its full value immediately, but rises from zero to a practically steady value in an appreciable time, which depends on R and L. To find the law by which it rises, let i be the current at time t from the moment of switching on. Then we have

$$V = Ri + L\frac{di}{dt}, \quad . \quad . \quad . \quad (5)$$

and the solution of this equation is

$$i = \frac{V}{R}\left(1 - \epsilon^{-\frac{R}{L}t}\right). \quad . \quad . \quad . \quad (6)$$

When $t=0$, $i=0$ and $\frac{di}{dt}=V/L$;

when $t=\infty$, $i=V/R$ and $\frac{di}{dt}=0$.

Thus we see that the current starts from zero value with an initial rate of rise equal to V/L and reaches its steady value asymptotically, the time taken to reach any given fraction of its steady value depending only on L/R, which is called the *time constant* of the circuit. It is defined as the time taken by the current to rise until it only differs from its steady value by $1/\epsilon$th part of this value. Thus since $\epsilon=3$ approximately the current always rises to approximately two-thirds of its full value in L/R seconds. As a simple example the curve in *Fig.* 25 shows the rise of current when R=1 ohm, L=2 henries, and V=10 volts.

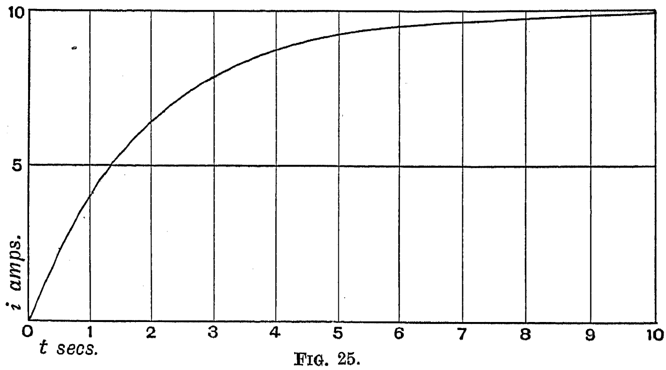

Fig. 25.

The time constant is here 2 seconds; in 10 seconds the current is within less than $\frac{1}{100}$th part of its full value. This is a case of a large time constant, such as would occur with an iron-cored coil. In ordinary standard inductance coils the time constant is of the order of 0·2 millisecond.

If ϕ be the angle of lag of the current behind the terminal voltage, then $\tan\phi = (\text{time constant}) \times \omega$, and the *power factor* is $\cos\phi$.

§ (40) NON-INDUCTIVE RESISTANCE COILS.—A resistance coil of which the self inductance is negligible is commonly called "non-inductive," but this term can only be taken as relative, for in even the best coils it is nearly always possible to detect and measure the small residual inductance. In the older coils and resistance boxes it was customary to attempt to annul the self inductance by using bifilar winding, in which the whole length of wire was doubled back on itself from the middle point and the two wires together were wound on to the bobbin. This system gives considerable self capacity in the coil if the wire is long, for points of the wire having the full applied potential difference between them are very close together (near the terminals), having only thin insulation between them. The result is that in such boxes the lower coils have slight inductance, the middle coils (say 100 ohms) may be nearly non-inductive, while in the 1000 and 10000 ohm coils there may be considerable negative effective self inductance, as the capacity predominates. The capacitance is here distributed all along the winding.

To calculate its amount from the dimensions of the bifilar loop and the inductive capacity of the insulating material, to a first approximation, we may consider the loop as a long twin cable connected across at the distant end. If K be the capacity when the circuit at the end is open, then the distributed capacity (when the end is on closed circuit) may be replaced by an equivalent capacity K/3 connected across the terminals. To find the effect of this capacity upon the effective inductance of a coil, in *Fig.* 26 let AB be the terminals of a con-

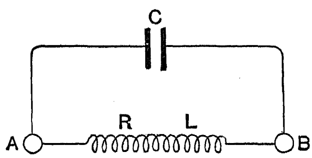

FIG. 26.

ductor of resistance R and self inductance L with capacitance C connected in parallel. If R′ and L′ be the effective resistance and inductance of the combination, we have

$$\left.\begin{matrix} R+Lj\omega \\ 1/Cj\omega \end{matrix}\right\} \text{ in parallel equivalent to } R'+L'j\omega,$$

or $$R'+L'j\omega=\frac{(R+Lj\omega)/Cj\omega}{R+Lj\omega+1/Cj\omega}$$

$$=\frac{R+[L(1-\omega^2LC)-R^2C]j\omega}{(1-\omega^2LC)^2+R^2C^2\omega^2}.$$

Separating the real and imaginary terms, we have

$$R'=\frac{R}{(1-\omega^2LC)^2+R^2C^2\omega^2}, \quad . \quad . \quad . \quad (7)$$

and $$L'=\frac{L(1-\omega^2LC)-R^2C}{(1-\omega^2LC)^2+R^2C^2\omega^2}. \quad . \quad . \quad . \quad (8)$$

In many cases in practice the term $R^2C^2\omega^2$ may be neglected and then

$$R'=R/(1-\omega^2LC)^2, \quad . \quad . \quad . \quad (9)$$

and $$L'=\frac{L(1-\omega^2LC)-R^2C}{(1-\omega^2LC)^2}. \quad . \quad . \quad . \quad (10)$$

At moderate frequencies, for inductance coils usually ω^2LC is small compared to 1 and R^2C may be neglected. Then the equations become

$$R' \doteqdot R(1+2\omega^2LC), \quad . \quad . \quad . \quad (11)$$

and $$L' \doteqdot L(1+\omega^2LC). \quad . \quad . \quad . \quad (12)$$

These last are Dolezalek's formulas.[1]

For resistance coils used with frequencies up to at least 2000 ~ per sec. the terms in $LC\omega^2$ may be neglected, and we have

$$L' \doteqdot L-R^2C, \quad . \quad . \quad . \quad (13)$$

and $$\text{time constant}=L/R-CR. \quad . \quad (14)$$

In this last equation R is in ohms, L in henries, and C in farads.

From equation (13) it will be seen that to a close approximation the effect of the self capacitance is independent of frequency.

§ (41).—If $R^2C=L$, then the effective inductance L′ is zero. So, if the self capacitance have the proper value (L/R^2), the inductance L will be exactly counterbalanced and the resistance coil will be non-inductive. Table II. gives the values of the compensating C required for some typical values of R and L. The examples in the table show that for the lower resistances the compensating capacities are relatively large, while for the high resistances they are very minute.

TABLE II

R.	L.	Compensating K.
ohms.	microhenries.	microfarad.
1	0·1	0·1
10	0·3	0·003
100	1·0	0·0001
1 000	10	0·00001
10 000	100	0·000001

G. A. Campbell[2] in 1904 suggested the above system of compensation by self capacity and investigated the design of compensated coils. A little later various observers (Curtis and Grover[3] at the Bureau of Standards, A. Campbell at the National Physical Laboratory, Orlich[4] at the Reichsanstalt, Wagner and Wertheimer[5] at the Kaiserliches Telegraphen-Versuchsamt) independently designed and constructed coils on this compensation prin-

[1] F. Dolezalek, *Elekt. Zeits.*, 1904, xxv. 152.

ciple, and nearly all of them used the same devices for the large and small resistances. The coils of lower resistance (1 ohm and 10 ohms, for example) are wound bifilar with thin manganin strip, the two halves of the loop being separated from one another by a thin strip of silk or mica. At the N.P.L. special silk-covered strip was used. Time constants as low as 0·05 and 0·015 microsecond for 1 ohm and 10 ohms respectively can be attained. For 100 ohms, if the proper length be measured off of double silk-covered manganin wire of 0·19 mm. diameter (No. 36 S.W.G.), doubled back as a loop and the two wires twisted together, the effective inductance usually is extremely small. The double wire can be wound in single layer on a bobbin or a piece of mica and the whole paraffined or shellacked. The effective self inductance comes out about 0·2 or 0·1 microhenry (or less) and the time constant of the order of 0·0015 microsecond. For 1000-ohm coils ten sections (in series) of 100 ohms each may be used (or five sections of 200 ohms each); in the latter case Curtis and Grover use manganin wire of 0·10 mm. diameter. When only small current-carrying capability is required, a 1000-ohm coil can be wound without sections by using a much shorter length of thinner wire. 10,000-ohm coils can be built up from thousands.

§ (42) Very Thin Wire Resistances.—For use with very small currents the lower resistances of the order of 1 to 10 ohms can be made of bifilar loops of very thin constantan wire up to a few centimetres in length, and this system has the advantage that it is applicable to radio frequencies as it avoids increase of effective resistance due to skin effect. These thin wire resistances should be immersed in oil to give better current capability. Consider, for example, constantan wire of 0·04 mm. diameter, which has a resistance of about 3·6 ohms per cm. If the distance apart of the two wires of the bifilar loop is 0·4 mm., the self inductance will be roughly 0·0065 microhenry per cm. of total length, and hence the time constant will be about 0·002 microsecond per cm. The difficulty of adjusting such short loops is a distinct disadvantage in this type of resistance.

§ (43).—Orlich's method of construction is applicable to coils of resistance from 3000 up to 20,000 ohms. It consists of unifilar winding in two layers with opposite directions of winding (heterochiral), one being directly over the other but separated from it by a considerable distance (2 to 5 mm.). A coil of 25,000 ohms on this system gave a time constant of −0·45 microsecond.

An older system of reducing the capacitance in the coils of higher resistance is that of Chaperon,[1] in which the winding is unifilar in an even number of layers, the direction of winding being reversed in alternate layers. It is much better than the old bifilar system, which gives in certain cases time constants ten times as great.

When considerable power has to be dissipated in the resistance the type introduced by Duddell and Mather[2] is convenient for high resistances. In it fine silk-covered resistance wire is woven into a warp of silk threads. The spacing of the wire is arranged so as to make the capacitance compensate the inductance as nearly as possible.

High resistances of very small inductance can be made from rods of suitable mixtures of graphite and clay baked at a high temperature.[3] Good connection is made to the ends by copper-plating them.

Another system is that devised by Kundt, in which a film of platinum is deposited on a porcelain tube, and then by means of screw thread tracks divided into two parallel spiral strips joined at one end.

§ (44).—For the higher resistances tubes containing poorly-conducting liquids are sometimes employed. A good solution for the purpose is that suggested by Nernst[4] (from the results of Magnanini's experiments). It[5] consists of a $\frac{5}{8}$ normal solution of mannite and boric acid (121·1 gm. of mannite and 41·2 gm. of boric acid made up to one litre in water). Its resistance temperature coefficient is negative below 15° C. and positive above it. The addition of 0·04 gm. of KCl per litre raises the point of minimum resistivity to about 20° C. and gives smaller temperature coefficients. A tube 50 cm. long of cross-section about 0·75 sq. cm. gives a resistance of about 50000 ohms. The electrodes are flat discs of platinum foil. Schering and Schmidt found that the apparent self capacity of a tube of 10000 ohms resistance falls off with increase of frequency as shown in Table III.

Table III

Frequency.	Capacitance.	Frequency.	Capacitance.
~ per sec.	$\mu\mu$F.	~ per sec.	$\mu\mu$F.
25·3	67	500	2·1
49·4	21	997	1·6
91·6	7·9	2025	0·1
261	2·5		

§ (45).—For the winding of large air-cooled resistance frames capable of dissipating 100 to 150 watts, a system due to A. Campbell has

[1] Chaperon, *Comptes Rendus*, 1889, cviii. 799.

[2] W. Duddell and T. Mather, *Electrician*, 1905, lvi. 54.

[3] J. A. Fleming, *Electrician*, 1899, xliii. 492 and 497.

[4] *Zeits. Phys. Chem.*, 1894, xiv. 622, and 1890, vi. 58.

[5] H. Schering and R. Schmidt, *Archiv f. Elektrotech.*, 1913, i. 423.

been in use in the N.P.L. since about 1902; it is convenient for values from 50 ohms up to 1000 ohms and even higher. On slotted rails at the top and bottom of a wooden frame two insulated wires (of equal resistance) are wound in opposite directions, as shown diagrammatically in *Fig.* 27.

There are fifteen to twenty slots and the wires are tied together at many points to ensure

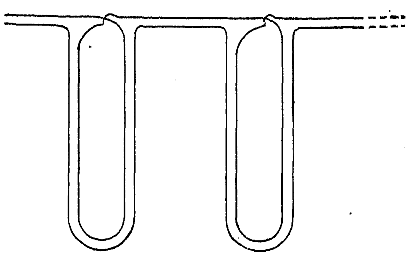

FIG. 27.

closeness. The two windings are connected in parallel. Some years later this system of winding was applied by Ruhstrat to non-inductive rheostats in which the wires, insulated merely by a film of oxide, are wound heterochirally on a porcelain cylinder.

With regard to all the systems described it should be kept in mind that, when the highest accuracy is required, the residual self inductances of all coils used should be tested by actual measurement; this is particularly advisable during the construction of new coils. The permanence of the compensation of inductance by capacitance depends on the constancy of these quantities, and care must be taken to avoid variation in capacitance due to changes in the insulating material, as for example when moisture is absorbed by shellacked silk.

§ (46) LOW RESISTANCES.—Resistances from 0·1 ohm downwards are usually constructed of thin sheet metal (such as manganin), and should have four terminals, one pair being for the current and the other for the potential difference. By doubling the strip of sheet metal back on itself and bringing the two halves as close as possible (with insulation between) the self inductance can be made very small. Ayrton and Mather[1] on this system constructed non-inductive resistances using varnished silk ribbon between long metal strips. Orlich[2] investigated this system for small resistances and constructed a series going down to 0·001 ohm, using manganin strips clamped together with thin mica (0·1 to 0·3 mm. thick) between them. The 0·01 ohm had a time constant of 1·3 microseconds, and the 0·001 ohm one of 5·1 microseconds.

In *Fig.* 28 is shown a diagrammatic end view of the 0·003 ohm, which is oil-cooled. The strip, which has a total length of 50 cm., is in three pieces, A, B, C, bent as shown. A and C are hard-soldered at P and Q to thick copper strips, and the upper ends of these at H and J are connected to massive terminals. Copper strips are hard-soldered to the four lower edges of A, B, and C, and when the whole is fitted together these copper strips are sweated together with soft solder at D and E, being drawn tightly together with screws when the solder is fluid. The dotted lines indicate insulating material, which is shellacked mica between the sheets and thin ebonite between the copper strips. The case, which has a vane stirrer at the bottom, is immersed in an oil bath. If the bath is water-cooled the resistance will bear a load of 100 watts.

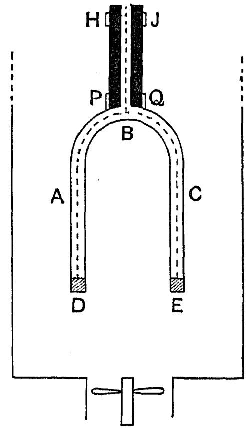

FIG. 28.

§ (47). A quite different system was suggested by A. Campbell,[3] having been foreshadowed by Lichtenstein.[4] In this the self inductance was compensated for by arranging the leads to the potential terminals in a special manner. In *Fig.* 29 let ACB represent a resistance

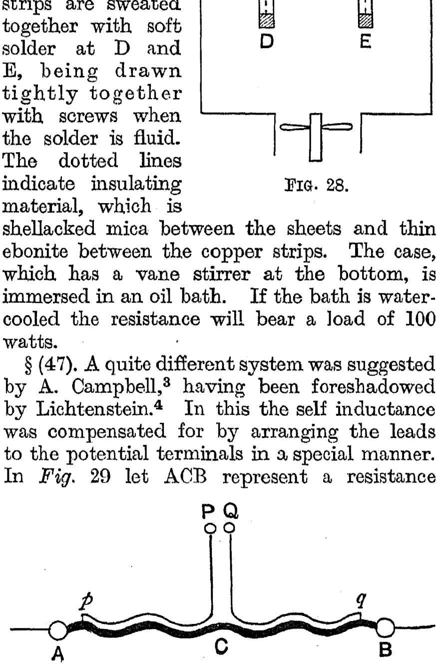

FIG. 29.

having self inductance, A and B being the current terminals, and p and q the potential points. If the leads from p and q to the potential terminals P, Q be of similar form to ACB and brought as close to it as possible (with insulation between), then the effective self inductance will be very much reduced, since the closeness of the potential leads to ACB excludes from the voltage circuit the greater part of the magnetic field round ACB which causes the self inductance. This system was carried out by Paterson and Rayner[5] in

[1] W. E. Ayrton and T. Mather, *Phys. Soc. Proc.*, 1892, xi. 269.
[2] E. Orlich, *Zeits. Instrumentenk.*, 1909, xxix. 241.

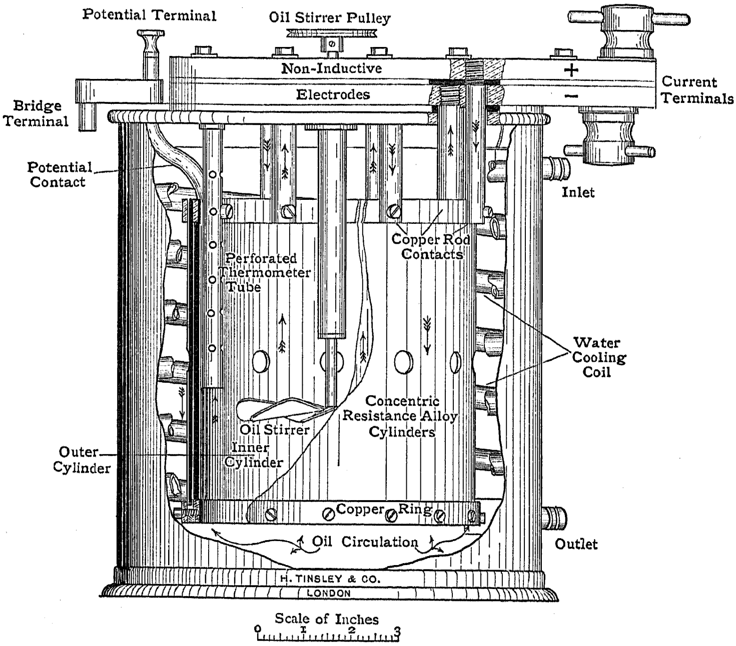

FIG. 31.

the construction of a series of water-cooled tubular resistances at the National Physical Laboratory. In these the leads to the potential terminals consist of two tubes of thin sheet metal concentric with the main tube and separated from it by a layer of varnished cloth 0·2 mm. thick. The time constants varied from 0·16 microsecond for 0·04 ohm up to 3·0 microseconds for 0·001 ohm. The two resistances, which are shown in *Fig.* 30, have current capabilities of 50 and 2000 amperes respectively.

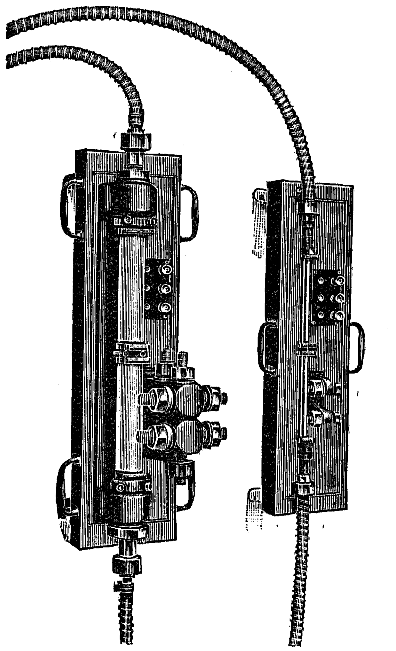

FIG. 30.—Paterson and Rayner's Water-cooled Resistances of 0·001 and 0·04 ohm at the National Physical Laboratory.

§ (48).—Silsbee [1] has discussed the theory of tubular resistances and has suggested a variety of interesting forms. One of these (0·001 ohm) gave a time constant as low as 0·5 microsecond. This was constructed like a concentric main with an inner tube of resistance material and an outer of copper forming the return circuit.

For resistances from 0·001 down to 0·0002 ohm Drysdale [2] used a pair of concentric cylinders close together and joined at the lower end. The current passes down one of them and returns by the other. In this system, as in Orlich's and Silsbee's, the external field produced by the current is very small and hence not liable to cause disturbance in other circuits. An oil-cooled resistance of this type is illustrated in *Fig.* 31.

It is provided with an oil stirrer, and an outer spiral tube traversed by running water keeps the oil cool.

[1] F. B. Silsbee, *Bureau of Standards Bulletin*, 1916, xiii. 375.

[2] C. V. Drysdale, *Electrician*, 1910, lxvi. 341.

§ (49) Rheostats.—Along with non-inductive resistance boxes it is often necessary to use a continuously adjustable rheostat to give sufficiently fine setting of the resistance. A rheostat for this purpose does not always require to be non-inductive; it is sometimes quite sufficient that it should have constant inductance over its whole range of resistance.

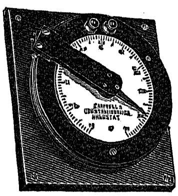

Fig. 32.—Campbell Constant Inductance Rheostat.

Campbell's constant inductance rheostat is illustrated in *Fig.* 32. It consists of a marble or slate disc having a manganin and a copper wire of equal diameters mounted parallel to one another on its rim, with turning radial arm carrying sliding contact pieces which make connection across from one wire to the other. The principle of working is made clearer in *Fig.* 32A, in which *a* and *b* are the terminals, *p* and *r* the manganin and copper wires respectively, *q* the return lead running between them, and *s* the cross contact piece carried by the turning arm. As *s* is moved from left to right the resistance is increased as more of the manganin is brought into circuit while an equal length of copper is cut out. As the wires are equal in diameter the self inductance remains constant to a close

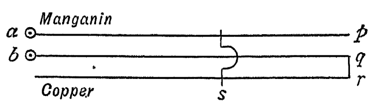

Fig. 32A.

approximation. The most usual range is 1 ohm. The turning arm carries a pointer indicating the approximate resistance on a scale. As the contact resistances come into the total resistance, the contacts should be kept good by applying a trace of paraffin oil to the wires from time to time. When very fine adjustment is required, in series with this rheostat may be put a double channel containing mercury with a sliding copper piece connecting across from the one channel to the other. This may consist of a piece of ebonite having two deep grooves cut in it, say 10 cm. long and 3 mm. wide, with a very thin wall (1 to 2 mm.) left between them. The total inductance is small, and only small movements of the slider are required if the rheostat is first set with care.

§ (50).—Another rheostat of practically constant inductance is that of Wenner and Dellinger,[1] and it is particularly adapted for very low resistance adjustment. It is shown in section in *Fig.* 33.

A vertical ebonite tube *a*, with copper terminal blocks *c*, *c′* at the top and bottom, contains mercury (*b*), into which dips a copper rod *d* held in position by a spring clip *e*. The rod and terminal blocks are amalgamated where they touch the mercury. As the rod is moved up or down it short-circuits less or more of the mercury resistance, and very smooth and fine adjustment is thus obtained. By using tubes of different-sized bores a variety of ranges can be got, but it is not desirable to go below 1 mm. diameter of bore. With this minimum size of bore a tube 12 cm. long gives a range of about 0·1 ohm.

Another type of Wenner and Dellinger's rheostat is shown in *Fig.* 33A in the form made by R. W. Paul. It consists of a U-tube with one limb wide and the other narrow, thus giving both a fine and a coarse adjustment.

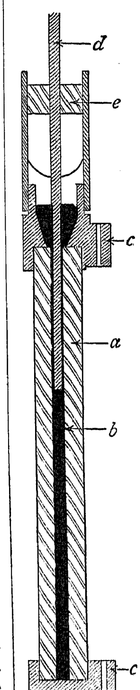

Fig. 33.

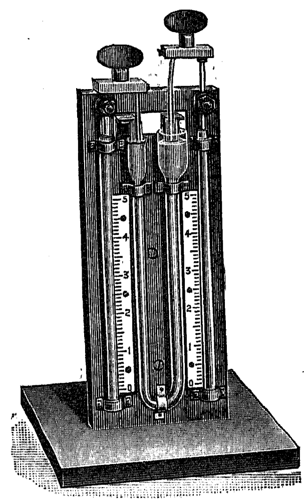

Fig. 33A.—Wenner and Dellinger's U-Tube Mercury Rheostat (R. W. Paul's Pattern).

V. Construction of Standard Inductances

§ (51) Mutual Inductance, Fixed Standards.—Of primary standards of mutual inductance the most commonly used form has been a long solenoid with a secondary coil near the middle of its length. The solenoid (which forms the primary circuit) is wound as evenly as possible on a supporting tube, and the secondary coil is either (1) outside the primary and as close as possible to it, or

[1] F. Wenner and J. H. Dellinger, *Phys. Review*, 1911, xxxii. 614, and 1911, xxxiii. 215; also *Bureau of Standards Bulletin*, 1912, viii. 584.

(2) inside it and wound on a separate supporting tube or bobbin. In case (1) the mean area of the secondary coil is taken as equal to that of the solenoid, while in case (2) the mean area of the secondary coil must be carefully measured: its supporting tube or bobbin should be made of some permanent material (*e.g.* stabilit or marble) constructed so as to allow of accurate measurement. It is a good plan to cut holes or radial slots in the flanges of the bobbin permitting the winding to be seen and the diameters measured by a micrometer microscope. Care should also be taken to mount the bobbin with its mean plane perpendicular to the axis of the solenoid. Two sources of uncertainty may be mentioned: the measurement of the small secondary coil is liable to error and there is great difficulty in winding the long solenoid uniformly enough.[1] The supporting tube should be of insulating material such as ebonite or (better) stabilit, and the winding should be in a screw thread if possible.

§ (52).—Let the solenoid be l centimetres long, with N_1 turns. If H is the magnetic field at the centre due to a current of i amperes, then

$$H \doteqdot \frac{4}{10}\,\frac{\pi N_1 i}{l}. \quad . \quad . \quad . \quad (15)$$

More nearly $$H \doteqdot \frac{4}{10}\,\frac{\pi N_1 i \cos\phi}{l}, \quad . \quad . \quad (16)$$

where $\tan\phi = (\text{solenoid diameter})/l$.

If $\tan\phi$ is a small fraction,

$$\cos\phi \doteqdot 1 - \tfrac{1}{2}\tan^2\phi.$$

As an example of this correcting factor, let the diameter be 8 cm. and the length 100 cm. Then $\cos\phi \doteqdot 0{\cdot}003$, a correction of 3 parts in 1000. If the secondary coil have N_2 turns and mean area s, and if M be the mutual inductance, then

$$M \doteqdot \frac{4\pi N_1 N_2 s \cos\phi}{l} \text{ in abhenries} \quad . \quad . \quad (17)$$

$$\doteqdot 4\pi N_1 N_2 \left(\frac{s}{l}\right) \cos\phi \times 10^{-9} \text{ in henries.} \quad (17\text{A})$$

§ (53).—Searle and Airey[2] have given a much more accurate formula for the calculation of the mutual inductance of a system of this kind with single layer coils, when the dimensions are known with accuracy. It is not easy, however, to get a conveniently large inductance with this type of construction, as will be seen from the following example:

Primary Coil: length 30 cm., diameter 10 cm., turns 300.

Secondary Coil: length 5 cm., diameter 8 cm., turns 200, giving a mutual inductance of 1·1999 millihenries.

[1] See E. Gehrcke and M. v. Wogau, *Verhandl. Deutsch. Phys. Gesellschaft*, 1909, xi. 664, and 1911, xiii. 448.

[2] G. F. C. Searle and J. R. Airey, *Electrician*, 1905, lvi. 318.

The standard solenoid used in the Physikalisch-Technische Reichsanstalt[3] belongs to the first type, in which the secondary coil is outside the solenoid. It consists of a solid marble cylinder a little more than 80 cm. long, on which the primary coil of bare copper wire is wound in a screw thread of 1 mm. pitch, the diameter of the cylinder being about 4·8 mm. The secondary coil has a winding of 1290 turns.

§ (54) Campbell Standard Mutual Inductance.—In a primary standard of mutual inductance, as the value is calculated from the dimensions, the design must be such as to allow of accurate measurement of all the important dimensions. Also the nature of the materials and the construction must be such as to ensure permanency. There is always considerable uncertainty in determining the dimensions of many-layered coils, and modern experience has shown that a single-layered coil wound with bare wire in a screw thread on a marble cylinder gives the nearest approach to ideal conditions. If, however, both primary and secondary circuits are single-layer coils, it is not easy to obtain a value of the mutual inductance (M) large enough for practical requirements, since with given dimensions M is proportional to N_1N_2, the product of the primary and secondary turns. In Campbell's type[4] of fixed mutual inductance the primary only is single-layered, while the secondary is a many-layered coil of many turns, but the geometrical design of the system is such that the dimensions of the secondary coil do not need to be determined with high accuracy, as the accuracy of the calculated value of M is made to depend very much more on the measurement of the

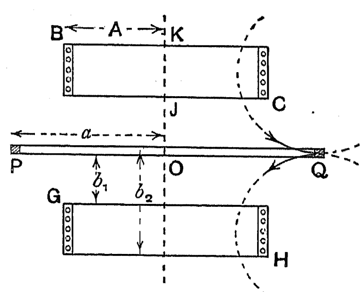

Fig. 34.

dimensions of the primary coil. The arrangement of the coils is shown in the diagram of *Fig.* 34. The primary circuit consists of two equal single-layer coils BC and GH in series, wound on the same cylinder with a gap

[3] E. Gumlich, *Wissenschaftl. Abhandl. der P.T.R.*, 1918, iv. 276.

[4] A. Campbell, *Roy. Soc. Proc.*, 1907, lxxix. 428, and 1912, lxxxvii. 391.

between them. The axial length of this gap is equal to the axial length of one of the coils. The secondary consists of a channel-wound coil PQ concentric and coaxial with the primary coils and placed midway between them. Its mean radius a is made about 1·46 times that of the primary coils (A), and for this size the mutual inductance M is a maximum. Thus the central winding of the secondary coil lies in a region throughout which the magnetic field (due to current in the primary) is zero.

As shown in the figure, the magnetic lines of force due to the upper and lower primary coils are tangential to one another at Q and in opposite directions, and hence the resultant field at that point is zero. Table IV. has been calculated for the following dimensions: $A=10$ cm., $b_1=5$ cm., $b_2=10$ cm., and $N_1N_2=100{,}000$. It will be seen from the values given that near the value $a=14·6$ cm. a considerable change

TABLE IV

a.	M.	$\delta M/\delta a$.
cm.	millihenries.	
14·1	9·1631	+0·05595
14·3	9·1722	+0·03182
14·5	9·1759	+0·009109
14·7	9·1754	−0·012401
14·9	9·1696	−0·032148

in a makes very little change in M. In this position the M is a minimum for axial displacements. Thus the value of M is not much affected (1) by slight variations in a, or (2) by small radial or axial displacements of the whole coil.

Result (1) allows a many-layered coil to be used, and result (2) ensures that very exact adjustment of the position of the secondary coil relative to the primary is not necessary.

The value of M is calculated by Viriamu Jones's formula.[1]

Fig. 35 shows the actual standard of this type constructed at the National Physical Laboratory.

The dimensions are approximately as follows:

Primary Coils (75 turns each): diameter 30 cm., distance between inner ends of coils 15 cm., between outer ends 30 cm.

Secondary Coil (485 turns): mean diameter $43·73_7$ cm., axial depth 1·00 cm., radial depth 0·86 cm.

The actual value of M is 10·0178 millihenries.

The secondary coil is wound in a channel in a thick marble ring, which is supported on a ring tray of mahogany with ebonite feet and levelling screws. By these screws and the other horizontal ones shown in the figure the secondary coil is brought into its correct position before the standard is used. The vertical adjustment is made as follows: An alternating current is sent through the primary coils in series but with the connections of one of them reversed (to make their magnetic fields oppose one another), a telephone or vibration galvanometer is connected to the secondary terminals and the height of the coil is adjusted until the telephone or galvanometer shows that no voltage is induced in the coil. The chief disadvantage of this type of standard is that the secondary coil possesses considerable self-capacity, arising from the necessary crowding

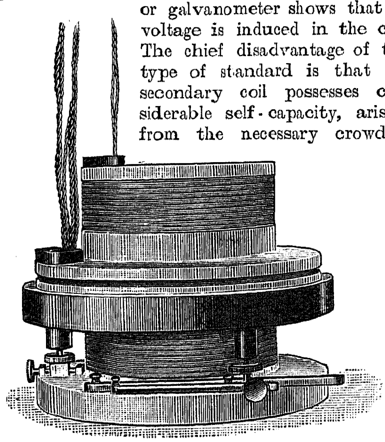

FIG. 35.—Campbell Primary Standard of Mutual Inductance at the National Physical Laboratory.

of its turns into a small channel. There is, however, very little intercapacity between the primary and secondary coils. As the primary coils are wound with bare hard copper wire under considerable tension the temperature coefficient of the mutual inductance may be taken as that of the expansion of the marble, namely, about +3·5 parts in 1,000,000 per degree C. Careful remeasurements in 1914 gave $M=10·0177_8$ millihenries, which is almost identical with the value ($10·0178_5$) obtained in 1908.

§ (55) SECONDARY STANDARDS.—When an accurate primary standard of mutual inductance has been set up, it is easy, by methods to be described below, to derive from it secondary standards having the same magnitude or being multiples or fractions of its value. These can be designed of a much more portable and

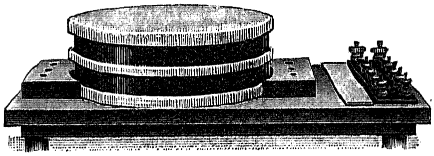

FIG. 36.—Secondary Standard of Mutual Inductance at the National Physical Laboratory.

convenient form than the primary standard. For ordinary and large values a good type consists of two many-layered coils wound on a double bobbin made from a single piece of marble or well-paraffined wood. In *Fig.* 36 is shown a standard of this kind which was constructed in 1905 at the National Physical Laboratory.[2]

The bobbin is of white marble and has two winding

[1] J. Viriamu Jones, *Roy. Soc. Proc.*, 1898, lxii. 247.

[2] A. Campbell, *Phys. Soc. Proc.*, 1907, xx. 626, and *Phil. Mag.*, 1907, xiv. 494.

spaces of 2·5 cm. axial length each, separated by a flange 1 cm. thick. The inner and outer diameters of the winding spaces are about 19 and 24 cm. respectively. The primary winding fills one of the spaces, and in the other space there are three coils (superimposed) giving mutual inductances of 50, 10, and 1 millihenries respectively. Double silk-covered wire was used, and, after winding, the whole bobbin was heated for several hours in melted paraffin. In a standard of this type the various sections can be brought very near to their correct values by small adjusting coils fixed underneath the large bobbin. An external adjustment of this kind is particularly necessary for coils of small number of turns, whether for self inductance or mutual. When the adjustment has been made correct to within one turn, the final setting can often be made by bringing one end of the wire out along one flange of the bobbin (in a groove or otherwise) so as to form the equivalent of a fraction of a turn either positive or negative in value. This system of adjustment is quite applicable to coils that are inaccessible due to the super-position of other windings.

§ (56).—A more modern standard of this type at the National Physical Laboratory consists of a much smaller double marble bobbin wound with well-stranded double silk-covered copper wire and kept immersed in paraffin oil. It has a temperature coefficient of about 10^{-5} per degree C., and has shown very satisfactory constancy. In a standard wound in this way the variation with temperature is mainly due to the expansion of the copper wire.

Campbell has found that temperature compensation can be to some extent applied by using a copper coil overwound with an aluminium one. With proper choice of their relative dimensions complete compensation is theoretically possible. If both coils had the same coefficient of expansion the M would increase with rise of temperature, but as the aluminium is more expansive than the copper, the mean distance between the coils is more than proportionately increased, and this causes a diminution of the M, which can be arranged to balance the increase.

The small temperature coefficients of mutual inductance standards is of more importance than may appear at first sight, for the physical embodiment of mutual inductance has greater permanence in accuracy than that of any of the other electrical quantities, as it depends so entirely on geometrical configuration and so little on the materials of which the standard is constructed. Also for this reason mutual inductance forms the most usual basis for the absolute determination of the units of voltage and resistance.

§ (57).—A commoner form of secondary standard consists of a single bobbin with two windings one over the other. In order to avoid intercapacitance between the two circuits, which always gives troublesome effects, the coils should not be close up to one another, but should be separated by a good thickness of insulating material such as a number of layers of silk ribbon afterwards paraffined. In cases where the self-capacitance of the coils is objectionable, it can be reduced by using one of the special methods of winding to be described further on.

To obtain a number of values of M with one bobbin, the secondary coil may be wound in sections. Their separate values will add correctly when they are put in series and all have the same direction of winding. If any are connected up in the reverse direction, their values will count as negative and have to be subtracted from the sum of the others.

§ (58) Astatic Coils.—When using standards such as have been already described, the external magnetic fields produced by them may cause disturbance in the other working circuits, or the other circuits may in the same way induce disturbing voltage in them. This trouble can generally be avoided by care in the arrangement of the circuits. It can, if necessary, be more completely cured by winding the coils astatically, so that their currents produce no external field, and that a uniform alternating magnetic field induces no voltage in them. For complete astaticism the primary and secondary coils should both be evenly wound one over the other on an anchor ring of insulating material, and every layer of each circuit must go exactly round the ring. Such a system is difficult to construct and adjust. Less perfect astaticism is obtained when only the primary winding completely fits

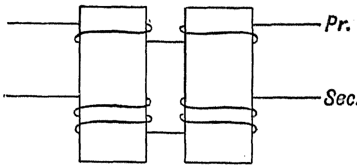

Fig. 37.

the ring, but sometimes this is sufficient. A simpler but less effective way is to wind two equal bobbins each with an identical primary and secondary winding, fix them close together and connect the windings in the directions shown in *Fig.* 37.

Astatic coils have the disadvantage that they require considerably more wire (for a given value of M) than coils with ordinary winding.

§ (59) General Conditions.—For the winding of secondary standards the wire should always be well stranded to minimise *skin effect*, by which in solid wire an alternating current tends to distribute itself un-uniformly through the section of the wire, having its greatest density at the surface of the wire. As the frequency is raised the skin effect increases, and the value of the mutual inductance will usually alter also. The strands

should be of thin wire well insulated. For a like reason, in the construction of the coils no metal parts (such as terminals) should be very near the windings, as induced eddy currents must be avoided. The insulation between the primary and secondary circuits should be extremely good, and all the materials of construction should be non-magnetic.

§ (60) VARIABLE MUTUAL INDUCTANCES.—For a great many measurements it is desirable to use a mutual inductance standard whose value can be varied continuously over a long range if possible. A standard of variable self inductance was named an *inductometer* by Heaviside,[1] and the name *mutual inductometer* is sufficiently distinctive to fit the corresponding mutual standard.

The more modern term *mutual inductor* is perhaps preferable, as it is more descriptive of the actual function of the instrument. The name *variometer*, introduced by M. Wien to designate a variable self inductance, seems too indefinite to be adopted with advantage. Mutual inductometers may be divided into classes according as their ranges are short or long.

For short-range standards it is sufficient to arrange that one of the two circuits (primary or secondary) can be moved relatively to the other, and that its position can be read off on a scale, which can be marked so as to read the inductance directly.

The mutual inductometer used by Lord Rayleigh [2] consisted of two narrow circular coils, of which the secondary was the larger and was fixed, while the smaller was inside it and could be rotated round a common diameter. The whole positive range is comprised within 90° of turning, the position for zero M being when the coils are at right angles; after passing through this position the M is negative and rises to a maximum at 90° on the other side. Lord Rayleigh showed that if the ratio of the mean diameters of the coils is $\sqrt{0{\cdot}3}/1$, *i.e.* 0·548, the mutual inductance is very nearly proportional to the angle through which the turning coil is displaced from the zero position up to about 70° of range. Thus for the greater part of the range the scale can be made almost uniform; it is also approximately symmetrical on the positive and negative sides of the zero line.

When two coils or circuits are so placed that there is no mutual inductance between them, the one is said to be in a *conjugate* position with respect to the other. In the Rayleigh inductometer there are two conjugate positions 180° apart.

§ (61) CAMPBELL MUTUAL INDUCTOMETERS.—Although a uniform scale may be useful in some cases, in general it is far better that the scale should open out very much as the readings diminish down to zero, for this allows the smaller values to be read with much greater accuracy, and thus extends the useful working range. If two coils P and Q be so mounted that one (P) is kept fixed and the other can be rotated about an axis such that the mean plane of Q is always parallel to that of P, then by proper choice of dimensions the mutual inductance scale can be made very open towards the zero reading and a range of nearly 180° can be obtained. This system is used in Campbell's mutual inductometers,[3] of which there are two types, one having a number of short ranges and the other having one very long range with proportionately increased accuracy.

The general arrangement of the coils for the short range type is shown diagrammatically in *Figs.* 38 and 39, which give plan and

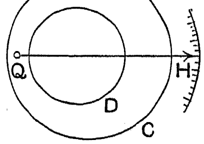

FIG. 38.

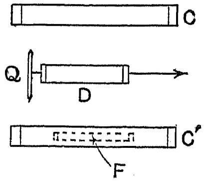

FIG. 39.

vertical section respectively. One of the circuits, which we may call the primary, consists of the two equal coils C and C′, which are coaxial and connected in series, with their windings in the same direction of turning. The secondary circuit consists of the coil D which can turn (midway between C and C′) about the excentric axis Q. The movable coil carries a pointer H which indicates the mutual inductance on a scale either directly or by the help of a multiplier. The character of the scale depends on a number of variables, namely, the diameters of the coils, their distance apart, and the distances between the axis Q and the axes of the coils. A sample scale is shown in *Fig.* 40; it will be noticed that it

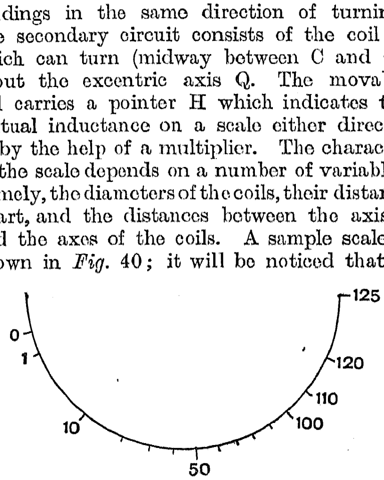

FIG. 40.

opens out at the higher readings as at the lower end, and includes a small negative part. This last portion is often useful, as it enables us to pass continuously through the zero

[1] O. Heaviside, *Phil. Mag.*, 1887, xxiii. 173.
[2] Lord Rayleigh, *Phil. Mag.*, 1886, xxii. 469.

[3] A. Campbell, *Phys. Soc. Proc.*, 1908, xxi. 69, and *Phil. Mag.*, 1908, xv. 155.

value. In *Fig.* 41 is given a picture of a short-range inductometer. The instrument also includes ratio arms to form a bridge. The scale is not long, but there are seven ranges corresponding to multipliers 1, 2, 5, 10, 20, 50, and 100, the lowest range being

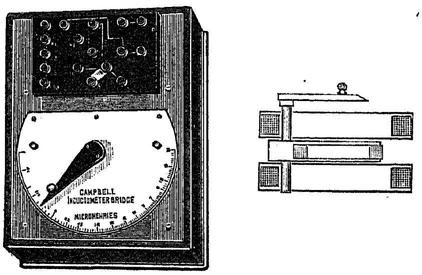

FIG. 41.—Campbell Inductometer Bridge.

from 0 to 10 microhenries. In this way a reasonably large reading can always be had for any inductance from 2 up to 1000 microhenries. The variety of ranges is got by a device which we proceed to describe.

§ (62) SUBDIVISION OF MUTUAL INDUCTANCES BY STRANDED WIRE COILS.—If the secondary coil of a mutual inductor be wound with well-stranded wire (of insulated strands) the mutual inductances between the primary and each of the strands of the secondary will be all practically equal, and these inductances can be added or subtracted by connecting the strands in series, the positive or negative sign being taken according to the respective directions of winding. For example, if ten strands are put in series, all in the same direction, the total mutual inductance will be almost exactly ten times that of one strand. To ensure close proportionality, the stranding must be as symmetrical as possible, every strand coming in turn to a similar position in the section. When sufficient care is taken in the stranding, and if the secondary coil consists of at least several turns not too close up to the primary coil, the accuracy of subdivision is usually within 1 part in 10,000. The equality of the strands can be best tested by opposing each in turn to any selected one, which should give almost zero mutual inductance. The same system can be applied to the primary winding, and in both cases it is only necessary to adjust the winding so as to make the total M correct, or to set one of the strands to the correct value. Thus we can either step up to multiples or down to submultiples of any M to which the adjustment is made. By this method the six ranges of the inductometer bridge (*Fig.* 41) are obtained. Caution must be used, however, in applying this system of subdivision, for the stranding introduces considerable distributed capacity which may cause error in certain cases. As already shown (equation (12)), the effective self inductance of a coil is given by the equation

$$L' \doteqdot L(1+\omega^2 LC),$$

and the self capacity C causes very little error when $\omega^2 LC$ is very small compared with 1. The conditions therefore are favourable when the frequency and L are small, for C is, in general, small. The effects of self capacity in the primary and secondary coils are more complicated and depend on the circuit in which the secondary is included. However, it will be found that, when the frequency is not high or the mutual and self inductances are small, no large error is introduced by the stranding system.

§ (63).—The Campbell mutual inductometer [1] of long range is illustrated in *Fig.* 42, and the

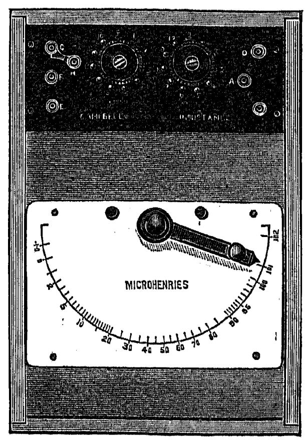

FIG. 42.—Campbell Mutual Inductometer (Long Range).

internal connections and the arrangement of the coils are shown in *Fig.* 43. One circuit, which for convenience of description we may call the *primary*, consists of two equal coils P and P_1, on fixed bobbins. For a purpose to be explained later, the exact centre point of the primary is brought out to the terminal *a*.

The secondary circuit consists of the movable coil S and the multiple coils BB and A, which can all be put in series, and the terminals are EF. By altering the link GH the connections of S are reversed and it can be checked against the first step on the lower dial. The moving coil S is mounted similarly to that of the inductometer bridge. As its plane is always midway between the two primary bobbins and not very near them, small variations in its vertical position have very little effect on the mutual inductance. The pointer

[1] A. Campbell, *Phys. Soc. Proc.*, 1908, xxi. 69, and *Phil. Mag.*, 1908, xv. 155.

and scale belong to this coil. The coils BB and A form the fixed part of the secondary and are on the same bobbins as P and P_1. They are each divided into ten equal sections which are brought out to two stud-switch

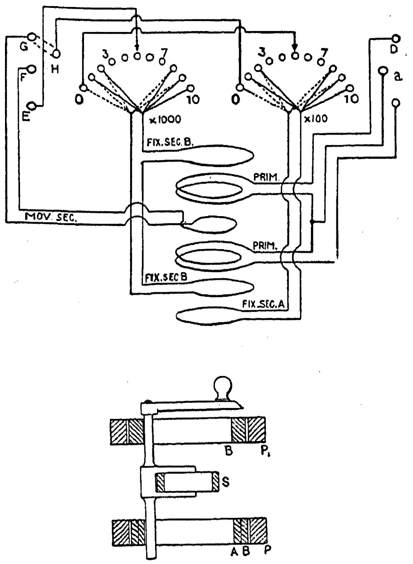

FIG. 43.—Arrangement of Coils and Connections in Campbell Inductometer.

dials, the first reading in steps from 100 up to 1000 microhenries, and the second from 1000 up to 10,000 microhenries. The higher sections are all adjusted separately. The total range extends from $-0{\cdot}2$ up to 11,000 microhenries, and at the higher part of the range the accuracy of reading is to 1 or 2 parts in 100,000. (In a slightly different type this instrument has a range up to 110 millihenries.) In the large inductometer at the National Physical Laboratory great permanence has been secured by winding all the coils on white marble bobbins which are themselves supported by a marble framework. It has a temperature coefficient of $+10$ parts in 1,000,000 per degree C. The mutual inductance increases by about 3 parts in 1000 when the frequency is raised from zero to 2000 ~ per sec.

§ (64). Other experimenters [1] have introduced mutual inductometers which are made astatic by duplicating the fixed or the moving coils or both. Toroidal coil mutual inductors have been constructed by Hanson [2] and by Fortescue; [3] in Fortescue's form the coils are wound on marble cores.

The system of subdivision by means of insulated strands forms a very simple method of constructing accurate mutual inductance standards having very small values. It is easy, for example, to build an inductometer reading to thousandths of a microhenry.

§ (65) SELF INDUCTANCE, FIXED STANDARD.—For primary standards of self inductance calculable from the dimensions much the best form consists of a single-layer coil of bare wire wound in a screw thread on a marble cylinder. The wire should be of copper, hard drawn to ensure elasticity. As it is wound on under considerable tension, it remains in close contact with the marble at all ordinary temperatures, and the temperature coefficient of the dimensions is practically that of the marble. The coefficient of expansion of marble varies with the thermal treatment, and lies between 2×10^{-6} and 12×10^{-6}.

As an example of a primary standard of this kind we may take the 10-millihenry coil constructed at the Physikalisch-Technische Reichsanstalt.[4] The marble cylinder has an outer diameter of 354 mm. and an axial length of 185 mm. It is wound with 162 turns of bare copper wire 0·5 mm. thick in a screw thread of 1 mm. pitch.

§ (66) SECONDARY FIXED STANDARDS OF SELF INDUCTANCE.—The best modern secondary standards of self inductance (fixed) usually consist of multiple-layered coils wound on white marble bobbins. To obtain the maximum self inductance with a given length and thickness of wire the coil should be of square cross-section and wound on a bobbin of the relative dimensions [5] shown in *Fig.* 44.

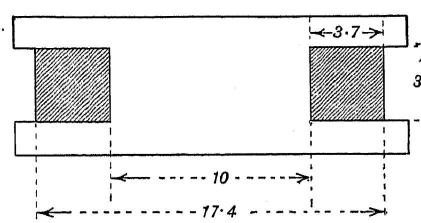

FIG. 44.

Here the outer diameter $=1{\cdot}74\times$ (inner diameter) and depth of winding $\doteq 0{\cdot}37\times$ (inner diameter). For these proportions the self inductance is given approximately by the formula

$$L \doteq 6\pi N^2 a \times 10^{-9} \text{ henries}, \quad . \quad . \quad (18)$$

where N is the total number of turns, and a the mean radius of the coil.

Professor T. Mather has shown that the time constant L/R is equal to $5{\cdot}4 \times 10^{-4}a^2$, when the wire is of copper of resistivity 1·630 microhm-cm. From this formula he has calculated the values given in Table V.:

Table V

a.	L/R.	Power Factor.
cm.	secs.	at 100 ~ per sec.
5	0·0135	0·117
10	0·054	0·0295
15	0·122	0·0131
20	0·216	0·00737
30	0·486	0·00328
40	0·864	0·00184
50	1·35	0·00118

To find the weight of copper wire required for a given time constant, H. Armagnat has given the following formula:

$$\text{Mass in kgm} = q(100\text{L/R})^{\frac{3}{2}}, \quad . \quad . \quad (19)$$

where q lies between 2 and 3.

§ (67). To minimise variation of inductance with frequency, due to skin effect, the coils should be wound with well-stranded wire. In the most perfect system of stranding the wires are first stranded in groups of 3 wires each, these groups being again combined three at a time, and so on. When very thin strands are used there is great risk of some of them being broken. Enamel insulation has the advantage of occupying little space, but silk gives more certain insulation and at least should be used on the complete stranded wire. After winding the coils should be kept in hot melted paraffin wax for several hours and allowed to cool slowly before being taken out. The process is best carried out in an air-tight enclosure partially exhausted by a filter pump.

The series of standard coils of this type at the National Physical Laboratory have the

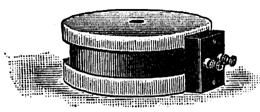

Fig. 45.—Self Inductance Coil (Secondary Standard) at National Physical Laboratory.

form shown in *Fig.* 45. The terminals are mounted at the side for two reasons, (*a*) in order to keep them away from the stronger part of the magnetic field of the coil and so avoid errors due to eddy currents, and (*b*) to allow of one coil being placed immediately over the top of another when it is desired to use them together. The coils are wound with wire stranded from double silk-covered copper wire of 0·19 mm. diameter with 7 strands for the larger coils and 19 for the smaller. The amount of space occupied by the insulation in such a case makes formula (18) inapplicable, and this must always be borne in mind when designing coils with stranded wire. For the 7-strand wire, with thin paper between each layer, about twice the winding space is required.

Giebe[1] has wound somewhat similar coils with much more highly stranded wire; in two of his coils, for example, the wire has $4 \times 3 \times 3 \times 3$—*i.e.* 108 strands of enamelled wire of 0·07 mm. diameter. He finds that for well-paraffined coils with various kinds of stranded wire the temperature coefficient of the self inductance varies from -23 to $+13$ parts in 1,000,000 per degree C.

§ (68) Distributed Capacitance in Multiple-layer Coils.—In closely wound multiple-layered coils the effects of distributed capacitance become more and more pronounced as the self inductance becomes greater. The following data given by Orlich[2] for two standard coils will indicate the order of the self capacitance to be expected:

Table VI

Thickness of Wire.	Number of Turns.	Mean Diameter.	Resistance.	Self inductance.	Self Capacitance.
mm.		cm.	ohms.	henry.	$\mu\mu$F.
0·5	1130	7·8	24	0·1	40
0·5	2894	12·2	94	1·0	150

From the values given it will be found (by equations (11) and (12)) that the self inductance of the 1 henry coil is 2·4 per cent less at 2000 ~ per second than at zero frequency, while its effective resistance is 4·8 per cent higher at the higher frequency.

For self capacities of single layer coils see § (115).

§ (69) Coils of very small Self Capacitance.—As the frequency is raised the self capacitance has more and more effect, and, especially when radio frequencies are reached, it becomes necessary to make the standard coils of such design as will give the smallest possible self capacitance. For the smaller values (up to about 1 millihenry) single layer coils can be used, but for the larger values special systems of winding are required. Various devices are employed, of which the two following will serve as examples.

(1) *H. Rein's System.*[3]—In this type the insulated wire is wound, as shown in *Fig.* 46, on a circle of spokes of insulating material fixed radially in a central disc. The single element thus formed is sometimes termed a pancake coil, and the larger inductances are constructed by assembling a number of these

[1] E. Giebe, *Zeits. Instrumentenk.*, 1911, xxxi. 33.
[2] E. Orlich, *Elekt. Zeits.*, 1903, xxiv. 504.
[3] H. Rein, *Radiotelegraphisches Practicum*, 2nd ed., Springer, Berlin, 1912.

flat coils one above the other with a small space between each coil and the next.

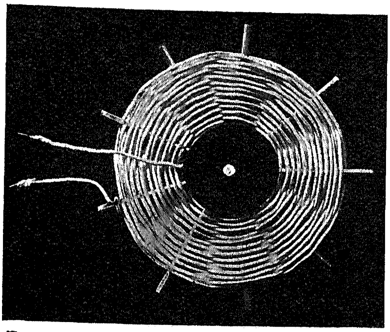

FIG. 46.—Single Coil of Rein Self Inductance.

(2) *A. Campbell's System.*—This method of winding is illustrated in *Fig.* 47. Two rectangular pieces of ebonite P and Q are fixed together at right angles as in the end view B. P and Q have at each of their outer edges a number of deep slots, each slot being just

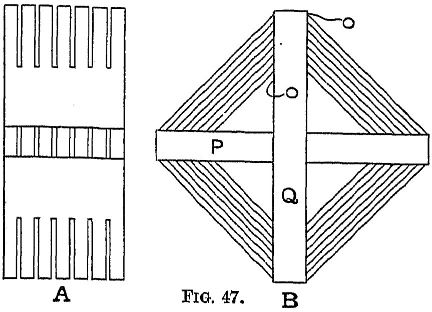

FIG. 47.

slightly wider than the diameter of the insulated wire to be used. The wire is wound into the slots so as to fill one after another, and thus the complete winding is formed of a number of pancake coils separated from one another by small spaces and held rigidly in their relative positions.

The system of winding in pancake coils ("slice winding") has long been used in another way by makers of large spark coils, and in that application it affords protection from breakdown, as it prevents points of the secondary circuit which are at very different potentials from being near each other.

§ (70) INSULATION OF INDUCTIVE COILS.—It is very important that in all standard inductance coils the insulation shall be very good. The effect of leakance on the effective resistance and inductance was first investigated by Rayleigh,[1] and later for a more general case by Campbell and Eckersley.[2]

[1] Lord Rayleigh, *Collected Papers*, ii. 566.
[2] A. Campbell and T. L. Eckersley, *Electrician*, Dec. 10, 1909.

In the more general case, let a leaky inductance coil be represented as in *Fig.* 48, R and L being resistance and self-inductance, K the self capacitance and S the leakage resistance. Let G be the leakance, where $G=1/S$, and let $Z=\sqrt{R^2+L^2\omega^2}$, where the pulsatance $\omega=2\pi\times$frequency.

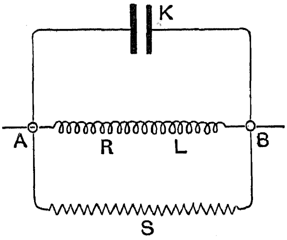

FIG. 48.

If R′ and L′ are the effective resistance and self inductance of the coil, then

$$R'=\frac{Z^2(R+GZ^2)}{(R+GZ^2)^2+\omega^2(KZ^2-L)^2} \quad . \quad (20)$$

and

$$L'=\frac{Z^2(L-KZ^2)}{(R+GZ^2)^2+\omega^2(KZ^2-L)^2}. \quad . \quad (21)$$

When $K=0$ we have the case treated by Lord Rayleigh, where

$$R'=R+\frac{G(Z^2-2R^2-RGZ^2)}{1+2RG+G^2Z^2}. \quad . \quad (22)$$

and

$$L'=\frac{L}{1+2RG+G^2Z^2}. \quad . \quad . \quad (23)$$

For a highly inductive coil, where R is small compared with the impedance Z, if the leakance G is relatively small (S very large compared with R), the equations become

$$R'\doteqdot R+GZ^2 \quad . \quad . \quad . \quad . \quad (24)$$

and

$$L'\doteqdot L(1-2RG-G^2Z^2). \quad . \quad . \quad (25)$$

An examination of equations (20) to (23) shows that a shunt (leakance) across the terminals of an inductive coil always lowers the effective self inductance, but may either raise or lower the effective resistance. For example, if $R=20$ ohms, $L=0{\cdot}1$ henry, at a frequency of 1000 ~ per sec. a shunt of 100,000 ohms put across the terminals increases the effective resistance to 24 ohms. The important practical fact is that, as the effective leakance includes the energy loss due to dielectric hysteresis in the insulation, its effect is not usually constant for different frequencies, as in nearly all insulating materials the energy loss increases with increase of frequency. For this reason if an inductance coil is wound with cotton-covered wire (and even boiled well in paraffin wax) it will usually be found useless as a standard owing to the presence of large dielectric hysteresis. Here, as in many other cases, the trouble arises largely from absorbed moisture, and the greatest care should be taken to avoid all insulating materials of this nature.

§ (71) EDDY CURRENTS.—In the construction of inductance coils metal parts of any kind should be avoided, particularly in positions

near the winding. If screws have to be used they can be of bone, ivory, or stabilit. If metal screws are necessary they should be of a high resistance material such as constantan. When these conditions are not observed, eddy currents, which are proportional to the square of the frequency, may be set up in the metal parts and cause both the effective resistance and the self (or mutual) inductance to vary with frequency.

A piece of metal anywhere near a coil (of resistance R and self inductance L) may be considered as a closed secondary circuit of resistance Q and self inductance N with mutual inductance M to the coil. Then the alterations in R and L due to the presence of the metal are given by the equations

$$R'-R=\frac{QM^2\omega^2}{Q^2+N^2\omega^2} \quad . \quad . \quad . \quad (26)$$

and

$$L'-L=-\frac{NM^2\omega^2}{Q^2+N^2\omega^2}. \quad . \quad . \quad (27)$$

§ (72) STANDARDS OF SMALL SELF INDUCTANCE.—When standards of small self inductance with high resistance are required, it is a common practice to use a pair of equal very thin wires stretched parallel to one another and joined at one end, since the self inductance of such a system is calculable with fair accuracy from the formula

$$L_0=\left[4l\log_e\left(\frac{2b}{d}\right)+l\right]10^{-9}\text{ henries,} \quad (28)$$

where l is the length of one wire, d the diameter, b the distance from wire to wire, and L_0 the low frequency self inductance. The effective self inductance L' is got from L_0 by correcting for the distributed capacity as already shown in equation (13)

$$L'=L_0-R^2C,$$

where $C=K/3$, K being the capacity between the wires when the ends are disconnected. When b is small compared with the distance from earth, K may be got from the formula [1]

$$K\doteq\frac{l\times10^{-6}}{3\cdot6\ \log_e(2b/d)}\text{ microfarads} \quad . \quad (29)$$

This formula assumes the wires to be in air. Sometimes they are used immersed in oil for cooling purposes, and then the above value of K must be multiplied by the specific inductive capacity of the oil.

§ (73) VARIABLE SELF INDUCTANCE STANDARDS.—Self inductometers (or inductors) have very much the same forms as those already described for mutual inductance. A long range is not conveniently obtained with self as it is with mutual inductance, for self inductances do not add algebraically in the simple way that mutual inductances do. The types to be described have all short ranges.

[1] A. Russell, *Alternating Currents*, i. 135, and O. Heaviside, *Phil. Mag.*, 1887, xxiv. 81.

Ayrton and Perry Inductometer.—One of the earliest inductometers is that of Ayrton and Perry [2] (*Fig.* 49). The fixed and moving coils are both wound on spherical surfaces of mahogany built up of sheets with the grains crossed to ensure permanence of form. It has a single range (from 5 to 50 millihenries) and its resistance is about 13 ohms, giving a time constant of 3·8 milliseconds at the top

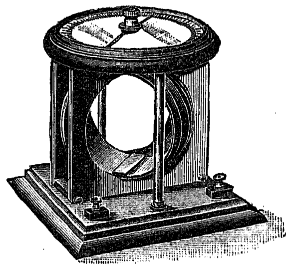

FIG. 49.—Ayrton and Perry Self Inductometer.

reading. Probably owing to the use of metal parts in the construction, the effective resistance at the higher readings is about 13 per cent greater at 1000 ~ per second than at low frequency, while the self inductance is less at the higher frequency by about 8 in 1000. The large areas of the coils cause the magnetic field to produce disturbance at considerable distances.

The coils are always used in series, and the range of angular motion of the inner coil (whose axle carries the indicating pointer) is about 165°. The scale can be graduated to read directly.

If two coils (fixed and movable) of self inductances L_1 and L_2 are in series and so placed that their mutual inductance is M, then M, being either positive or negative, may either help or oppose the self inductances. In one position of the movable coil the total self inductance is L_1+L_2+2M; if that coil be now turned round a diameter through 180°, the M will have the same value but of opposite sign, and the total self inductance will now be L_1+L_2-2M. This turning is equivalent to reversing the connections of the coil. Thus it is seen that in this type of inductometer the whole range lies within the limits L_1+L_2-2M and L_1+L_2+2M. Since it can be shown that L_1+L_2 is always greater than M, it is impossible to make the minimum reading zero. It is not difficult, however, by making the coils fit close to one another, with very little clearance between, to have the minimum reading not more than 1/10th of the maximum.

§ (74) WIEN INDUCTOMETER.—M. Wien [3] introduced an inductometer of the same type,

[2] W. E. Ayrton and J. Perry, *Electrician*, 1895, xxxiv. 546.
[3] M. Wien, *Wied. Ann.*, 1896, lvii. 249.

but of very much greater capability, for it has a large number of overlapping ranges from 0·6 up to 120 millihenries. To furnish so many ranges the fixed coil has four separate windings consisting of 2, 4, 8, and 16 layers respectively, and the turning coil has two windings of 2 and 4 layers. By the help of a small plug board the successive ranges are obtained by suitable combinations of the windings. The scale is in degrees and unfortunately requires a different calibration curve or table for each range.

The inductometers made by C. Lorenz of Berlin are very similar in form to the Ayrton and Perry instrument, but are wound with highly stranded wire on ebonite bobbins, so that they can be used at radio frequencies.

§ (75) Parallel Coil Self Inductors.—The system in which a movable coil turns round an axis perpendicular to the mean planes of the other coils has already been described for mutual inductors, and any of them could be calibrated so as to be used for self inductance also. A number of experimenters have brought out self inductors of this type, one or two of which may be noticed here.

In the Mansbridge inductometer, shown in *Fig.* 50, an ebonite disc carrying two "D"

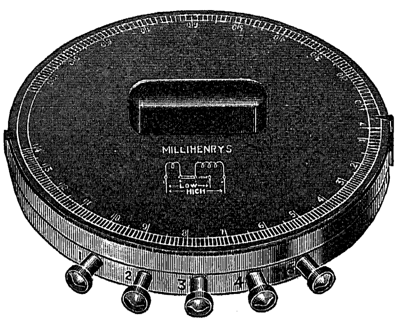

Fig. 50.—Mansbridge Self Inductometer.

shaped coils can rotate over another disc carrying a second pair of similar coils.

The coils are placed thus, ᗡD, and are embedded in the discs, this construction allowing the two circuits to be brought very close together, which gives relatively large mutual inductance and hence greater range of scale. There are two ranges with a direct-reading scale for each. All the coils are used in series for the higher range (9 to 105 millihenries), but only portions of each in series for the lower range (0·7 to 12 millihenries). The arrangement of the coils is astatic and the time constant is about 1·6 milliseconds at the maximum.

In an inductor of this type with only four coils, any slight accidental tilt of the moving disc may cause error. A better plan is to use two pairs of fixed coils above and below the moving system. Inductors of this kind were constructed some years ago at the National Physical Laboratory by D. W. Dye, using thin flat coils embedded in paraffin wax. The fixed and moving systems are moderately close together, and the coils are all made as nearly identical as possible in order to use Heaviside's device[1] of paralleling to give extra ranges. By means of two small switches the coils can be altered from series connection to parallel, giving two lower ranges of $\frac{1}{2}$ and $\frac{1}{4}$ of the maximum range.

At the Bureau of Standards, Brooks and

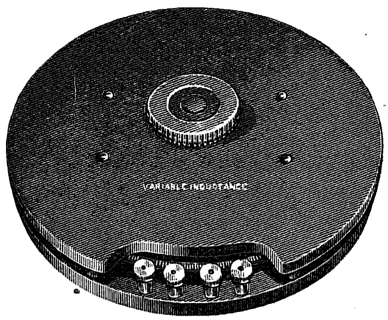

Fig. 50a.—Brooks and Weaver Variable Inductor.

Weaver[2] have built an inductor with three pairs of link-shaped coils designed to give a uniform scale over the greater part of its range. The dimensions of the coils were also chosen so as to approach the conditions for maximum self inductance (such as given by Maxwell for circular coils) at the highest reading. The complete instrument is illustrated in *Fig.* 50a, and consists of three ebonite discs (35·5 cm. diameter), each carrying a pair of coils, two of the discs being fixed together parallel to one another, while the third is between them and can be rotated about a central spindle. The shape of the coils and their relative positions and dimensions are shown in the illustration of the inner disc given in *Fig.* 50b. The coils are all connected in series when the instrument is used for self inductance, but by separating the circuits of the fixed and movable coils it can also be used for mutual inductance. As the scale reads directly for self inductance (from 125 to 1225 microhenries), when used for mutual inductance M is obtained from the formula

$$M = \tfrac{1}{2}(\text{Scale Reading} - 669).$$

The scale is practically uniform from a reading of 325 up to 1025. For the exact dimensions

[1] O. Heaviside, *Phil. Mag.*, 1887, xxiii. 186.
[2] H. B. Brooks and F. C. Weaver, *Bureau of Standards Bulletin*, 1917, xiii. 369.

of the coils which give this result the reader is referred to the original paper. The coils are wound with stranded wire (7 strands of

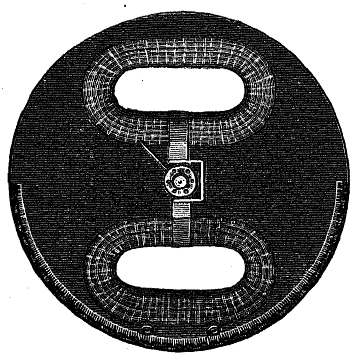

FIG. 50B.—Inner Disc of Variable Inductor.

0·8 mm. diameter each), and the time constant is 3·4 milliseconds at the reading for maximum self inductance.

VI. THE MEASUREMENT OF MUTUAL INDUCTANCE

§ (76) METHOD OF AMMETER AND VOLTMETER.—If no standard of inductance is available, an unknown mutual inductance can sometimes be measured by means of an ammeter and an electrostatic voltmeter. It is only necessary to send a known alternating current I of pure sine wave form through the primary coil and measure by an electrostatic voltmeter the voltage V_2 at the terminals of the secondary; the frequency n should be determined at the same time.

In *Fig.* 51 let M be the unknown mutual inductance, A an ammeter, and B an electrostatic voltmeter. Let i be the instantaneous value of the primary current, where $i=i_{\max}\sin\omega t$, and v_2 the instantaneous value of the secondary

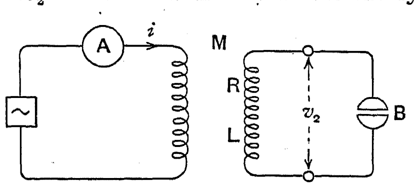

FIG. 51.

terminal voltage, I and V_2 being the corresponding effective values. Then

$$v_2=\mathrm{M}\frac{di}{dt}=\mathrm{M}\omega i_{\max}\cos\omega t. \quad . \quad . \quad (30)$$

Therefore $$\mathrm{V}_2=\mathrm{M}\omega\mathrm{I}, \quad . \quad . \quad . \quad . \quad (31)$$

or $$\mathrm{M}=\mathrm{V}_2/\omega\mathrm{I}.$$

For example, with mutual inductance of 10 millihenries a current of 1 ampere at a frequency of 100 ~ per sec. will give a voltage of about 6·28 volts at the secondary terminals.

If the wave form of i is not pure the harmonics will cause error, particularly as they induce components in v_2 proportional to their frequencies. The electrostatic voltmeter always has capacitance; let this be K. Then if R be the resistance and L the self inductance of the secondary circuit, it can be shown that

$$\mathrm{V}_2=\frac{\mathrm{M}\omega\mathrm{I}}{[\mathrm{R}^2\mathrm{K}^2\omega^2+(1-\mathrm{LK}\omega^2)^2]^{\frac{1}{2}}}. \quad . \quad (32)$$

In nearly all cases $\mathrm{R}^2\mathrm{K}^2\omega^2$ may be neglected, and then we have

$$\mathrm{M}\doteqdot\frac{\mathrm{V}_2}{\omega\mathrm{I}}(1-\mathrm{LK}\omega^2). \quad . \quad . \quad . \quad (33)$$

The capacity of an electrostatic voltmeter varies with the deflection; it may be as large as 0·0001 μF. For moderate values of L and ω this capacity will be found by equation (33) to introduce very little error. Care must be taken, however, to avoid the use of long twisted leads (particularly of flexible cord) in the voltmeter circuit.

§ (77) METHOD OF SIMPLE OPPOSITION.—For the measurement of mutual inductance

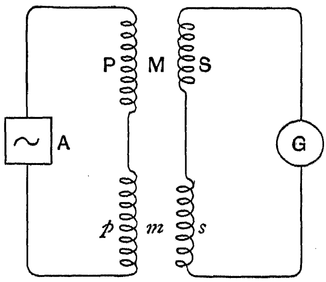

FIG. 52.

the simplest method is that of direct opposition as shown in *Fig.* 52.

If M is the mutual inductance to be measured, it is connected to a mutual inductometer, so that their primary coils P and p are in series with each other and an alternating source A, while the secondaries are in series and connected to a detector G, such as a vibration galvanometer or a telephone. The secondaries must be connected so that their induced voltages are in opposition; the right direction is found by trying which way gives the smaller want of balance in the detecting instrument. The inductometer (m) is then adjusted until a balance is obtained, the galvanometer or telephone indicating that the secondary current is zero. Then $\mathrm{M}=m$.

In this test, as in most others also, if a vibration galvanometer is used, it is well to have a turning switch with a graduated series of shunts connected across the leads to the

galvanometer, which should be kept shunted until an approximate balance has been obtained. With a long-range inductometer and at the high part of its range it is easy to *read* to an accuracy of 1 part in 100,000. This method is only limited by the condition that the value of the unknown inductance must lie within the range of the inductometer. If a multiple-range inductor be used the greatest accuracy will be got by reading on the lowest range on which a balance can be obtained.

Sometimes it will be found that an exact balance cannot be got, but only a minimum in the galvanometer or telephone. This is generally due to distributed capacitance or eddy currents in one or both of the inductances (M and m). Let us consider capacitance first.

In *Fig.* 53 for simplicity let only the secondary coil of M have self capacitance K, the inductometer

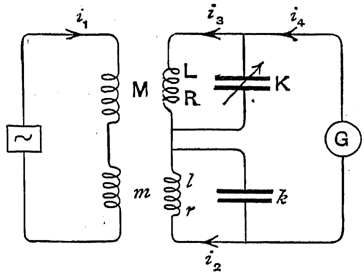

FIG. 53.

being supposed to have none. Then if an adjustable condenser k be put across the secondary of m, by adjusting k as well as m a perfect balance can be obtained.

Let the resistances and self inductances of the secondary circuits be R, r and L, l respectively, and let the instantaneous currents be i_1, i_2, i_3, and i_4 as shown, ω being the pulsatance $2\pi n$.

Then, when a balance has been obtained, $i_4=0$, and the voltages across K and k must be equal and opposite. Thus we have

$$i_2/j\omega k=i_3/j\omega \mathrm{K},$$

also
$$\left(r+j\omega l+\frac{1}{j\omega k}\right)i_2=j\omega m i_1$$

and
$$\left(\mathrm{R}+j\omega \mathrm{L}+\frac{1}{j\omega \mathrm{K}}\right)i_3=j\omega \mathrm{M} i_1.$$

Hence
$$\frac{\mathrm{M}}{m}=\frac{1-\omega^2\mathrm{LK}+j\omega\mathrm{RK}}{1-\omega^2 lk+j\omega rk}$$

Separating the real and imaginary parts we obtain

$$\frac{\mathrm{M}}{m}=\frac{\mathrm{RK}}{rk}=\frac{1-\omega^2\mathrm{LK}}{1-\omega^2 lk}. \quad . \quad . \quad (34)$$

If $\omega^2 lk$ and $\omega^2\mathrm{LK}$ are both small compared with 1, then $\mathrm{M} \doteqdot m$, and

$$\mathrm{M}/m \doteqdot 1-\omega^2 k(\mathrm{L}r/\mathrm{R}-l). \quad . \quad . \quad (35)$$

Thus we can find the correct value of M in spite of the presence of self capacity.

At the National Physical Laboratory this method is used in comparing secondary standards (inductometers) with the primary standard already described. The secondary coil of this latter has a self induction of 0·26 henry and a self capacity of about 0·0026 μF. Both of these values would of course be excessive in any working secondary standard.

The method can be carried out without alternating current by replacing the alternating source by a battery with a reversing switch, and using a ballistic galvanometer as the detector. The inductometer is then adjusted until reversal of the primary current gives no throw of the ballistic galvanometer. This system avoids the effects of self capacity, but is in general much less sensitive than when alternating current is used.

§ (78).—In an ideal mutual inductance ϕ, the angle of lag between the primary current and the secondary induced voltage is exactly 90°, and when this is the case the inductance is termed "pure" by Silsbee;[1] where self capacitance is present, we have a case of "impure" mutual inductance, and if $\theta=\frac{\pi}{2}-\phi$, then θ is called the "phase defect."

For an impure mutual inductance in symbolic rotation

$$e_2=(\mathrm{P}+j\omega\mathrm{M})i, \quad . \quad . \quad . \quad (36)$$

and for a pure one $\quad e_2=j\omega\mathrm{M}i. \quad . \quad . \quad . \quad . \quad (37)$

Then $$\mathrm{E}_2{}^2=(\mathrm{P}^2+\omega^2\mathrm{M}^2)\mathrm{I}^2 \quad . \quad . \quad . \quad (38)$$

and $$\tan\theta=\cot\phi=\mathrm{P}/\omega\mathrm{M}. \quad . \quad . \quad . \quad (39)$$

The term P is of the order of a resistance, and its presence indicates expenditure of power in the system. The angle θ is usually very small, ϕ being nearly a right angle.

§ (79) EFFECT OF EDDY CURRENTS.—If there are pieces of metal or other closed conducting circuits near the coils of the mutual inductance M, then eddy currents may be induced in them which will alter the effective mutual inductance and, owing to the presence of the P term, make it impossible to obtain a balance by a pure mutual inductance m.

Campbell[2] has shown how a balance can be got by associating with m a resistance r as in *Fig.* 54. Here the eddy current system is represented by a closed circuit of resistance R and self inductance L, having mutual inductances F and G to the primary and secondary circuits respectively of the unknown mutual inductance M.

As r is usually small it should consist in whole or in part of a slide wire. Let the instantaneous values of the currents in the primary, secondary, and tertiary

[1] F. B. Silsbee, *Bureau of Standards Bulletin*, 1916, xiii. 380.

[2] A. Campbell, *N.P.L. Report for 1908* (March 1909), *Phys. Soc. Proc.*, 1910, xxii. 214, and *Phil. Mag.*, 1910, xix. 503.

circuits of M be i_1, i_2, and i_3 respectively, their effective values being I_1, I_2, and I_3.

By adjusting m and r a balance can be got, when i_2,

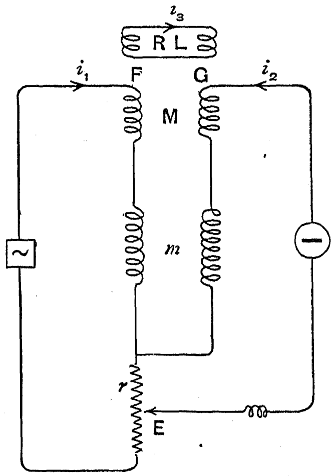

FIG. 54.

the current in the vibration galvanometer or telephone, is zero.

Then we have

$$(R+j\omega L)i_3=j\omega F i_1,$$

and therefore

$$(R^2+\omega^2L^2)I_3^2=\omega^2F^2I_1^2. \quad . \quad . \quad (40)$$

Also

$$\begin{aligned} j\omega(M-m)i_1 &= -ri_1-j\omega Gi_3 \\ &= -ri_1+\frac{\omega^2FGi_1}{R+j\omega L} \\ &= -ri_1+\frac{\omega^2FGRi_1}{R^2+\omega^2L^2}-\frac{j\omega^3FGLi_1}{R^2+\omega^2L^2}. \end{aligned}$$

Hence, separating real and imaginary parts,

$$M=m-\frac{\omega^2FGL}{R^2+\omega^2L^2} \quad . \quad . \quad . \quad (41)$$

and

$$r=\frac{\omega^2FGR}{R^2+\omega^2L^2}. \quad . \quad . \quad . \quad (42)$$

Also

$$M=m-rL/R. \quad . \quad . \quad . \quad (43)$$

From this investigation we see how an impure mutual inductance of the form $P+j\omega M'$ can be measured by being balanced against a known $r+j\omega m$, the r and m being connected as in *Fig.* 55, in which they form an elementary pair with current terminals AB and potential terminals CD. (Silsbee has pointed out the close analogy here to a four-terminal resistance with current and potential leads. AB and CD are interchangeable, as in the case of the resistance.)

The unknown mutual inductance may have an iron core, in which case the resistance P corresponds to power loss arising from both hysteresis and eddy currents. When this total iron loss is relatively small we can determine it from the above equations; when the primary current i_1 is of sine wave form and the iron is in the form of a uniform ring wound with

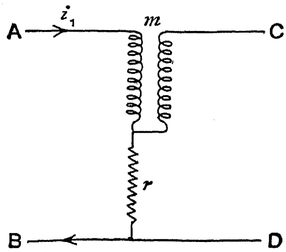

FIG. 55.

superimposed primary and secondary coils of N_1 and N_2 turns respectively,

then the power loss $=RI_3^2=rI_1^2 \cdot N_2/N_1$. . . (44)

The method also gives a convenient way of testing a current transformer (under load). Let part of the load be a known resistance S.

Then

$$\tan\phi=\omega m/r \text{ and } I_1^2/I_2^2=S^2/(r^2+\omega^2m^2). \quad (45)$$

When ϕ is small we have

$$\begin{aligned} I_1/I_2 &\doteqdot \frac{S}{r}(1-\omega^2m^2/r^2)^{\frac{1}{2}} \doteqdot \frac{S}{r}(1-\tfrac{1}{2}\tan^2\phi) \\ &\doteqdot \frac{S}{r}\left(1-\frac{\phi^2}{2}\right). \quad (46) \end{aligned}$$

In practice ϕ is generally so small that we may take

$$I_1/I_2=S/r. \quad . \quad . \quad . \quad . \quad (47)$$

The elementary pair $(r+j\omega m)i_1$ of *Fig.* 55 has been used in other methods of testing transformers by various experimenters.[1] Larsen[2] has used it as the basis of his alternating current potentiometer, as by adjusting r and m any unknown voltage can be balanced and so resolved into two components in phase and in quadrature with a given current i_1.

§ (80) MAXWELL'S METHOD OF COMPARING MUTUAL INDUCTANCES.—For the comparison of unequal mutual inductances Maxwell's[3] method is probably the best. It can be worked either with a battery and reversing key as source and a ballistic galvanometer as detector, or with alternating current and a vibration galvanometer or telephone. The latter case is illustrated in *Fig.* 56. The primaries of the two inductances and the source A are connected in series, while the secondaries are connected to two resistances, Q_1 and Q_2 respectively, and form

[3] Maxwell, *Electricity and Magnetism*, 2nd ed. ii. § 755.

two branch circuits bridged over by the galvanometer G.

Case 1.—When a battery and ballistic galvanometer are used, one or both of the resistances Q_1 and Q_2 are adjusted until the

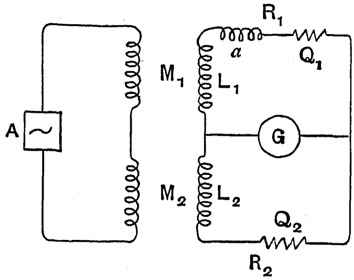

FIG. 56.

galvanometer shows no throw on reversal of the primary current.

Then $$M_1/M_2 = R_1/R_2, \quad . \quad . \quad . \quad (48)$$

where R_1 and R_2 are the resistances of the two branch circuits and include the resistances of the secondary coils. (If no balance can be obtained, the connections of one of the secondary coils should be reversed.) This is the simplest way of using the method and gives excellent results if a sufficiently sensitive galvanometer is available. When by gradually altering Q_1 or Q_2 the point of balance is passed the throws of the ballistic galvanometer are in the reverse direction, which makes the adjustment easier than with alternating current when the detecting instrument has not this power of discrimination. If possible the resistances of the copper-wound secondary coils should be swamped by Q_1 and Q_2 to prevent uncertainty of temperature causing error. In comparing an unknown mutual inductance against a fixed standard whose value is a power of 10 it is best to set the total resistance in the standard branch to a power of 10 (say 1000 ohms), and then the method becomes almost direct reading. The method is applicable to the comparison of two secondary coils with one primary, and is useful for checking the proportionality at different readings on an inductometer.

In using a ballistic galvanometer it is important to set the needle in the mean plane of the coils, or the moving coil facing symmetrically with respect to the magnet. If this is not done the galvanometer may respond somewhat to alternating current, and give a throw even though the total quantity of electricity passing is zero. If the throw will not come quite to zero, it is advisable to carry out the second condition of Case 2 here as well.

Case 2.—With alternating currents the conditions for a balance are not so simple as in Case 1. Two conditions must be fulfilled, namely,

$$M_1/M_2 = R_1/R_2$$

and $$L_1/L_2 = R_1/R_2. \quad . \quad . \quad . \quad (49)$$

To ensure the fulfilment of this last conditiou an adjustable self inductance a is introduced into one or other of the secondary branches. By alternate adjustments of R_1/R_2 and a a balance is finally reached.

It should be noted that in this case, when two secondary circuits have the same primary, instead of equation (49) the condition is

$$\frac{L_1 \pm m}{L_2 \pm m} = \frac{R_1}{R_2}, \quad . \quad . \quad . \quad (50)$$

where m is the mutual inductance between the two secondaries.

It is evident from equation (49) that the method can be used to compare two self inductances. It will be discussed further in the chapter on the measurement of self inductance.

The equations still hold if the alternating source A and the detecting instrument G have their positions interchanged.

§ (81) CAMPBELL'S COMPARISON METHOD FOR UNEQUAL MUTUAL INDUCTANCES.—If a mutual inductance is beyond the range of a given inductometer, it can be tested by the following method.[1] Let the primary circuits of the inductometer (L_1) and the unknown inductance (L_2) be connected up in a bridge with ratio arms R and S as in *Fig.* 57, adding to L_2,

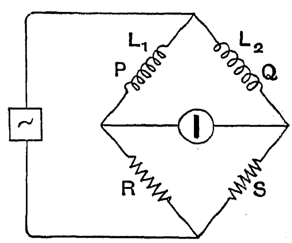

FIG. 57.

if necessary, a coil c of sufficient self inductance to make L_2 considerably greater than L_1. By altering R or S and P or Q let a balance be obtained.

Then $$PS = RQ$$

and $$L_2R = L_1S.$$

Now let the secondary circuits be introduced (in opposition) into the galvanometer

[1] A. Campbell, *Phys. Soc. Proc.*, 1907, xxi. 69, and *Phil. Mag.*, Jan. 1908, xv. 155.

circuit as in *Fig.* 58, and let the balance be restored by adjusting the inductometer M_1.

Then $$M_2 = M_1 S/R.$$

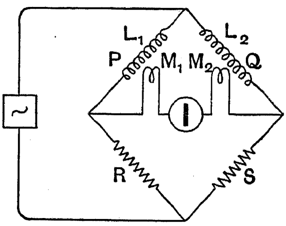

FIG. 58.

§ (82) METHODS OF MEASURING MUTUAL INDUCTANCE IN TERMS OF RESISTANCE.—A standard mutual inductance, being calculable from the dimensions of the coils, is much more easily constructed than a standard of resistance, and in the most accurate methods the standard resistance is derived from a known mutual inductance. Since, however, accurately calibrated resistance coils and boxes are in much more general use than mutual inductances, it is sometimes convenient to determine mutual inductance in terms of resistance. The two following methods will serve as examples.

Method with Ballistic Galvanometer.[1]—The secondary coil of the unknown mutual inductance M is connected through added resistance to a ballistic galvanometer, the whole secondary circuit having a total resistance R. A current i_1 is now reversed in the primary circuit, which causes a quantity of electricity $2Mi_1/R$ to be sent through the galvanometer, giving a throw α.

Then $$\frac{2Mi_1}{R} = k\frac{T}{\pi}\left(1+\frac{x}{2}\right)\sin\frac{\alpha}{2}, \quad . \quad . \quad (51)$$

where k is the galvanometer constant, T the time (in secs.) of a complete period of the galvanometer, and x the logarithmic decrement of its oscillations (for half period). Then k is determined by measuring the current i_1 on the same galvanometer shunted so that a fraction $1/b$ of the current i_1 passing through it gives a steady deflection θ.

Thus $$i_1 = bk\tan\theta,$$

and hence $$M = R\frac{T}{2b\pi}\left(1+\frac{x}{2}\right)\frac{\sin\frac{\alpha}{2}}{\tan\theta}. \quad . \quad . \quad (52)$$

If R is in ohms, M will be in henries. It is best to choose b so that θ and α are approximately equal. T, the time in seconds between successive passages of the light spot through zero in the same direction, is found by counting a number of these and taking the time with a chronograph or stop-watch. If the lengths $a_1, a_2, a_3 \ldots$ of successive swings are observed, then

$$x = \frac{2}{n-m}\log_e\left(\frac{a_m}{a_n}\right). \quad . \quad . \quad (53)$$

§ (83) CAMPBELL'S TWO-PHASE METHOD.—When two-phase alternating current of nearly pure sine wave form is available Campbell's method[2] may be used. The connections are shown in *Fig.* 59.

Let M be the mutual inductance to be measured and R a non-inductive resistance. The secondary coil of M is connected in series with R to a vibration galvanometer G. Currents in exact quadrature are sent through

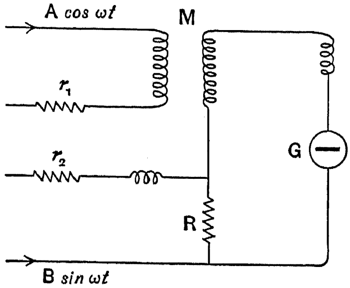

FIG. 59.

the primary coil and R respectively. By adjusting the ratio of these currents or the value of R the deflection of the galvanometer is reduced to zero. The ratio A/B of the currents is now determined by the readings of an electrostatic voltmeter put across the resistances r_1 and r_2 in turn, and the frequency is accurately observed.

Then $$M = \frac{B}{A}\cdot\frac{R}{\omega}, \quad . \quad . \quad . \quad (54)$$

where $\omega = 2\pi \times$ frequency.

§ (84) MEASUREMENT OF MUTUAL INDUCTANCE IN TERMS OF CAPACITANCE.—There are a number of methods by which mutual inductance can be determined in terms of capacitance. These will be discussed in detail in the article on the measurement of capacity. For convenience of reference, however, brief descriptions of two of them are given here.

Campbell's Sifter Method.—The simplest method is that of Campbell,[3] which is shown in *Fig.* 60.

Let the mutual inductance be m and the condenser k. One terminal of the primary coil of m is connected to one of the secondary at F. Alternating current (of frequency n)

[1] R. T. Glazebrook, *Roy. Soc. Phil. Trans.*, 1883, clxxiv. 223.

[2] *Roy. Soc. Proc.* A, 1908, lxxxi. 450, and 1912, lxxxvii. 398.

[3] A. Campbell, *Phys. Soc. Proc.*, 1908, xxi. 69, and *Phil. Mag.*, 1908, xliv. 155; also *Phys. Soc. Proc.*, 1917, xxix. 350.

is sent through the primary coil in series with k, a vibration galvanometer (or telephone) G being connected across k and the secondary

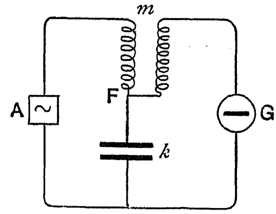

FIG. 60.

coil. When by adjusting k a balance is obtained, we have

$$\omega^2 mk = 1, \quad . \quad . \quad . \quad (55)$$

where the pulsatance $\omega = 2\pi n$.

The proper ends of the primary and secondary coils to connect must be found by trial. In order to get a good balance the condenser should be as free as possible from absorption.

§ (85) CAREY FOSTER'S METHOD WITH HEYDWEILLER'S MODIFICATION.—The connections for Carey Foster's [1] method are shown in *Fig.* 61, M being the mutual inductance and K the condenser. R and S are non-inductive

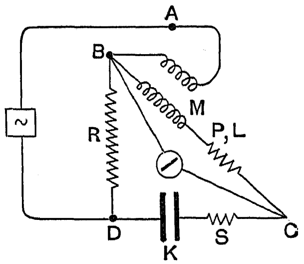

FIG. 61.

resistances, and the arm BC consists of the secondary coil of M in series with an adjustable resistance. The detector (telephone or vibration galvanometer) is connected across BC. A balance is obtained by adjusting P and S. Then, if P is the total resistance of the branch BC, and L its self inductance, we have

$$M = 10^{-6} KPR, \quad . \quad . \quad . \quad (56)$$

where K is in microfarads;

also $$S + s = R(L - M)/M, \quad . \quad . \quad . \quad (57)$$

where s represents the dielectric losses in the condenser K.

Since $S + s$ cannot be less than zero, M must not be greater than L. Sometimes to ensure this condition an additional self inductance has to be inserted in the branch BC. In the original form of the method single reversal of direct current was used, with a ballistic galvanometer, and the resistance S in the condenser branch was absent. Except in the accidental case when $s = R(L - M)/M$, the method did not work with alternating current until the resistance S was introduced by Heydweiller.[2] In connecting the primary and secondary coils at B, the right direction must be found by trial.

[1] G. Carey Foster, *Phil. Mag.*, 1887, xxiii. 121.

§ (86) MUTUAL INDUCTANCE MEASURED AS SELF INDUCTANCE.—A mutual inductance can always be determined by any method for measuring self inductance (for example, by resonance at high frequencies) merely by the device of connecting the primary and secondary into one circuit. Let the self inductances of the two coils be L and N respectively and their mutual inductance M. The coils are connected in series and the total self inductance measured. Then the connections of one of them are reversed and the self inductance again measured. Let A and B be the two values found, A being the greater.

Then $$A = L + N + 2M. \quad . \quad . \quad (58)$$

and $$B = L + N - 2M. \quad . \quad . \quad (58\text{A})$$

Hence $$M = \tfrac{1}{4}(A - B). \quad . \quad . \quad (58\text{B})$$

If self-capacity is not present, B cannot be negative, and therefore 2M is never greater than L + N; but M may be either greater than L or greater than N.

VII. THE MEASUREMENT OF SELF INDUCTANCE

§ (87) CLASSIFICATION OF METHODS.—The various methods of measuring self inductance may be classified according to the chief electrical property in terms of which the unknown self inductance is determined. The determination may be in terms of:

(A) another self inductance,
(B) mutual inductance,
(C) resistance (including current and voltage), and
(D) capacitance.

The following descriptions of a number of typical methods will be set forth in the order of this classification, and some special cases will be discussed by themselves.

(A) *Comparison with Known Self Inductance*

§ (88) MAXWELL'S BRIDGE METHOD.—The comparison of two self inductances may be made by Maxwell's [3] bridge method as shown in *Fig.* 62, which refers to the most general case. The unknown self inductance L (of resistance P) is connected with a standard

[2] A. Heydweiller, *Ann. d. Physik*, 1894, liii. 499.
[3] J. C. Maxwell, *Electricity and Magnetism*, 2nd ed. ii. § 757.

inductance N (of resistance Q) in a Wheatstone's bridge with proportional arms R and S,

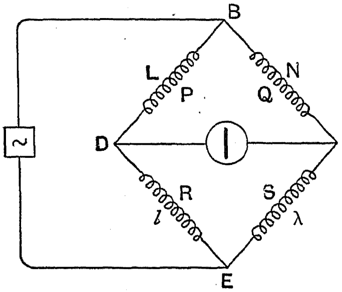

FIG. 62.

whose residual self inductances are l and λ respectively.

In the original arrangement a single reversal of direct current was used in the source, and the detector was a ballistic galvanometer, but the modern system with alternating current and a telephone or vibration galvanometer as shown in the figure is easier to use and much more sensitive. When a balance is obtained

$$\frac{P+j\omega L}{Q+j\omega N}=\frac{R+j\omega l}{S+j\omega\lambda}.$$

Hence $\quad PS-QR=\omega^2(L\lambda-Nl)$

and $\quad LS-NR=Ql-P\lambda,$

or $$\frac{P}{Q}=\frac{R}{S}+\omega^2\left(\frac{L\lambda-Nl}{QS}\right) \quad . \quad . \quad (59)$$

and $$\frac{L}{N}=\frac{R}{S}+\frac{Ql-P\lambda}{SN}. \quad . \quad . \quad (60)$$

In practice l and λ are usually very small. When they can be neglected, we have

$$P/Q=R/S \quad . \quad . \quad . \quad (61)$$

and $$L/N=R/S, \quad . \quad . \quad . \quad (62)$$

which give the effective resistance P and the self inductance L in terms of Q, L, and R/S.

In the most accurate work, since l and λ cannot be neglected, it is best, if possible, to adjust the ratio coils R and S by the addition of a small self inductance to one of them so as to make

$$l/\lambda=R/S. \quad . \quad . \quad . \quad (63)$$

Combining this condition with (59) and (60) and eliminating l and λ we obtain

$$-(PS-QR)^2=\omega^2(LS-NR)^2. \quad . \quad (64)$$

Hence $\quad PS-QR=0=LS-NR,$

or $\quad P/Q=R/S=L/N,$

and the balance is independent of the frequency.

Condition (63) is particularly important when the ratio arms have to be unequal, as, for example, in stepping up from a 10-millihenry coil to 100 millihenries.

In nearly all bridge measurements, however, the best conditions exist when the ratio arms R and S are approximately equal. Their self inductances should also be nearly equal. To ensure this, their positions in the bridge should be interchangeable, and repeated adjustments should be made until the interchange does not alter the balance. (Heaviside's system may be used, in which the wires forming R and S are first twisted together, then doubled back to form a loop and wound on to a single bobbin.) In any case each reading should be repeated with the ratio arms interchanged and a mean taken.

§ (89). For measurements of the highest precision Giebe[1] used the arrangement shown in *Fig.* 63 (with the source and galvanometer omitted). The ratio arms R and S each consisted of a bifilar loop of two bare manganin wires stretched parallel to one another,

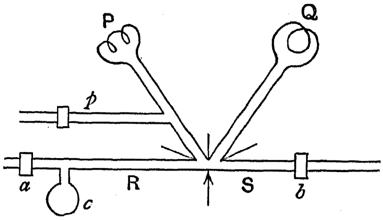

FIG. 63.

with short-circuiting sliders a and b, by which the resistances could be set. The self inductances of these loops were small and were calculated from their dimensions.

A small circular loop, also of calculable inductance, could be inserted at c, so as to make the inductances of the loops proportional to their resistances. An adjustable resistance p in the L arm was also a bare bifilar. Between R and S was a very short slide wire for fine adjustment. After each balance with alternating current the ratio R/S was accurately determined by switching over to a direct current bridge.

§ (90) CAPACITY EFFECTS.—In the ordinary use of the Maxwell bridge Q (*Fig.* 62) consists of a self inductometer, and a non-inductive resistance box and rheostat are inserted in either the P or the Q arm. The balance is obtained by alternate adjustments of the inductometer and the added resistance. Repeated adjustments are necessary, since the two different adjustments are not independent in their effects. The range of the inductometer should include the value of the unknown L, so that equal ratio arms may be used. To minimise disturbing capacity effects, the detecting instrument should *always* be connected across the ratio arms (as in *Fig.* 62).

Especially at the higher audio frequencies the capacities of the coils to earth may introduce error. To protect against this

[1] E. Giebe, *Zeits. Instrumentenk.*, 1911, xxxi. 6.

Giebe put screens round the coils L and N (*Fig.* 62) and connected the screens to the point B, while the point E was earthed. A screen enclosing the telephone was connected to the point D.

A self inductance less than the minimum reading of the inductometer can be approximately determined by finding the change of reading produced when it is added (in series) to a larger coil already balanced.

Giebe measures small self inductances accurately by obtaining a balance first, and then introducing the small unknown inductance x into the S ratio arm. If ΔP be the change in P necessary to restore balance, then

$$(x+\lambda)-\frac{N}{L}l=\frac{S\Delta P}{\omega^2 L}. \quad . \quad . \quad (65)$$

As λ and l are known, x can be determined.

§ (91) Secohmmeter Methods.—Before the introduction of vibration galvanometers Brillouin [1] in the comparison of mutual inductances made a great improvement in the sensitivity and accuracy of the measurements by using a double rotating commutator in the battery and galvanometer circuits. Some years later Ayrton and Perry,[2] using the same system, brought out an instrument which they named a Secohmmeter, and they showed how it could be applied in a number of ways to the measurement of inductance and capacity. The hand-driven form of this is illustrated in *Fig.* 64; motor-driven types are also in use.

It consists of two rotary reversing commutators mounted on the same spindle, which

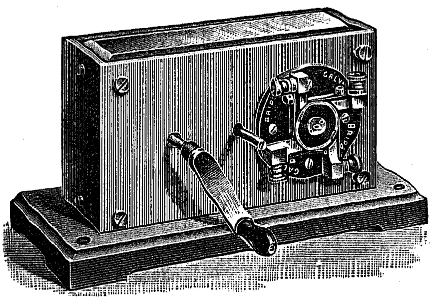

Fig. 64.—Ayrton and Perry's Secohmmeter.

can be driven at various speeds (giving from 3 up to 100 reversals per second). Each commutator has four fixed brushes, and one set of brushes can be set relatively to the other so that both series of reversals can be made at the same moment or one before or after the other. The commutators are connected with a Maxwell bridge as shown in *Fig.* 65, but the system is applicable to many other null methods. It will be seen from the figure that the battery with its commutator is equivalent to a source of alternating current,

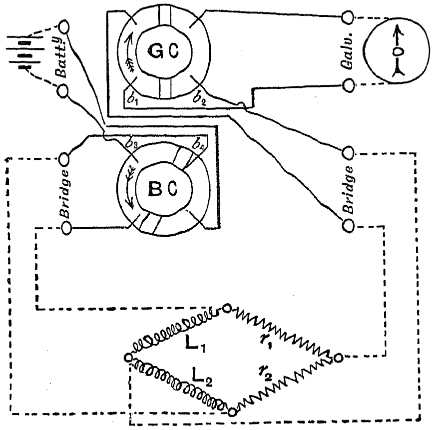

Fig. 65.

while the other commutator rectifies the alternating voltage in the galvanometer circuit and allows a direct-current galvanometer to be used. The speed must not be so great that the currents do not reach their steady states between consecutive reversals of the battery.

§ (92) Synchronous Reversing Key.—Instead of using a battery and reversing commutator as in the secohmmeter, ordinary alternating current may be used as the source, the galvanometer connections being periodically reversed at the right instants by a commutator driven on the alternator shaft or by a synchronous motor run on the circuit. Sharp and Crawford,[3] finding difficulties with the brush contacts of a rotary commutator, introduced a rectifier consisting of a reversing key with platinum contacts worked at synchronous speed by means of a synchronous motor and a cam. By adjusting the angular position of the contacts with respect to the poles of the motor, the reversal can be made to occur at any desired phase of the current. By properly setting the position the galvanometer may be made to respond to any given component of the current while it is insensitive to the component in quadrature with it. The double adjustments necessary in most bridge methods are made more easily by setting the rectifier contacts for sensitivity either to the resistance or reactance components. A detecting circuit formed thus of a synchronous commutator and a direct-current galvanometer is applicable to nearly all the null methods

[1] M. Brillouin, *Thèses présentées à la Faculté des Sciences de Paris*, 1882.

[2] W. E. Ayrton and J. Perry, *J. Inst. El. Eng.*, 1887, p. 292. See also S. R. Milner, *Phil. Mag.*, 1906, xii. 297.

[3] C. H. Sharp and W. W. Crawford, *Am.I.E.E. Proc.*, 1910, xxix. 1207.

used in testing inductances and capacities. It may be remarked, however, that it should be used with caution when harmonics are present in the wave form, for it is not a selective device like a vibration galvanometer.

§ (93) Electromagnet Galvanometer as Detecting Instrument.—The various iron-cored electrodynamometers already discussed can be used as detecting instruments for many inductance measurements. For the Maxwell bridge the connections are as in *Fig.* 66.

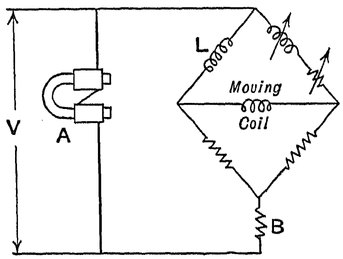

Fig. 66.

The field magnet A is connected directly across the supply voltage V, while the bridge is connected in, as shown, with a resistance B in series, sufficiently large to bring the current entering the bridge approximately into phase with V. As the field of the magnet is in quadrature with V, the moving coil will be particularly sensitive to reactance components of current—a condition favourable for the measurement of L. For measuring effective resistance, on the other hand, the magnet field and the bridge current should rather be nearly in phase, and in using the instrument for any particular null method, it should always be connected up with due regard to the quantity that is to be measured.

§ (94) Comparison of Self Inductances by Differential Transformer.—The differential transformer method of comparing self inductances is really a development of

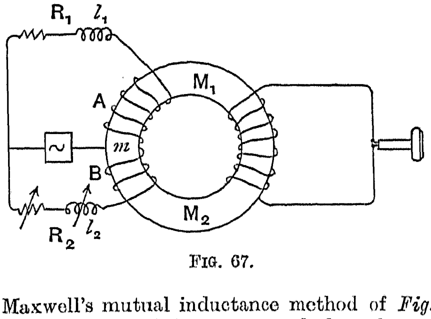

Fig. 67.

Maxwell's mutual inductance method of *Fig.* 56, Case (2). If the source and the galvanometer be interchanged and the two secondaries united in a single coil, we get the connections as in *Fig.* 67, in which also the three coils are shown wound on an iron ring core. The figure is a diagrammatic representation of a differential transformer. In practice, however, the three coils are each wound with uniform spacing over the whole of the iron ring. Two cases arise according as the coils A and B have unequal or equal numbers of turns.

Case 1. Let the turns of A and B be unequal, which is the system used by Hausrath.[1] If the respective mutual inductances are M_1, M_2 and m as in the figure, then, for a balance,

$$\frac{L_1 \pm m}{L_2 \pm m} = \frac{R_1}{R_2} = \frac{M_1}{M_2}, \quad . \quad . \quad (66)$$

where L_1, L_2, R_1 and R_2 refer to the total circuits of A and B. To measure a self-inductance l_1 in terms of a known variable l_2, a balance is obtained without l_1 and l_2 (*Fig.* 67) by adjusting R_1, R_2, L_1 and L_2. Then l_1 and l_2 are inserted as in the figure, and the balance restored by adjusting the variable l_2 and R_1 or R_2. Then

$$\frac{L_1 + l_1 \pm m}{L_2 + l_2 \pm m} = \frac{M_1}{M_2} = \frac{L_1 \pm m}{L_2 \pm m},$$

and hence

$$l_1/l_2 = M_1/M_2 = q \text{ (say)}. \quad . \quad . \quad (67)$$

Now q is equal to the ratio of the numbers of turns of the coils A and B, and so by proper choice of q a very small inductance can be measured in terms of a much larger standard or *vice versâ*. This arrangement gives a method of stepping up or down without the use of resistance ratio arms.

Case 2. When the coils A and B have equal numbers of turns, the system is much simpler. It has been used in the differential transformers of various experimenters. Elsas[2] and others used equal coil inductors for the measurement of electrolytic resistance, and Trowbridge[3] used a similar transformer for measuring self inductances and capacities. In this transformer the equality of the coils A and B was ensured by twisting the two wires together before winding them; with care in winding their self inductances were equal to within 1 part in 20,000. In this case when m is not zero, but $M_2 = M_1$, the conditions become independent of m, and we have

$$M_1/M_2 = R_1/R_2 = L_1/L_2 = 1. \quad . \quad (68)$$

The procedure for measuring l_1 against l_2 is the same as in Case 1, but l now must be within the range of l_2.

§ (95) Differential Transformer for Radio Frequencies.—On the same system Hund[4] used an equal-coil differential trans-

[1] H. Hausrath, *Die Untersuchung elektrischer Systeme*, J. Springer, 1907.

[3] A. Trowbridge, *Phys. Rev.*, 1905, xx. 56.
[4] A. Hund, *El. World*, May 22, 1915.

former (without an iron core) for measuring the effective resistances of coils at radio frequencies. Kennelly and Affel[1] employed his method in their tests of the skin effect in conductors. The arrangement of the connections as used by them is given in *Fig.* 68.

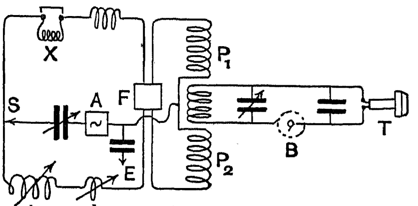

FIG. 68.

The equal primary coils are P_1 and P_2, and their connections can be interchanged by the reversing switch F. The source of current is a radio frequency alternator A, and the detecting instrument a telephone T. As the frequencies used were above the limits of hearing, a rotary interrupter B running at 1000 ~ per sec. is put in series with the telephone and, by the periodic breaking of the high-frequency current, gives audibility in the telephone. The coil under test is at X, and the balance is obtained by adjustments of L, l and the slide wire S.

§ (96) DIFFERENTIAL TELEPHONE. — An earlier method involving much the same principle is that of the differential telephone, which was introduced by Chrystal.[2] The working procedure is the same as with the equal-coil transformer.

(B) *Self Inductance determined in Terms of Mutual Inductance*[3]

§ (97) HISTORICAL INTRODUCTION.—In a Wheatstone bridge there are six circuits. When used with alternating currents if mutual inductance be introduced between two or more of these circuits, it is possible in certain cases to obtain a balance by which self inductance can be compared with mutual. For example, Maxwell[4] gave two bridge methods of making this comparison. In 1886 Hughes[5] introduced another bridge method, the correct theory of which was pointed out by H. F. Weber, Rayleigh and Heaviside.[6] Then Heaviside[7] discussed the problem thoroughly, examining all the cases in which mutual inductance is introduced between any pair of the circuits, and he pointed out the advantages of several of the combinations. (In more recent times other experimenters, unaware of his work, have rediscovered several of these methods.) The best of the methods is the following:

§ (98) HEAVISIDE MUTUAL INDUCTANCE BRIDGE.—In the Heaviside bridge the mutual inductance M is introduced between the alternator circuit and one of the bridge arms as shown in *Fig.* 69, which is for the general

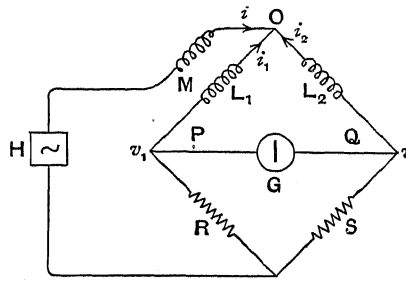

FIG. 69.

case (R not necessarily equal to S). The galvanometer circuit might have been used instead of the alternator branch, as in networks of this kind the alternator and galvanometer are interchangeable. Let the resistances of the bridge arms be P, Q, R and S, L_1 and L_2 being the self inductances of P and Q. Let the instantaneous potentials of the upper three corners be v_1, o and v_2 respectively, and the instantaneous values of the currents into the upper corner be i_1, i_2 and i as in the figure. When the vibration galvanometer shows a balance, the current through it is zero at every instant,

and hence $$v_1 = v_2.$$

Also $$i = -i_1 - i_2.$$

Hence
$$(P + j\omega L_1)i_1 - j\omega Mi = (Q + j\omega L_2)i_2,$$

and therefore
$$[P + j\omega(L_1 + M)]i_1 = [Q + j\omega(L_2 - M)]i_2 ;$$

also $$Ri_1 = Si_2.$$

Hence
$$S[P + j\omega(L_1 + M_2)] = R[Q + j\omega(L_2 - M)].$$

Separating the real and imaginary parts, we find the two conditions necessary for balance to be

$$SP = RQ, \quad . \quad . \quad . \quad (69)$$

and $$S(L_1 + M) = R(L_2 - M).^8 \quad . \quad . \quad (70)$$

[1] A. E. Kennelly and H. A. Affel, *Radio Engs. Proc.*, 1916, iv. 523.

[6] H. F. Weber, *El. Review*, 1886, xviii. 321, and 1886, xix. 30; Lord Rayleigh, *Phil. Mag.*, 1886, xxii. 469; O. Heaviside, *Electrician*, 1885-86, xvi. 489.
[7] O. Heaviside, *Phil. Mag.*, 1887, xxiii. 173.

[8] If $L_2 = 0$ we have Maxwell's method of comparing the M between two coils with the L of one of them, and equation (70) becomes $L/M = -(1 + R/S)$. The method requires unequal ratio arms.

If the connections of the inducing coil be reversed, the second condition for balance becomes

$$S(L_1 - M) = R(L_2 + M). \quad . \quad . \quad (71)$$

It will be noticed that the balance is independent of the frequency. The most useful case is when the ratio arms are made equal, *i.e.* $S = R$.

Then (69) and (70) become

$$P = Q, \quad . \quad . \quad . \quad (72)$$

and $$L_2 - L_1 = 2M. \quad . \quad . \quad . \quad (73)$$

§ (99) Campbell[1] has shown how the method can be used, with the help of a mutual inductometer, for the measurement of a wide range of self inductances, errors due to leads and connections being eliminated by differential reading, which is of great importance for small self inductances.

The simplest arrangement is given in *Fig.* 70.

The ratio arms are equal (R, R). The arm AB consists of the secondary coil *a* of the inductometer in series with *r* which is a non-inductive resistance box with a constant inductance rheostat for fine adjustment. In the arm AC there is a " balancing coil " *b*

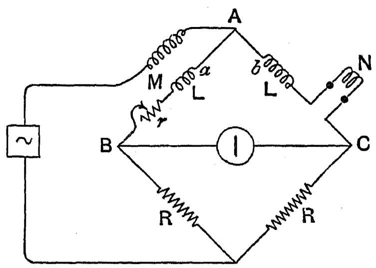

FIG. 70.

having the same self inductance as coil *a* and slightly greater in resistance; the self inductance N to be measured is also in this arm.

The coil N is first short-circuited across its terminals and a balance obtained by adjusting *r* and M. Let the readings be r_0 and M_0, where M_0 is almost zero (being due to the leads of N, etc.). Then the short-circuit is removed from N and a new balance obtained with readings r_1 and M_1. Then by (72) and (73)

$$N = 2(M_1 - M_0); \quad . \quad . \quad . \quad (74)$$

and the effective resistance $= r_1 - r_0$.

In this way any self inductance can be read directly, and the range of values that can be measured runs from 0 up to twice the maximum reading of the inductometer. For example, with a long range 10-millihenry inductometer self inductances from 0·2 microhenry up to 20,000 microhenries can be directly determined.

In the arrangement shown in *Fig.* 70 the addition of the balancing coil lowers the sensitivity.

The more modern inductometers are designed so as to avoid this by the arrangement shown in *Fig.* 71. Here the inducing circuit acts on both the P and Q

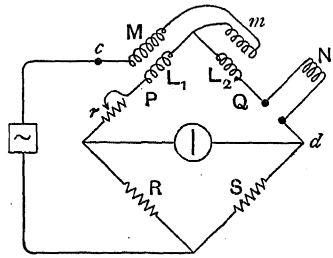

FIG. 71.

arms, L_1 and L_2 being the upper and lower fixed coils in the inductometer.

Case 1.—When $R = S$, the conditions for balance are

$$P = Q$$

and $$L_2 - L_1 + N = 2(m + M).$$

It is best to have L_2 set permanently equal to L_1 in the inductometer. Then, since $(m + M)$ is the reading of the instrument,

$$N = 2 \times \text{Reading}.$$

The balance in an equal arm bridge is independent of the mutual inductance between the P and Q arms.

Case 2.—When N is beyond the range of the inductometer, unequal ratio arms must be used. Let $R = \sigma S$, and let y be the mutual inductance between the coils L_1 and L_2. Then it can be shown that, for a balance,

$$P = \sigma Q \quad . \quad . \quad . \quad . \quad (75)$$

and $$\sigma(L_2 + N) - L_1 = (m + M)(\sigma + 1) + y(\sigma - 1). \quad (76)$$

Thus with unequal arms the balance depends on y. It is possible, but not easy, to arrange by a tapping from one of the inductometer coils to make $(\sigma L_2 - L_1)$ permanently equal to $y(\sigma - 1)$. It is better, however, to arrange the bridge as in *Fig.* 72, in which the unknown N is introduced at the left-hand side and the inducing coil of M reversed. The balancing coil L_2 is made equal to L_1/σ.

For a balance, by equation (71)

$$N = (\sigma + 1)M + \sigma L_2 - L_1$$

or $$N = (\sigma + 1)M. \quad . \quad . \quad . \quad (77)$$

The effective resistance of (N) is equal to the change in r required when the coil is inserted in the bridge arm.

[1] A. Campbell, *Phys. Soc. Proc.*, 1908, xxi. 69, and 1910, xxii. 207; also *Phil. Mag.*, 1908, xlix. 155, and 1910, xlvi. 497.

If the ratio R/S is given values of $\frac{1}{9}$, $\frac{1}{99}$, $\frac{1}{999}$, then N will equal 10 M, 100 M, 1000 M, and so on,

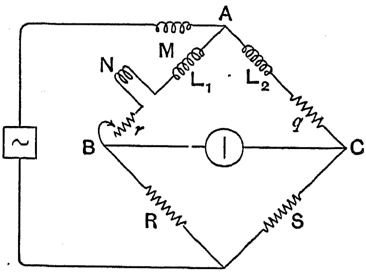

FIG. 72.

assuming that the M reading is zero when the bridge is in balance before (N) is inserted.

§ (100) EFFECT OF RESIDUAL INDUCTANCE IN THE RATIO ARMS.—Although nominally non-inductive, the ratio arms in general have appreciable residual self inductance. In measurements of high precision the effect of this must be taken into account or errors will come in, particularly at the higher frequencies. In *Fig.* 73 let the four arms have resistances P, Q,

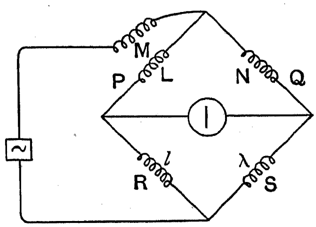

FIG. 73.

R, and S, and self inductances L, N, l, and λ respectively. It can be shown that the conditions for a balance are

$$PS-QR=\omega^2[(L-M)\lambda-(N+M)l] \quad . \quad (78)$$

and $$SL-RN=(S+R)M-P\lambda+Ql. \quad . \quad . \quad (79)$$

When M=0 these reduce to equations (59) and (60), given first by Giebe for the Maxwell bridge.

Case 1. *R not equal to S.*—If l and λ are known, equations (78) and (79) can be used to give accurate results. It will be found that in general the effective resistance result is much more affected than the self inductance by the presence of l and λ. Owing to the factor ω^2 in equation (78) the resistance effect increases rapidly as the frequency is raised.

Note.—The occurrence of ω in any equation giving a condition for balance indicates that the balance is dependent on the frequency, being different for different frequencies. If the frequency is not steady, this condition gives trouble; if the source has not a pure sine wave form, it makes the use of a telephone as detector difficult, for when the fundamental is balanced the harmonics are not.

With unequal arms, however, the best plan is to construct them so that their self inductances are proportional to their resistances. Then $l/\lambda=R/S=\sigma$ (say), and the equations reduce to

$$S(P-\sigma Q)=\omega^2\lambda[L-\sigma N-M(1+\sigma)]$$

and $$S(L-\sigma N)=SM(1+\sigma)-\lambda(P-\sigma Q).$$

Hence

$$S^2[L-\sigma N-(1+\sigma)M]=-\omega^2\lambda^2[L-\sigma N-(1+\sigma)M].$$

Now S^2 cannot be equal to $-\omega^2\lambda^2$, and therefore

$$L-\sigma N=(1+\sigma)M, \quad . \quad . \quad . \quad (80)$$

and hence $$P/Q=R/S. \quad . \quad . \quad . \quad . \quad (81)$$

So when the time constants of R and S are equal the corrections disappear, and the balance is independent of frequency.

Case 2. *Equal Arms.*—When R=S, but $l\neq\lambda$, we can find l and λ by the following method. After obtaining a balance, let R and S be interchanged and new balances found by altering (1) only P and M, and (2) only Q and M. If the changes required are p and m, and q and m', then

$$l=R\cdot\frac{2\omega^2(m-m')^2-q(p+q)}{\omega^2(m-m')(p-q)}, \quad . \quad . \quad (82)$$

and $$\lambda=R\cdot\frac{-2\omega^2(m-m')^2+q(p+q)}{\omega^2(m-m')(p-q)}, \quad . \quad (83)$$

The equations for balance are

$$(P-Q)R=\omega^2[(L-M)\lambda-(N+M)l]$$

and $$(L-N-2M)R=Ql-P\lambda,$$

showing that the balance is not independent of frequency. So, as in the case of the Maxwell bridge, it is best to make $\lambda=l$ once for all, and then the corrections vanish.

The coil under test should be placed at some little distance from the bridge and it should be set up with its mean plane passing approximately through the axis of the inducing coil of the inductometer. Each test should be repeated with the connections reversed at the terminals of the unknown coil, and also with the connections to the source reversed.

§ (101) HUGHES'S METHOD OF COMPARING A SELF INDUCTANCE WITH A MUTUAL.—*Fig.* 74 gives the connections for the Hughes method
